INLAND

ONE-PIECE PISTON RING

The Inland One-Piece Piston Ring, when contracted in a cylinder, tends to uncoil like a spring, in a perfect circle, exerting an even and gentle radial pressure against the cylinder. Its free ends are diagonally opposite, and all openings are effectually sealed so that no gas can escape. Being made of one piece, out of the best grade of gray cast iron, they cannot score or mar the cylinders.

TABLE OF CONTENTS

INSERTS.

There are several inserts dealing with E gines, Modern Cars, Dixie Magneto, Moto cycles, etc.

Use the Index--refer to it often. Any trouble you may have, refer to index. See pa 544 for Specifications of Leading Cars.

INTRODUCTORY

The Relation of the Automobile, Truck and Tractor.

Although this book was originally prepared to deal with the passenger car type of Automobile, the subjects of Trucks and Tractors have been added and right at the beginning, it is the purpose of this introductory, to point out to the reader the close **relation** of the Automobile, Truck and Tractor, so that when the study of the book is completed he will clearly understand the difference in construction.

In addition to the Truck and Tractor subject, the Airplane and Airplane Engine is also dealt with.

The same underlying principles of the Drive System of an Automobile are used in the Truck and Tractor, but of slightly different construction.

The same underlying principles of the Automobile Engine are used in the Truck, Tractor and Airplane Engines, but of slightly different construction. With this in mind, it will be easier for the student to understand the differences as he progresses.

Why the Instructions Begin With an Early Type of Car.

In order that the reader may clearly understand the details of the modern automobile and its parts, it was necessary to illustrate and describe the early type of cars and gradually work up to the more modern type. For this reason many of the subjects begin with early models or types, which is absolutely **necessary** before the reader can properly master the subject.

The reader will learn the principles of construction of the different parts of all automobiles in general use. The construction may vary, but the underlying principles remain the same. Consequently when the reader masters the principles involved, he masters the construction of **all** types of automobiles, engines, ignition systems, carburetors, etc.

The illustrations are not drawn to scale, in fact, the majority of the illustrations are exaggerated in a great many instances—in order to clearly describe the subject treated.

The writer makes no attempt to treat the subject in a theoretical manner, his idea being to adhere strictly to the practical side of the subject.

For many of the illustrations and much information to be found in this book, the writer is indebted to the "Automobile," of New York, "Motor Age" of Chicago, "Automobile Dealer and Repairer," of New York, and "Motor World" of New York, as well as a great number of manufacturers of automobiles and accessories.

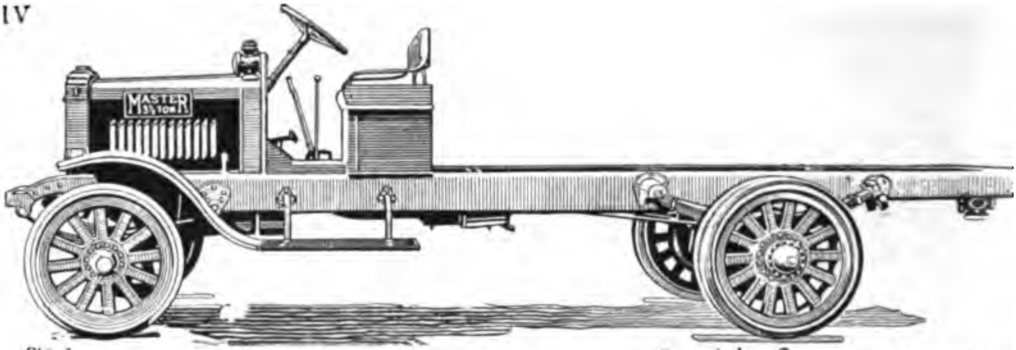

Fig. 1.

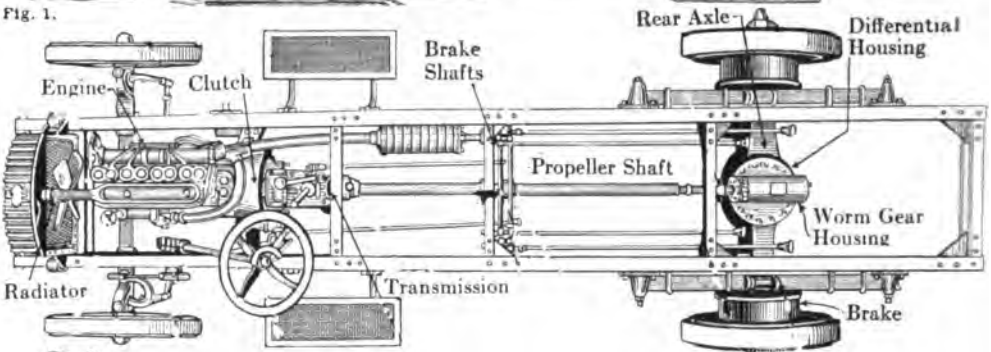

Fig. 2.

A Modern Truck.

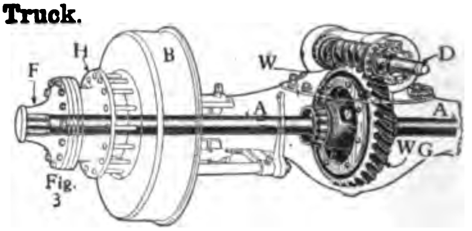

Fig. 3

The principle of the truck is similar to the principle of a passenger car type automobile.

The engine is usually a **four cylinder** type of engine, for reasons explained on page 747. See also, page 71. The truck engine is a slower speed engine than the automobile engine. The average maximum speed of a truck engine is 900 to 1000 r.p.m. The engine speed is controlled by a hand throttle and foot accelerator, the same as the automobile engine, but a **governor is employed,** for reasons stated on page 839, which is to prevent undue "racing" of engine when changing gears or releasing clutch.

By governing the engine speed, the car speed is also limited, for instance, the governor can be set to govern the engine speed at 950 r.p.m. which gives a maximum car speed of 14 m.p.h., which is the average speed of a heavy duty truck.

The speed of a passenger type automobile varies from 1½ m.p.h. to 50 or 60 m.p.h. and a governor is not employed. The engine speed of a passenger type automobile varies from 150 r.p.m. to as high as 2500 to 3000 r.p.m. The truck, however, being designed for commercial use must necessarily be more efficient, hence the employment of a governor.

All complicated devices are eliminated on a truck, for the sake of efficiency. For instance, the electric starting motor is seldom used, instead, the engine is **cranked by hand** in connection with an "impulse starter" (see page 747 and 832). Instead of a coil, battery, generator, cut-out, timer and distributor being used for **ignition,** a high tension magneto is usually employed. The gravity **fuel feed** system is used instead o vacuum or pressure feed. The tubular typ radiator (page 190), for **cooling** is used in steaд of the cellular type. The cellular typ as generally used on automobiles, is mor artistic in appearance, but the tubular typ has larger openings and is less liable to clo and easier to repair.

Drive method is usually by a propeller shaft cor nected with (D) to a worm (W) which meshes wit worm gear (WG) on differential. The worm gea gives a greater reduction and is silent and po sesses enormous strength.

Rear axle is usually a full-floating "live" axl Axle shafts (A) are split and inner ends connecte to differential gears and outer ends to hub flang (F). See also, page 751.

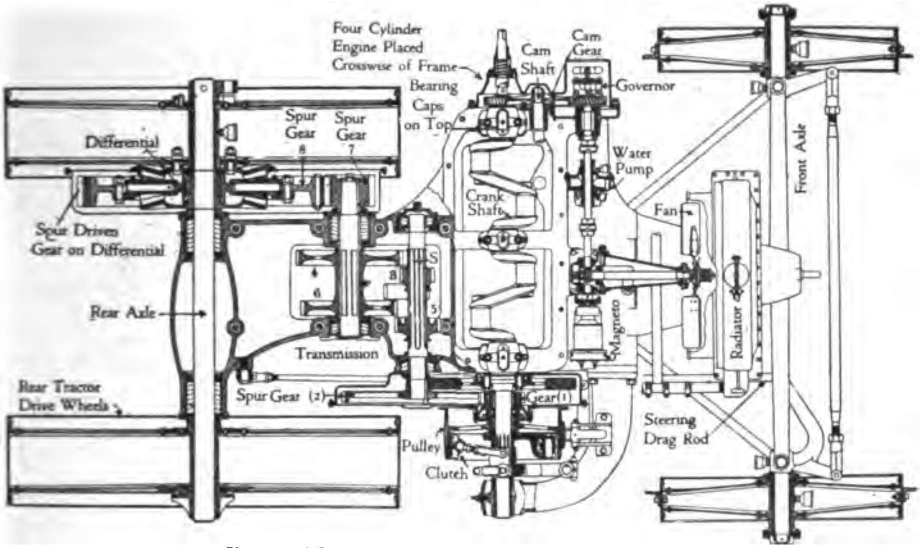
Transmission is usually a three speed forwar and reverse, and is similar to an automobile tran mission, but of heavier construction. **Gear ratios** On above truck (Master, models M & O), **firs speed,** rear wheels make 1 revolution to every 2 of crankshaft of engine; **second speed,** 1 to 13.6 **high speed,** 1 to 8.

Clutch used on above truck is a dry plate mul tiple disc type. The clutch shown on page 42 i extensively used as is also the cone type clutch.

Tires on above truck are solid 34"x4" singl front; 36"x7" rear. The "dual" solid tire, als the "pneumatic cord" truck tire, per page 555 are also extensively used.

Steering is the Ross, page 690.

From the above specifications of a truck an after a study of this book, it will be noted that a truck differs only in a few details from the prin ciple of the passenger car type of automobile.



Plan view of Case 17-25 tractor; showing layout of transmission and drive

The Modern Tractor.

The purpose of a tractor is explained on pages 753 and 831. Note that in addition to doing **tractor work**, such as pulling plows or other drawbar work, it is also possible to do **belt work**, such as operating threshing machines, etc.

The above illustration is that of a four-cylinder engine tractor. Most all tractor engines are four-cylinder, for reasons explained on page 831.

The construction of a tractor differs considerably from that of an automobile or truck, but the same underlying principles of engine and drive system are employed.

The engine used on a tractor is a slow speed engine, and usually a large bore. This particular tractor engine has a bore of 4½ in. and 6 in. stroke. A **governor** is employed for the purpose as explained on page 839. The speed of engine is governed to 900 r.p.m.

The **ignition** is usually a high tension magneto with an "impulse starter" (see page 832 for explanation of an impulse starter). Most tractor engines use magneto ignition for reasons stated on page 831.

The tractor engine operates for long periods of time at full power, therefore must be built heavier and more substantial than the automobile engine, for instance in the bearings, etc.

Fuel is usually gasoline to start with and kerosene to run on, after engine has started and became thoroughly heated. The **heating** of a tractor engine, in order to use kerosene or low grade fuels is a very important factor—see pages 827, 828, 831 and 71.

Drive system. The engine on above tractor is a four-cylinder, vertical type, mounted transversely on the frame. The power from crank shaft is transmitted to the **spur gear transmission** by means of a clutch. From transmission, power is transmitted to the rear axle by means of a spur gear drive. The differential is employed as shown in illustration. Power is transmitted to both rear wheels, which are 52 inches in diameter and have a 12 inch face.

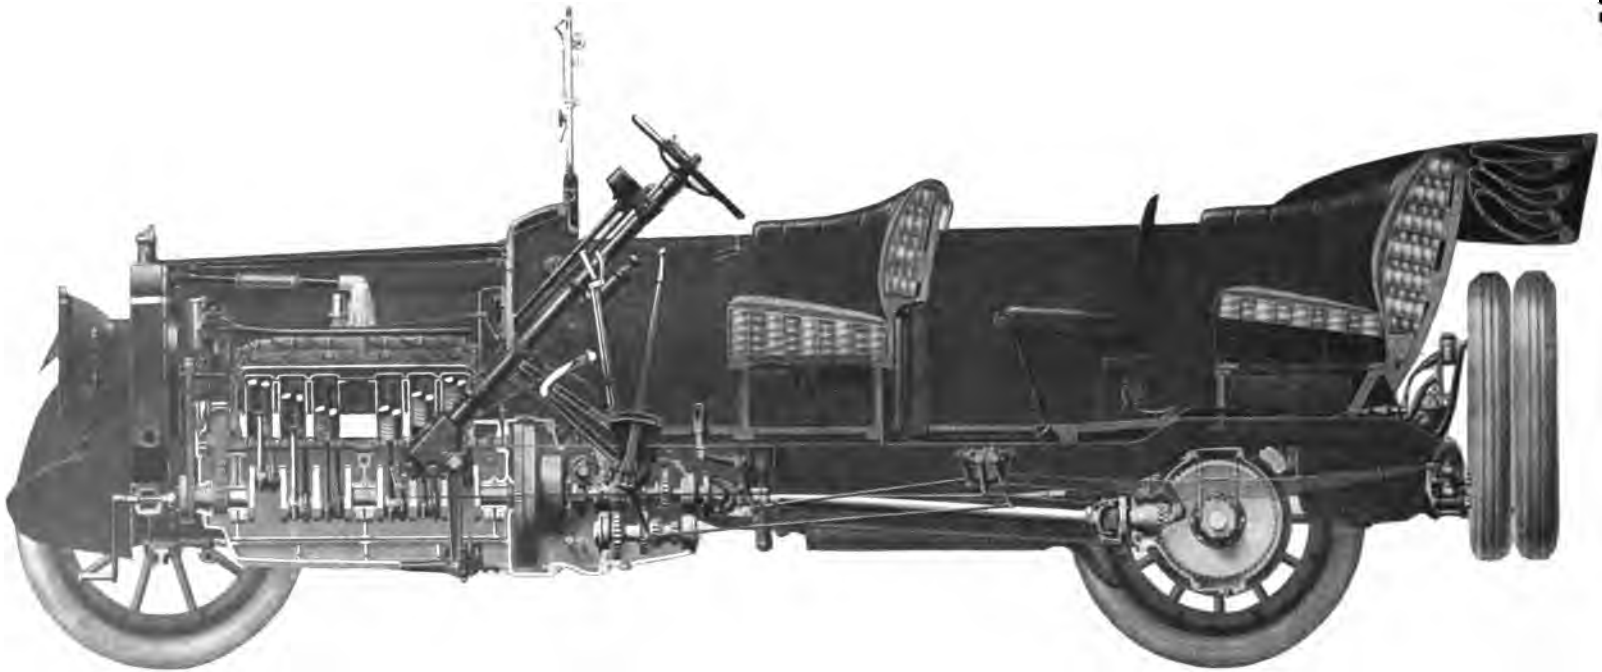
Speed of an average tractor is 2 miles per hour on slowest speed and 2¾ m.p.h. on high speed—see also, page 830.

The belt power is obtained from a 16 inch pulley mounted on an extension of the engine shaft, and therefore runs at engine speed—900 r.p.m.

The above tractor (the Case 15—27 h.p. tractor) has a wheel base of 76½ in., and its overall dimensions are: Length, 126 in.; width, 72 in.; height (without exhaust pipe), 68 in. The shipping weight is 5500 lbs.

The tractor pulls three 14-in. plows in tough sod or four plows under usual conditions. It is also adapted for other drawbar work (see page 752), requiring a similar amount of power, and it will operate either a 20x36 or 26x46 in. thresher (belt work).

It will be observed that the tractor, while it differs widely in construction, from that of the truck or passenger car automobile, it is, in many respects similar in principle, the main difference being in the drive system and fuel used by the engine.



A Modern Automobile.

The modern automobile employs either a four, six, eight or twelve cylinder engine.

The engine, clutch and transmission are housed in one unit, called a "unit-power-plant."

The drive on above car, is a propeller shaft with a spiral or helical drive pinion which meshes with a spiral driven ring gear on differential of rear axle. Straight tooth bevel gears are also used on many makes of cars.

The engine is started by an electric motor, which derives its electric current supply from a storage battery. The storage battery is kept charged by a dynamo or generator, driven from the engine.

Gasoline feed is from the gasoline tank in the rear of car. In this instance, the gasoline is fed to carburetor by air pressure, see page 854. On many other modern cars the vacuum principle as per page 165 is extensively used.

The speed of engine is controlled by a foot accelerator and hand throttle. Due to the great variations of speed, the governor is not em-

of automobile engines vary from 150 to 2500 r. p. m. and sometimes as high as 3000 r. p. m.

The ignition, in most instances, and in above car, is the coil, battery, timer and distributor type, but many use the high tension magneto.

Cooling is a forced circulation, by means of a water pump. A sylphon or water thermostat is used for reasons stated on pages 860 and 187. The cellular type radiator is used.

An Early Model Four Cylinder Automobile With Which We Will Start.

The reason for using the older model car as shown below, and in charts 1 to 10, is for two purposes; (1st) to familiarize the student with the **early** models and gradually work him up to the **modern** type of car as he progresses. (2nd) to show the relation between the parts. For instance, in the modern type of car, the engine, clutch and transmission are in one unit. It would be more difficult for the student to understand, if these **parts were all together.** Therefore, as he progresses he is gradually taken from the early model to the modern twelve cylinder car.

Why we use exaggerated illustrations—not drawn to scale—is due to the fact that we have found from experience that exact scale drawings would not explain the subject as clearly.

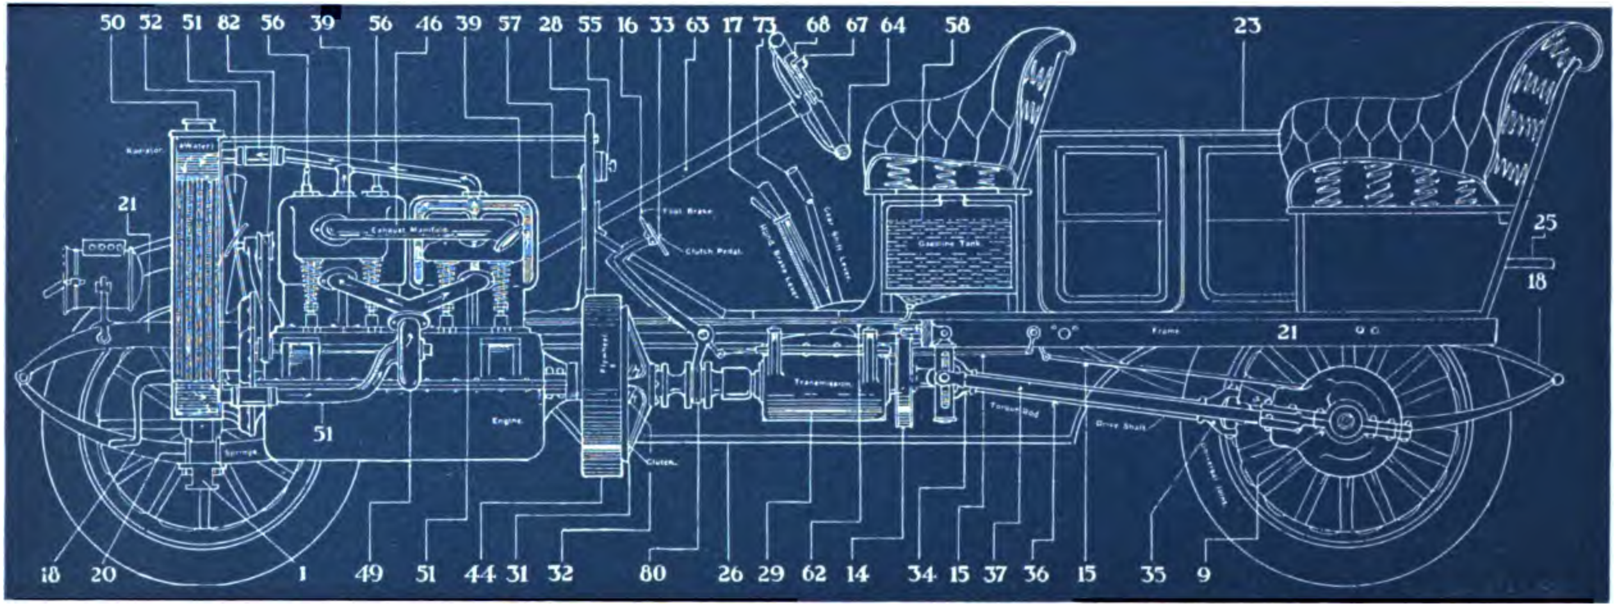

CHART NO. 1—Side sectional view of an automobile touring car. **Motive power**—four cylinder gasoline engine. **Type of clutch**—cone (the single plate clutch is now a popular type). **Drive**—propeller shaft. **Cylinders**—**T head type. Valves**—intake on one side, exhaust on other. **Cooling**—forced water circulation by pump (fan).

Gasoline feed—gravity (modern method is by vacuum, per page 163, or pressure feed, page 854).
Transmission—selective gear type. **Axle**—floating type, revolves inside of housing. The modern method of **gear shift**—both levers in the center, see page 486. The gear shift most used, is as per fig. 1, page 490.

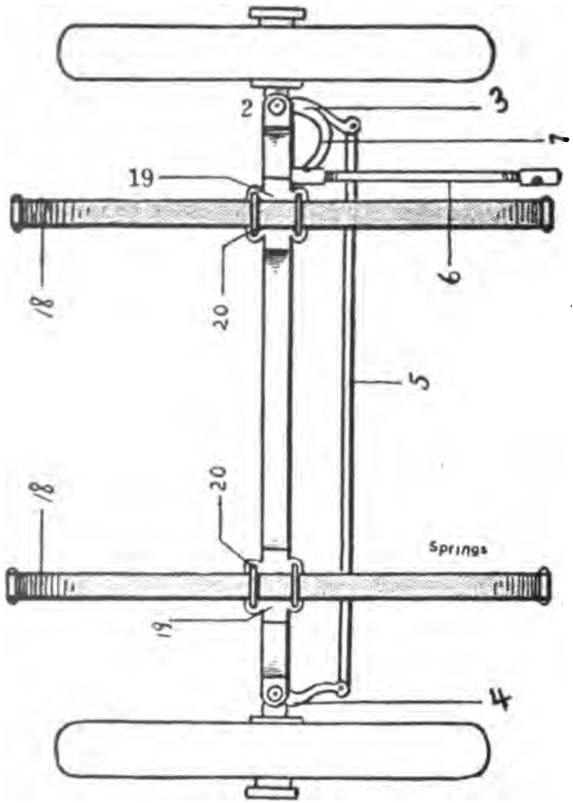
CHART NO. 2—Key to Motor Car Parts; illustrated in Charts 1, 3, 4, 5, 6, 7, 8, 9, 10. 31 and 32.

Note: Modern type of cars will be shown further on in this book. Read heading top of page IV.



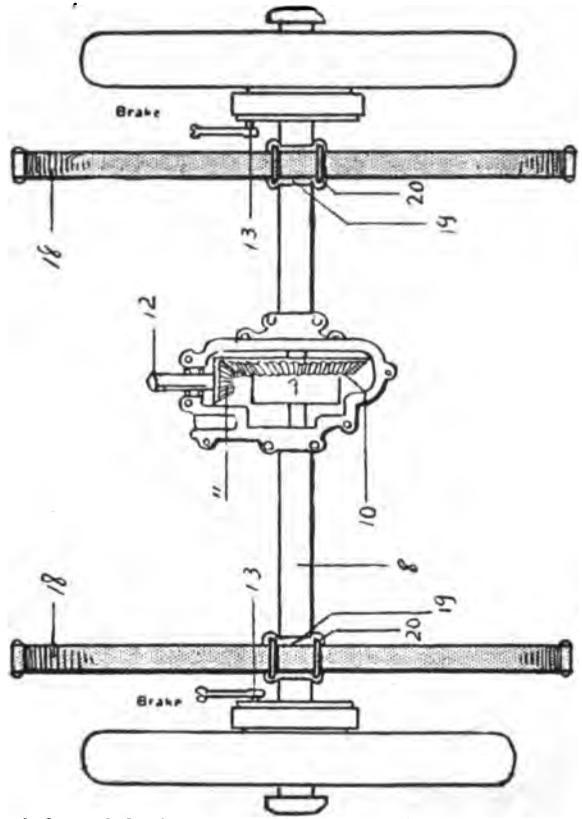


CHART NO. 3—Wheels, Rear Axle, Front Axle and Springs.

In building up a car the first parts to begin with are the **front and rear axles** (see chart 17, page 32, for the different types). The above illustration shows the **brakes** on the hubs of the rear wheels, (see chart 16).

The **differential** (9) (see chart 18, page 34), housed in the **differential gear case.** The drive pinion (11) is shown. Other types of drive gears used in the differential are spiral gears and worm gears, pages 21 & 35. The last mentioned are used more on trucks.

The **steering knuckle tie rod** (5) is shown connected from the **steering knuckle arms** (3 and 4) and the **steering gear connecting** rod (6) is shown connected to the **steering knuckle gear rod arm** (7).

The **springs** (18) are next mounted on the **spring seats** (19) on the front and rear axles, and are rigidly connected by means of **spring clips** (20).

For the various types of springs, see chart 15, page 26.

In many instances, manufacturers of automobiles do not manufacture all parts of cars, but secure the various parts from part manufacturers. See page 544.

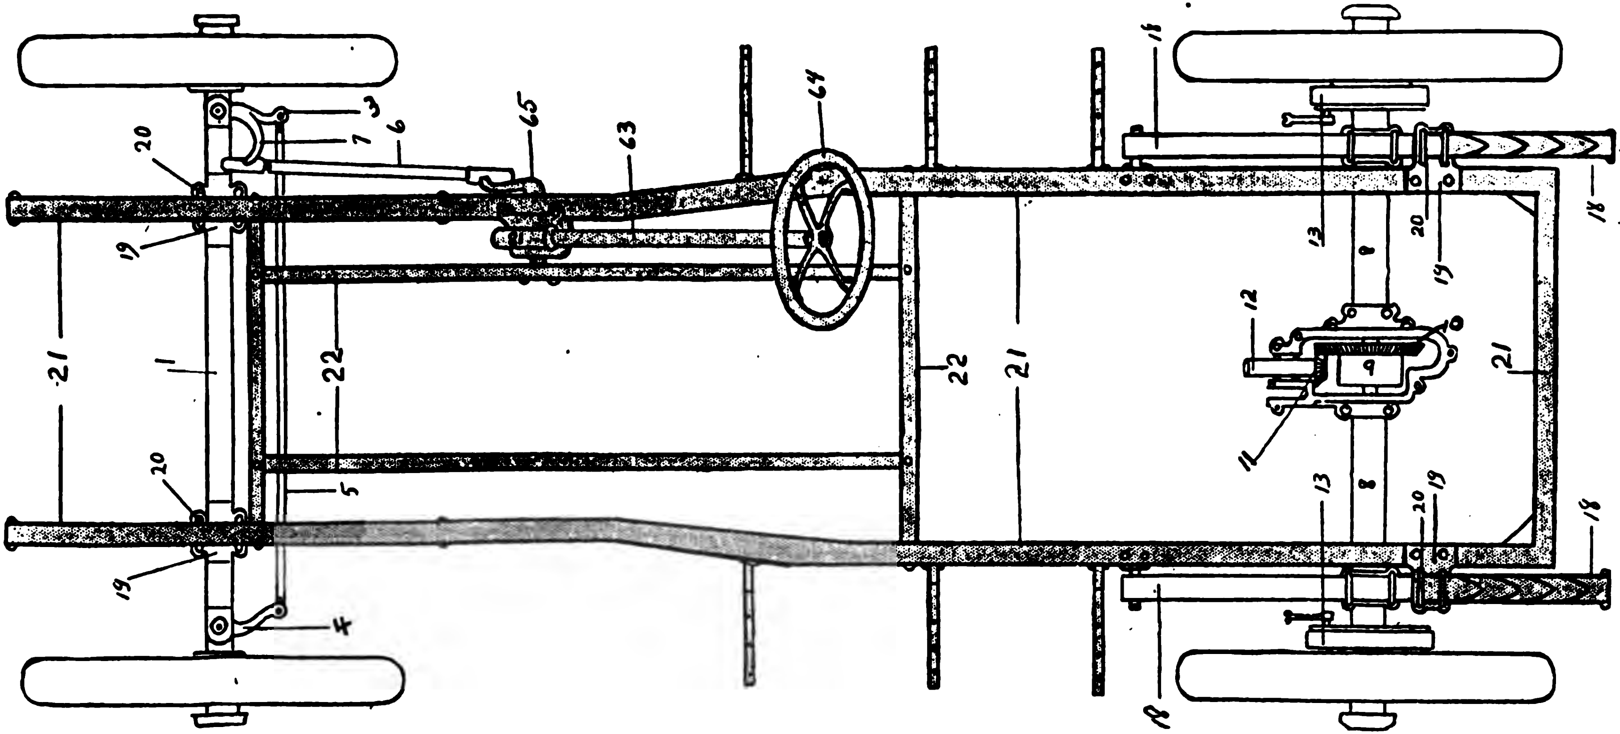

CHART NO. 4—THE RUNNING GEAR is Completed when the Main Frame and Sub Frame for supporting the Engine and Steering Device are added.

We now complete the running gear or foundation of the car, by adding the pressed steel frame (21) and sub frame (22).

The sub frame supports the power plant. Sometimes the sub frame is omitted when engine and transmission are equipped with supporting ears or lugs (which is now common practice). When so equipped, attachment is made to the main frame direct.

The steering device (see chart 14, page 24) is bolted to the frame and the steering gear arm (65) is connected with the steering gear connecting rod.

It will also be observed that the brackets for supporting the running board are attached to the side of the frame. We are now ready for the power plant.

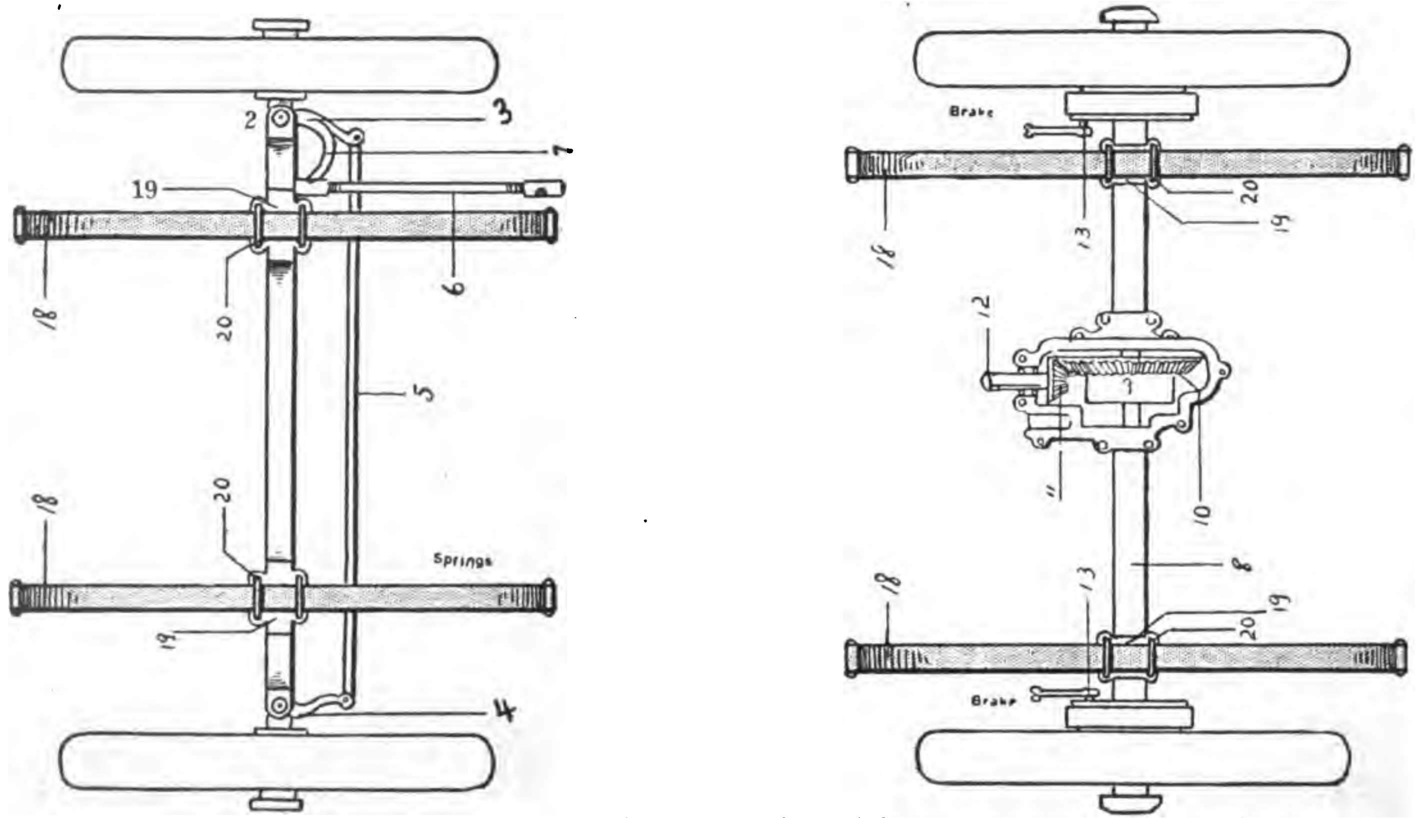

CHART NO. 3—Wheels, Rear Axle, Front Axle and Springs.

In building up a car the first parts to begin with are the **front and rear axles** (see chart 17, page 32, for the different types). The above illustration shows the **brakes** on the hubs of the rear wheels, (see chart 16).

The **differential** (9) (see chart 18, page 34), housed in the **differential gear case.** The **drive pinion** (11) is shown. Other types of drive gears used in the differential are spiral gears and worm gears, pages 21 & 35. The last mentioned are used more on trucks.

The **steering knuckle tie rod** (5) is shown connected from the **steering knuckle arms** (3 and 4) and the **steering gear connecting rod** (6) is shown connected to the **steering knuckle gear rod arm** (7).

The **springs** (18) are next mounted on the **spring seats** (19) on the front and rear axles, and are rigidly connected by means of **spring clips** (20).

For the various types of springs, see chart 15, page 26.

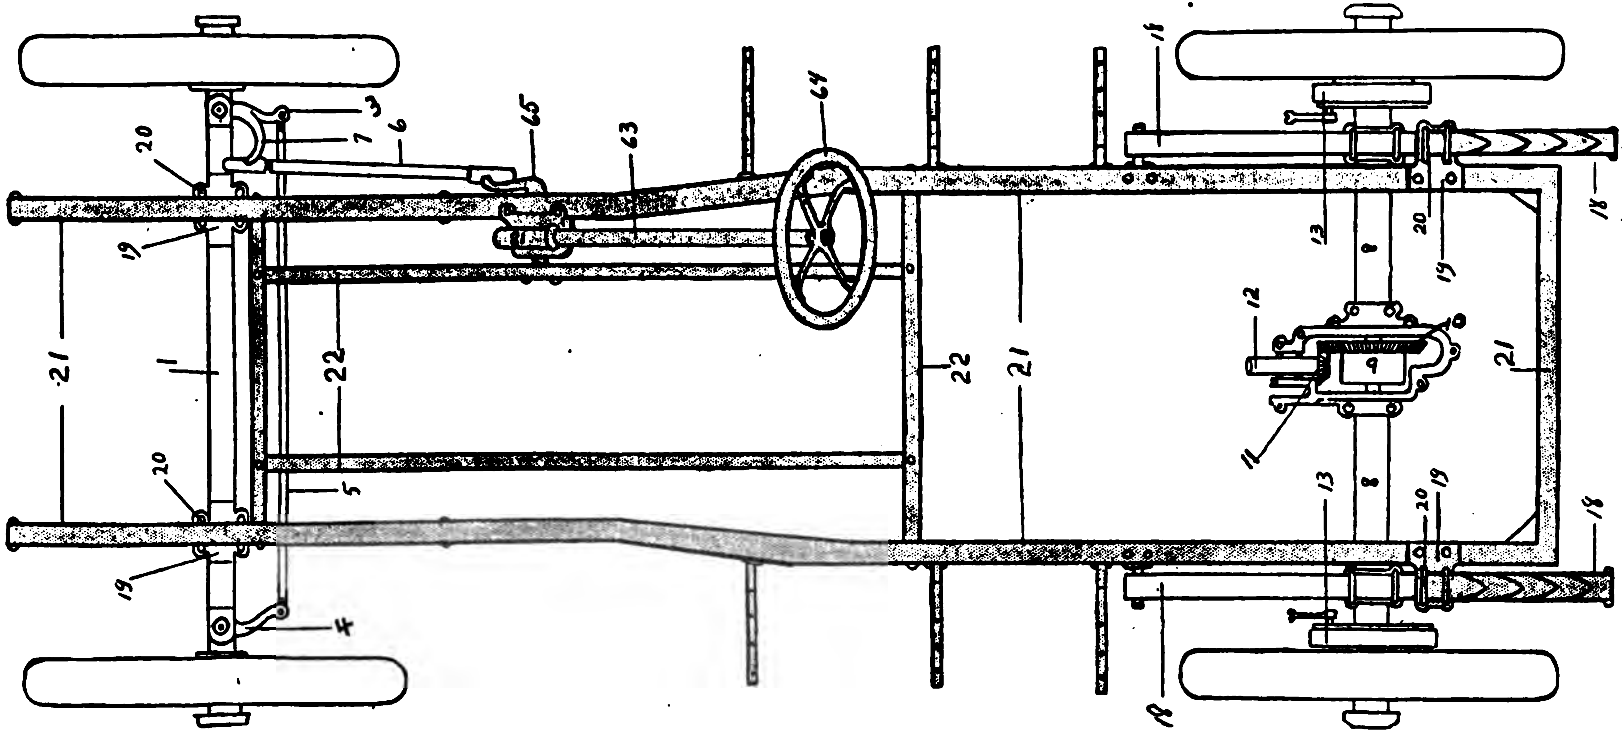

CHART NO. 4—THE RUNNING GEAR is Completed when the Main Frame and Sub Frame for supporting the Engine and Steering Device are added.

We now complete the running gear or foundation of the car, by adding the pressed steel frame (21) and sub frame (22).

The sub frame supports the power plant. Sometimes the sub frame is omitted when engine and transmission are equipped with supporting ears or lugs (which is now common practice). When so equipped, attachment is made to the main frame direct.

The steering device (see chart 14, page 24) is bolted to the frame and the steering gear arm (65) is connected with the steering gear connecting rod.

It will also be observed that the brackets for supporting the running board are attached to the side of the frame. We are now ready for the power plant.

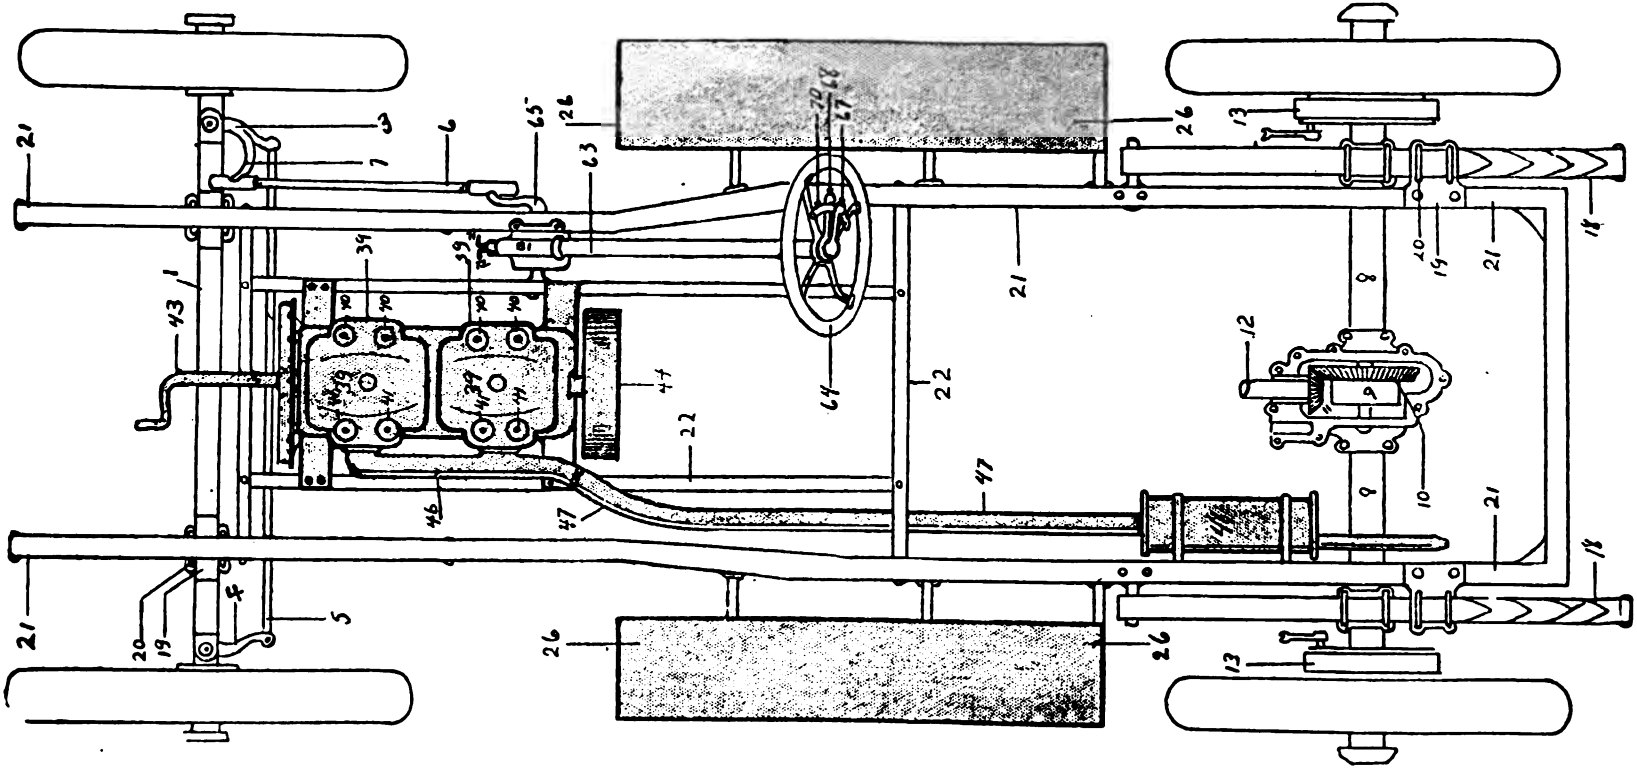

CHART NO. 5—THE POWER PLANT: the Engine, Exhaust Pipe and Muffler are now added.

The power plant is now ready to be mounted on the sub frame. First we will mount the ***engine** in place and bolt it down. We then attach the **exhaust manifold** (46), **exhaust pipe** (47), **muffler** (48) and **starting crank** (43). (see charts 31 and 32, pages 62 and 64).

The **running boards** (26) are attached to the brackets on the side of the frame—handy for holding tools while working on chassis.

*Although the above is a four cylinder T-head engine—it could be a 4, 6, 8, or 12 cylinder, and the cylinders instead of being cast in pairs could be cast singly or in-block.
Improvements: most of the power plants of today are "unit power plants." The clutch and transmission are in one unit with the engine (see principle, page 44).

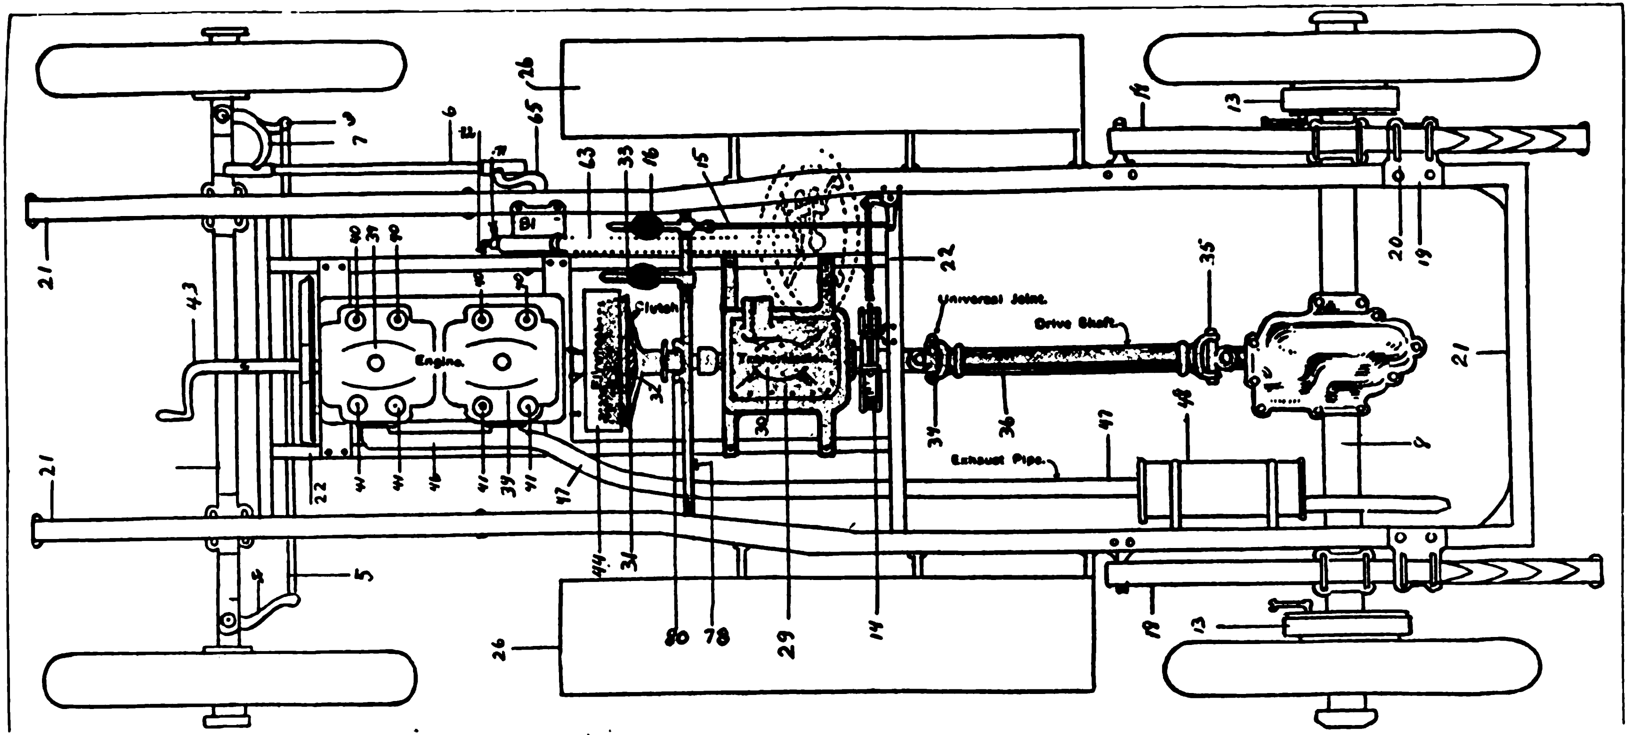

CHART NO. 6—THE PARTS FOR THE TRANSMISSION OF POWER **consisting of the Clutch, Transmission and Drive Shaft are now added.**

The *clutch (31) which is of the cone type (see chart 19, page 38) is placed in the fly wheel. The **clutch pedal shaft** (78), **clutch pedal** (33), **clutch yoke** (80) and **brake pedal** (16) are next mounted. The pedal (33) is fastened to the shaft (78) permanently. When this pedal is pressed by the foot, the yoke (80) forces the clutch from the fly wheel. When it is released, the spring (32) inside of the clutch forces the clutch back into the fly wheel. See Dyke's working model of transmission and clutch.

A clutch shaft extends from the clutch to the main drive gear shaft in the transmission (see pages 19 and 38).

The **transmission is bolted to the sub frame. The shaft from the transmission extends to a **universal joint** (34) then the **drive shaft** (36) extends to the rear universal joint (35) which connects with the **axle drive pinion shaft** (12), Illustration No. 3. The teeth on the **axle drive bevel pinion** (11), mesh with the teeth of **axle drive bevel gear** (10) on the **differential** (9).

*The clutch on this car is a cone type. A multiple disc type could be applied with same principle, see page 50 for the drive system showing the modern single plate clutch.

**The transmission on this car is the selective type—three speeds. The progressive type could be used, but the progressive type is seldom used, being more or less obsolete. The planetary type of transmission is used only on light cars, such as the Ford. It has but two speeds.

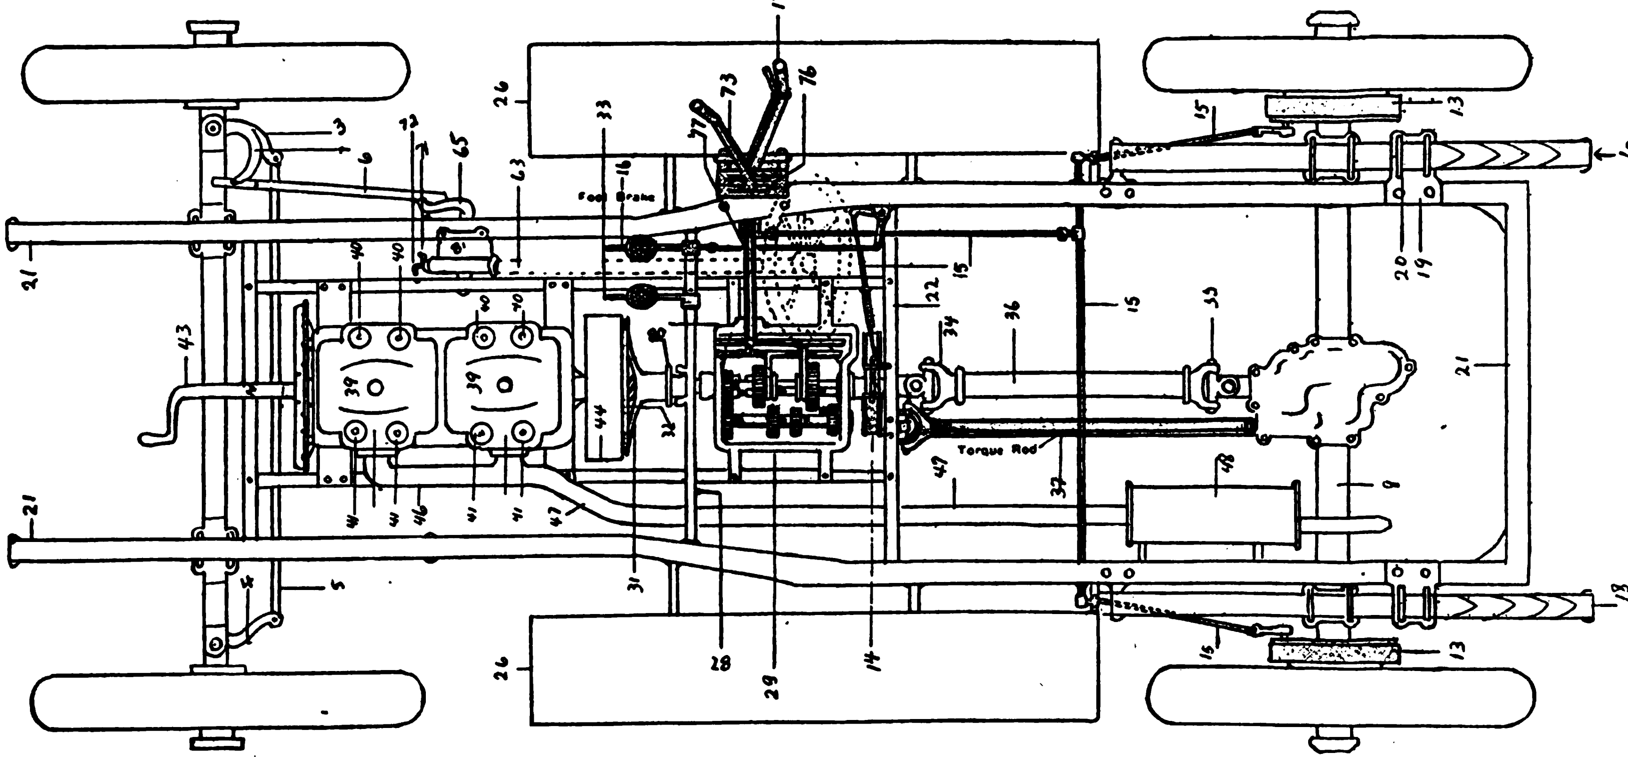

CHART NO. 7—THE CONTROL SYSTEM consisting of Gear Shifting Lever, Brake Lever, Brake Rod and the Steering Gear Assembly are now added.

The **gear shift lever** (73) and ****emergency brake lever** (17) are attached to the side of the frame in this illustration, but the modern method is to place them in the center per page 486. The full description of this gear shifting arrangement is shown on pages 48 and 49.

The **hand brake lever** (17) is seldom used for braking purposes only in case of emergency and when the car is standing on an incline. The lever can be locked in its ratchet. This brake control, on some cars, also connects with the clutch, so that when the brake is applied the clutch is thrown out simultaneously—this principle used on the Ford and Chevrolet.

The **brake pedal** (16) is not fastened to the shaft (78) but works free over it. This pedal connects through a system of rods and a bell crank to the Band Brake (14) which is mounted over the pulley on the transmission drive shaft (see chart 16). This brake is called the **foot brake,** as it is the brake used principally when running.

The **torque rod** (37) (sometimes called torsion rod) is now attached. There are several types of torque rods, see page 22.

The next step will be the installation of the ignition and carburetion systems and smaller parts of the power plant.

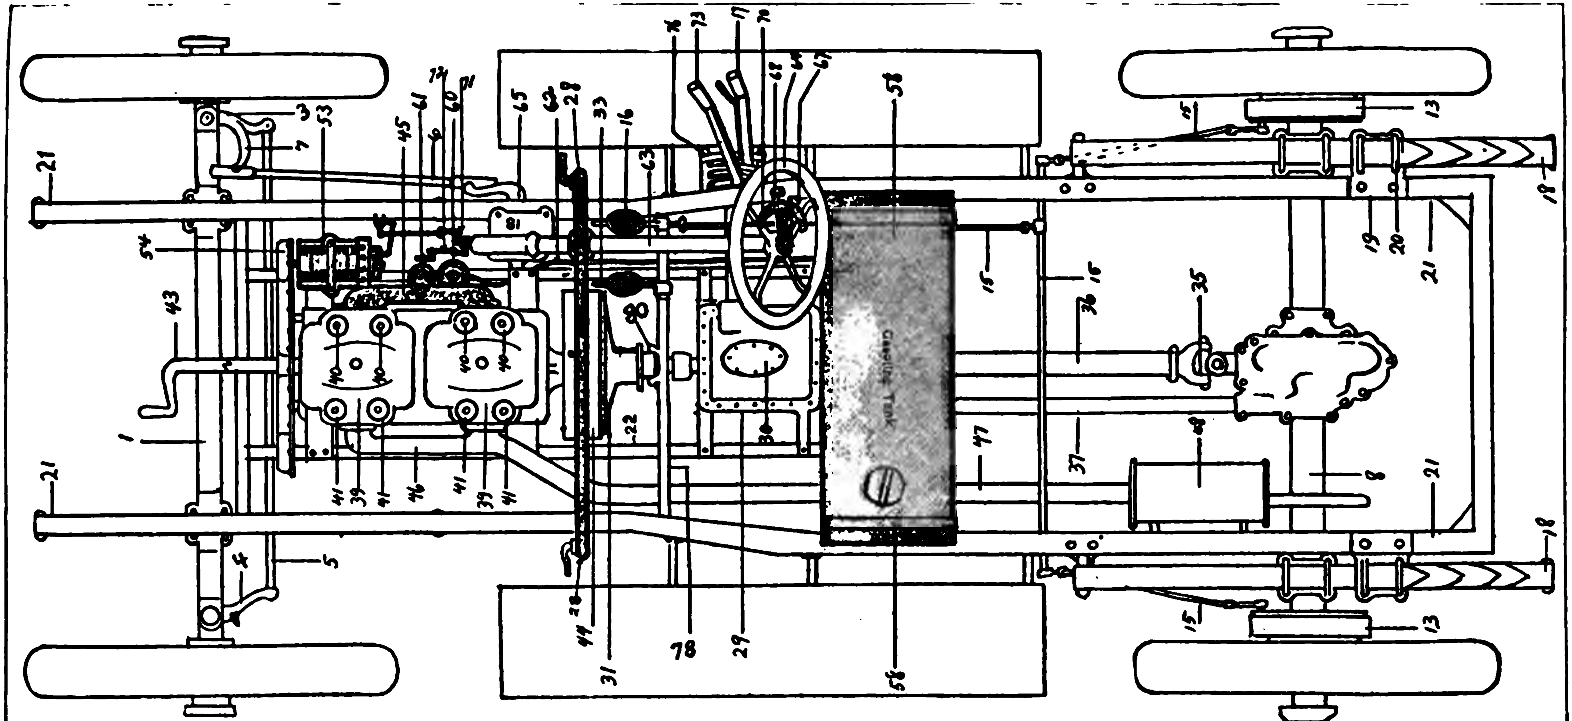

CHART NO. 8—A COMPLETE CHASSIS is now shown with the Control System, *Fuel System, Carburetion and Ignition System added.

First we will connect the inlet manifold (45). The **carburetor** (60) is then connected to the manifold. The **gasoline pipe** (62) is connected to the **carburetor**, thence to the **gasoline tank** (58) (see Instruction 12). The **throttle lever** (68) on steering wheel connects with throttle (61) on the carburetor by means of rod (72) which passes through the steering column tube (63) and connects by means of bell cranks, etc., (see chart 33, page 66).

†The **magneto** (53) is mounted to the side of the engine on a special bracket provided for same and geared to the cam shaft gear (see pages 294 and 302).

The **spark lever** (67) connects with the interrupter or "breaker box" (see page 66) on the magneto (or timer if a timer and coil is used) by means of a shaft passing through the steering column and by means of bell cranks. If a jump spark coil and timer is used, see chart 106, page 222.

The **dash board** (28) should now be added. This board supports the ignition and lighting switches and various instruments, as ammeter, oil pressure gauge, and the bracket to brace the steering column. The dash is attached by bolting to the frame.

*For different methods of gasoline feed; gravity and pressure, see pages 168 and 165. The modern method is the Vacuum or Pressure feed system.
†Other types of ignition (such as the coil and battery system with the distributor and timer) are now more universally used than the magneto. See page 245. Also see page 342 for the Electric Starting Motor and Generator.

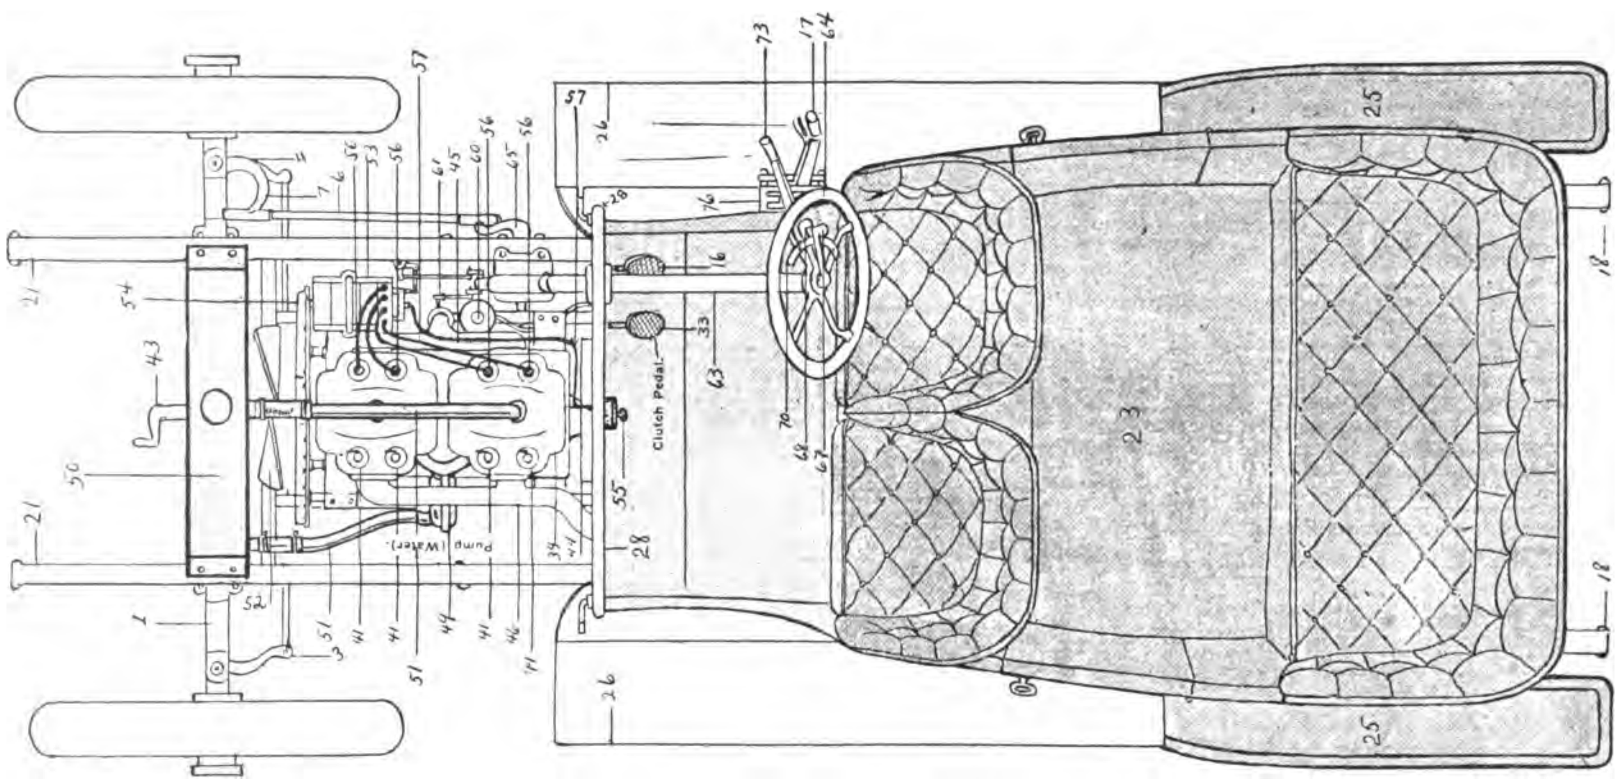

CHART NO. 9—WIRING: **The *Ignition System and the †Electric Starting, Generating and Lighting System are now connected up. Cooling System, Body and Fenders are also added.**

The **high tension cables or wires** (57) are run from the high tension magneto (53) to **spark plugs** (56) (see pages 294 and 296).

The **switch** (55) is placed on the dash and connects with magneto (page 268).

The **radiator** (50) is mounted on the front end of the frame. Water pipes (51) are connected from bottom of radiator to the **water circulating pump** (49) by pipes, thence around the cylinder to outlet pipe (51) to top of radiator—see chart No. 1.

Some cars do not have a **water circulating pump** but use what is called a thermo-syphon system of circulation—see page 185. The **fan** (52) is now connected (see page 187).

The lubrication system for engine is not shown on this illustration—see page 196.

*Some times two systems of ignition are used; a coil and battery and magneto called a

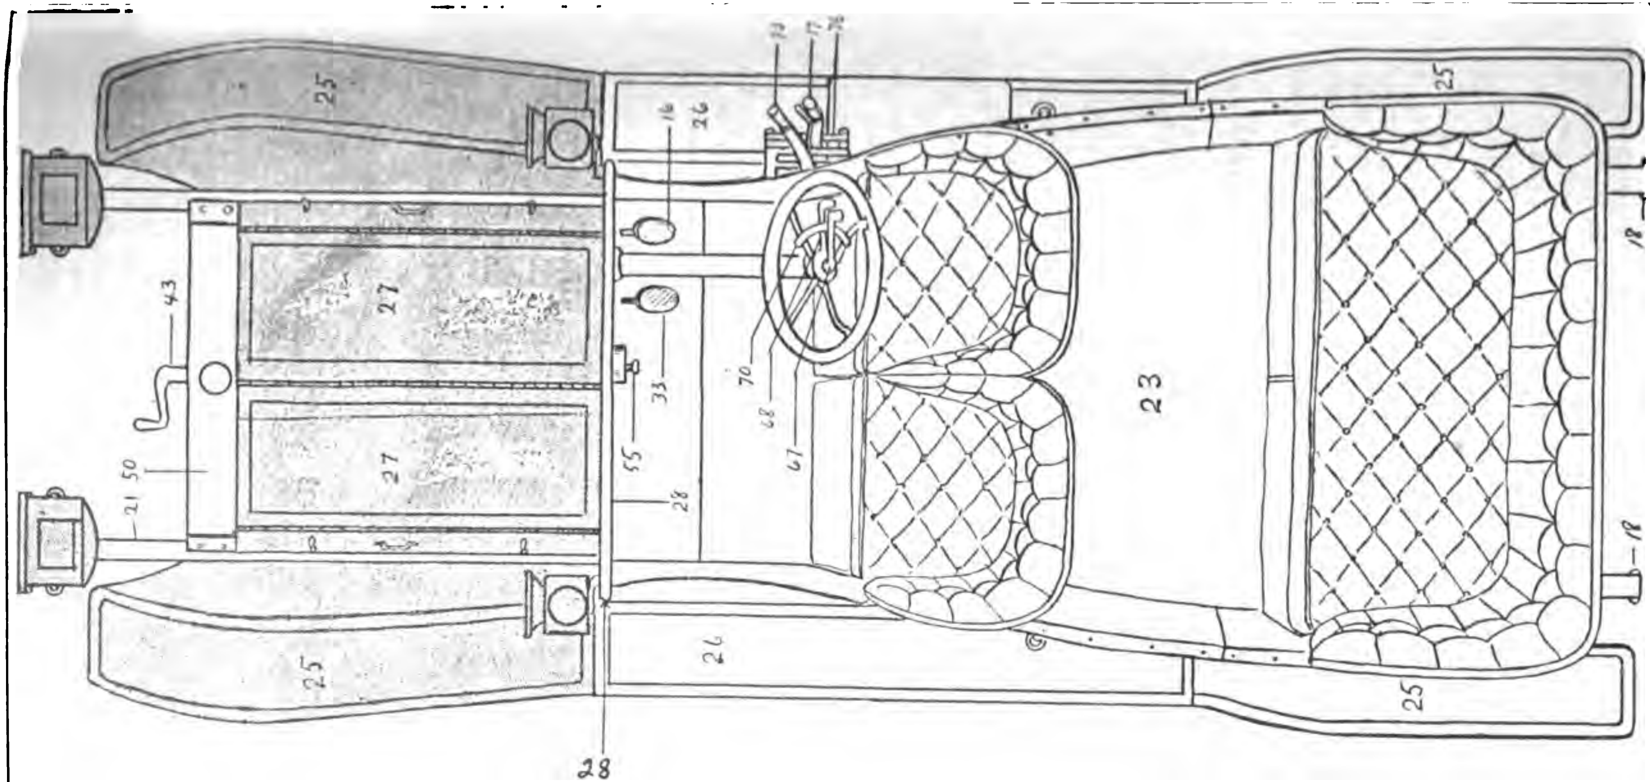

CHART NO. 10—The Completed Car.

†The **body, fenders** and the **hood are now added.**

Painting: the body is usually upholstered and painted separate from the mechanical part of car. The fenders and hood are usually enameled, which requires a heat treatment.

***The electric system on this car is a high tension magneto.** The electric system on a modern car, consisting of **ignition, storage battery, electric generator and starter** is not shown in this illustration, but is fully treated further on. See pages 204 and 357 for **location of battery,** starting motor, generator and ignition system of a modern car and pages 369 and 342 for plan of connections of these parts.

A lighting system, which is usually electric, is not shown in this illustration, see pages 342 and 426 for wiring principle.

To prepare car for service—see page 487. To start engine, start car and operate car, see pages 486 to 493.

†We have now illustrated a car built of standard parts. **While the construction may** vary in form of the number of cylinders to engine, a disk clutch instead of the cone and other forms of construction—the principle remains the same.

***The only electric system on this car is the high tension magneto** which supplies current for ignition only (see fig. 1, page 276). A majority of modern cars do not use the magneto but use the battery and coil system of ignition in connection with a mechanical generator or dynamo which charges the battery. **See bottom of page 287 and page 342.**

INSTRUCTION No. 1.

THE AUTOMOBILE: Assembly of the Automobile. Functions of the Principal Parts.

The Kinds of Motor Cars.

There are three different kinds of motor cars; first, the gasoline motor car; secondly, the steam car; thirdly, the electric car.

The gasoline motor car is by far the most popular, and it is with this that we are mainly going to deal.

The steam car, silent, smooth and easy on tires, is comparatively seldom seen.

The electric car, almost invariably in the form of a brougham or coupe, is heavily handicapped by being unable to run for more than a few hours without a fresh charge of electricity from its headquarters, and is quite in the minority. Our attention will be devoted to the car with the gasoline engine for the motive power.

The Component Parts of a Motor Car.

A car may be made up as a whole of two distinct parts, the body and chassis.

The body, which is the work of the body builder, which has been brought by him to a wonderful pitch of perfection, hardly concerns us so we will unscrew the half dozen or so bolts that secure it to the frame of the chassis and stand it to one side, for the present at least—so that we can examine the chassis underneath.

The chassis is the entire car with the exception of the body (see chart 8). The chassis, for our purpose, must also be divided into its main parts as follows: the running gear, power plant, transmission system, control system, equipment and accessories.

The running gear consists of parts as follows: front and rear axles, wheels, springs, frame.

The power plant consists of parts as follows: motor with its fuel system, carburetion system, ignition system, cooling system and lubrication system.

The transmission system consists of parts as follows: clutch, change speed gears, drive shaft with its universal joints and differential.

The control system consists of parts as follows: steering device, throttle and spark control, hand levers, foot pedals and brake system.

The necessary equipment consists of such parts as fenders, running boards, hood, dash, tires, lighting system, self starter, horn, etc.

The desirable equipment or accessories are such parts as speedometer, windshield, warning signal, shock absorbers, etc.

The construction of the parts of a motor car may vary, but their purpose is the same. While it is true there are hundreds of different firms making automobiles, they all employ in the construction of their cars the parts enumerated under the various headings. For instance, one manufacturer may suspend the power plant on the main frame, others use a sub-frame. Some use a clutch of the cone type, others use a clutch of the multiple disc type—but they all use frames and they all use clutches. Further on we will explain the different constructions involved in these parts, but bear in mind the principle or purpose of each part does not change.

As we progress the reader will gain an idea of the different constructions of the component parts now in general use—for instance, there are two kinds of front axles in general use; the tubular type and the solid type. There are two types of construction of rear axles in general use; the live axle which revolves and is driven by a bevel gear and pinion, and the dead axle which does not revolve, but the wheels are driven by chain and sprocket, and so on, throughout the whole construction of a car.

*It is now clear that if the reader masters the **principle and purpose of these parts** then it will be no difficult matter to understand the variation in construction, and when he will have completed the study of this construction he will have gained sufficient knowledge to enable him to understand the construction of **all cars.**

Purpose of the Parts of the Running Gear—see chart 4.

The front wheels run free on the axle, and guide the car. They are called the guiding wheels and are moved from side to side by means of a steering device (63-64-65) and the direction of the car is controlled in this manner. The rear wheels are revolved by the engine and drive the car.

The front axle is fitted with **steering knuckles** (3 and 4) on which the guiding wheels run. These steering knuckles are moved by means of the rod (6), which connects to the steering device (65). The front axle is fitted with **spring blocks** (19) and spring clips (20) which hold the springs in place.

The rear axle revolves. The housing over axle is fitted with spring blocks and clips similar to the front axle.

The springs act as a cushion and protect the machinery and the occupants of the car from undue vibration and shock. They also hold the frame.

The frame of an automobile is made of pressed steel and is the foundation which supports the power plant, change gears, levers, steering device, fuel tank, body, etc. Each part is bolted to frame and is kept in proper relation to each other. The frame is usually hung, with the springs resting on the axles as shown in upper illustration, fig. 1, to the left, called **overslung**. Sometimes the springs are fastened below the axles, called the **underslung** construction.

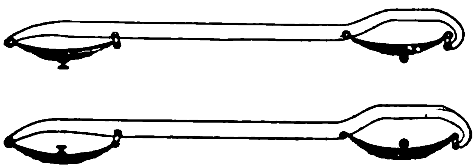

Fig. 1. In the upper illustration is shown the **overslung** spring suspension which is used on the majority of the cars today. Note that here both front and rear springs and also the frame are above the axles. In the lower illustration is shown the **underslung**, a form of spring suspension in which the frame is above the axles, but the springs below—seldom used.

A popular spring system is the cantilever, see page 27.

A sub-frame is sometimes placed inside of the main frame to support the power and drive plant.

The steering device (63-64-65) is usually attached to the frame. By turning, the wheel (64) the car is guided through the control of the direction of the front wheels.

Brakes (13) are fitted to motor cars for stopping or slowing down and are usually fitted to a drum on the hubs of the rear wheels.

Purpose of the Parts of the Power Plant—see chart 5.

The engine furnishes the power that drives the car. It is usually located in the front part of the frame, if it is a multiple cylinder vertical type of engine.

***Suspension:** multiple cylinder engines usually have four, six, eight or twelve cylinders. If it is a single cylinder engine, it is usually hung as shown

*See index for advantages of "three point suspension."

*The type of clutch, axle, engine, etc. which are used on leading cars given under "Specifications of Leading Cars"—page 542.

in chart 11, fig. 1; if double cylinder opposed type, it is usually placed across the frame. If a multiple cylinder, "**single unit power plant**" (see page 85), it is usually suspended at three points as per page 786, fig. 49. This is called "**three** point suspension."

The carburetor mixes air with gasoline, and is connected direct to intake pipe on engine. The carburetor is connected to the feed pipe (62) from the gasoline tank.

The gasoline tank is usually placed under the seat or at the rear of the car and gasoline is fed to the carburetor through a small pipe (62) (chart 8) or by the vacuum system (see carburetion instruction).

The exhaust pipe (47) connects to the exhaust manifold and runs to muffler (48), which is usually placed at rear of car. The exhaust pipe permits the burnt gases to escape. **The muffler** placed at the extreme end of the exhaust pipe, silences or muffles the noises from the explosions in engine cylinders.

The ignition system is a part of the electric plant; either a storage battery and coil, dry cells and coil, generator, or a magneto. The coil and battery electric system was formerly placed on the dash, while the magneto or generator is placed on the engine and is run by the cam shaft or crank shaft, through the medium of silent chains. The modern coil and battery system with a timer and distributor is now placed on the engine, see Delco and Atwater-Kent systems.

The cooling system consists of the radiator (50), water pipes (51) and circulating pump. The object of the cooling system is to keep the engine from getting too hot when the explosions take place inside of the cylinders.

The lubrication system of the engine is for the purpose of keeping the bearings and rings and other moving parts from wearing. This subject as well as all other subjects will be treated separately further on.

Transmission of Power—see charts 6, 7.

The transmission or the speed change gears is that part which transmits the power from the engine to the driving wheels through a system of speed change gears (29).

A clutch (31) is placed between the engine and transmission; this permits the engine to run free, or when "thrown in" connects the engine to the change speed gears and drive the car. The clutch is operated by a foot pedal (33) and is thrown in or out by the driver.

In a locomotive, **the piston rods** are connected direct with the wheels, through the medium of the cross head, and connecting rods so that when steam is applied the locomotive moves. In an automobile, the engine may be disconnected from the transmission by means of the clutch, so that the motion of the transmission or of the entire car may be stopped without stopping the engine.

Change gear principle: When a bicyclist wants to race on a level track he gears his wheel up high, so that one revolution of the crank takes him the greatest possible distance. Yet if he takes this wheel on the road and encounters a hill, he must get off and walk or exert an extra lot of power—he needs a wheel geared lower.

In the same way, when an engine is required to do more than ordinary work, as climbing a hill, the transmission or change speed gear contains from two to four changes of gears and helps out the engine by changing to the gear ratio required for less motive power. It allows the car to move at various speeds while the speed of the engine is unchanged.

When in low gear, the engine makes quite a number of revolutions (15 or 20), while the wheels revolve once which makes the auto move forward slowly, but with considerable force, so that it can go up a steep hill or through sand or mud.

When in second or intermediate gear, the engine makes from (8 to 12) revolutions to one revolution of the wheels, which moves the car faster than the low or first change of gears but with less force.

When in third or high gear the engine makes from (2 to 4) revolutions to one revolution of the wheels, which gives the car high speed over good roads.

If the car was going up a steep grade while on high gear, the work would be more than the engine could do, and it would stop unless one of the lower speeds were shifted in. There would be considerably more pull on the wheels.

The operation of the change of gears is by means of a **side or center lever** (73, chart 1, also see chart 23); change of gears can be made instantly. The transmission also contains a set of **reverse gears,** which when thrown in, will reverse the motion of the car without reversing the motion of the engine.

The transmission may be connected so that it **drives the wheels by the following methods.**

First—by a **driving shaft** (see chart 11, fig. 1, c and e, also (36) chart 6), connected to the rear axle, which it revolves by means of bevel gears, the wheels and axle turning together. This axle revolves and is called a "**live**" axle.

Second—by a **single chain** (see h, chart 11) connected to the rear axle, wheels and axle turning together.

Third—by **two chains** (see b, chart 11), one connected to each rear wheel, which run free on the axle, like a buggy and is called a "**dead**" axle because it does not revolve.

The Drive System—see chart 6.

The connection between the engine and the wheels is called the drive system.

The **drive shaft** connects with the end of the transmission shaft by means of a universal joint, it has also a universal joint at rear end connecting with the differential drive pinion shaft.

The **universal joints** (34-35) permit the parts mounted on the rear axle to move up and down, thus preventing the movement of the axle from interfering with the drive of the car.

The torque rod (37) is usually placed between the housing on rear axle and the transmission case. The object of the torque rod (or torque arm as it is now called) is to prevent the axle housing from twisting when the power or brakes are applied (see page 22).

The **drive pinion shaft** (12) connects to the rear universal joint (35) and drives the bevel gear (10), which is connected to the differential (9), (see chart 5).

The front wheels on an automobile run free on the axle. For this reason the outside wheel is able to revolve faster than the inside wheel when the car is turning a corner.

When a vehicle turns a corner, the outside wheels revolve faster than the inside wheels, because they travel a longer distance.

The wheels in rear must do the same thing; if they were forced to revolve at the same speed, one would slide because it could not keep pace with the other.

When they run free on the axle, they would take care of this themselves, but as both are driven by the engine, the transmission or rear axle is fitted with a **differential,** or at times erroneously called a **compensating gear** (see chart 18). This device is automatic, and permits the wheels to revolve at variable speeds, although both are driven by the engine.

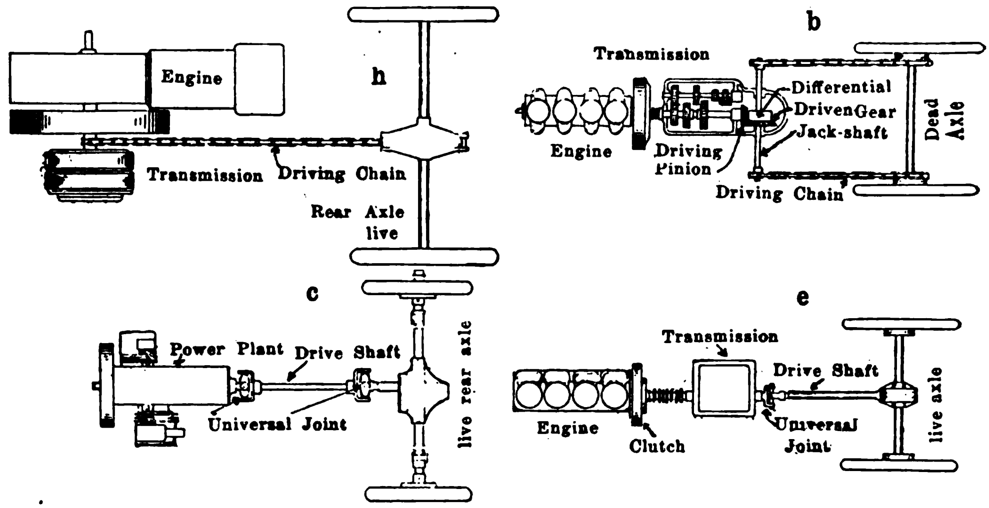

Fig. 1—Methods of Power Transmission to Rear Axle.
h—Single chain drive (obsolete). **b**—Double chain drive (used principally on trucks). **c**—Shaft drive with a double opposed type of engine (shaft drive is extensively used, but the opposed type engine is seldom used). **e**—Shaft drive with a four, six, eight or twelve cylinder engine (extensively used).

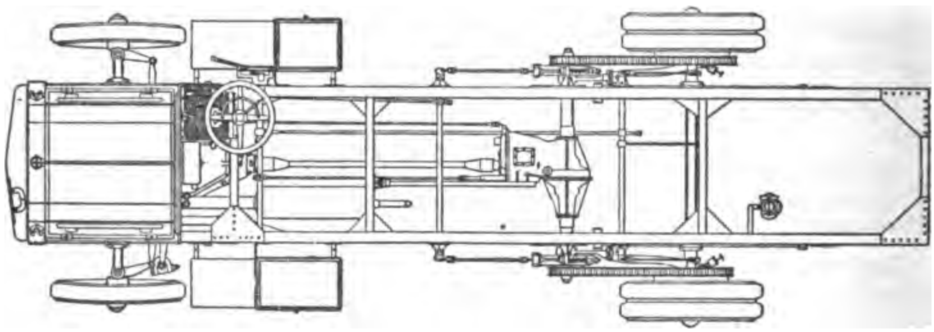

Fig. 2—Top view of a double chain driven truck. Rear axle is called the "dead" type because it does not revolve. Formerly employed by the Packard Motor Car Co.

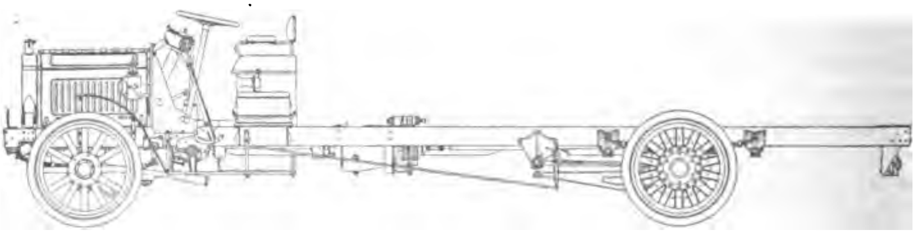

Fig. 3—Side view of a modern Packard chainless truck. Drive; worm: power; four cylinder gasoline engine; clutch; disk: transmission; four speed selective sliding: "live" rear axle; full floating.

Worm gear drive. This system is used on a large number of cars now, especially on trucks, and is coming more into favor every year. There is no difference in the transmission system, except as regards the drive, as compared with the usual bevel-gear system. In principle the worm drive is a simple arrangement; the usual bevel gear and pinion are replaced by a specially-shaped hollow helical toothed gearwheel and worm. A "live" rear axle is used.

CHART NO. 11—Methods of Transmission of Power to Rear Axle and Road Wheels.

Body.

The automobile frame, with all parts of the running gear, the transmission, engine and other parts of the mechanism, when it is **without the body is called the chassis.** Different types of bodies may be attached to a **chassis**, and are generally fastened down with bolts.

The bodies of pleasure automobiles are classed as follows:

Roadster—An open car seating two or three. It may have additional seats on running-boards or in rear deck.

Coupelet—Seats two or three. It has a folding top and full-height doors with disappearing panels of glass.

Coupe—An inside operated, enclosed car seating two or three. A fourth seat facing backward is sometimes added.

Convertible Coupe—A roadster provided with a detachable coupe top.

Clover Leaf—An open car seating three or four. The rear seat is close to the divided front seat and entrance is only through doors in front of the front seat.

Touring Car—An open car seating four or more with direct entrance to tonneau.

Salon Touring Car—A touring car with passage between front seats, with or without separate entrance to front seats.

Convertible Touring Car—A touring car with folding top and disappearing or removable glass sides.

Sedan—A closed car seating four or more all in one compartment.

Convertible Sedan—A salon touring car provided with a detachable sedan top.

Open Sedan—A sedan so constructed that the sides can be removed or stowed so as to leave the space entirely clear from the glass front to the back.

Limousine—A closed car seating three to five inside, with driver's seat outside, covered with a roof.

Open Limousine—A touring car with permanent standing top and disappearing or removable glass sides.

Berline—A limousine having the driver's seat entirely inclosed.

Brougham—A limousine with no roof over the driver's seat.

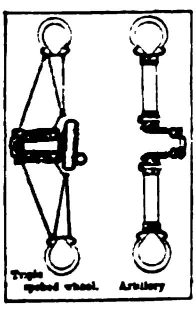
Landaulet—A closed car with folding top, seats for three or more inside, and driver's seat outside.

Body equipment consists of a **hood** or **bonnet** over the engine which connects with the **dash** of the body. Fenders or mud guards are usually attached independent of the body, also the **running board. Wind shields** are placed in front on the dash. **Steel pans,** which extend under the mechanism, protecting it from mud and dust.

Commercial vehicles are those used for business purposes such as taxicabs, delivery and trucks.

Wheels.

Tires made of rubber are fitted to the wheels to take up the vibrations that are too sudden for the springs to absorb.

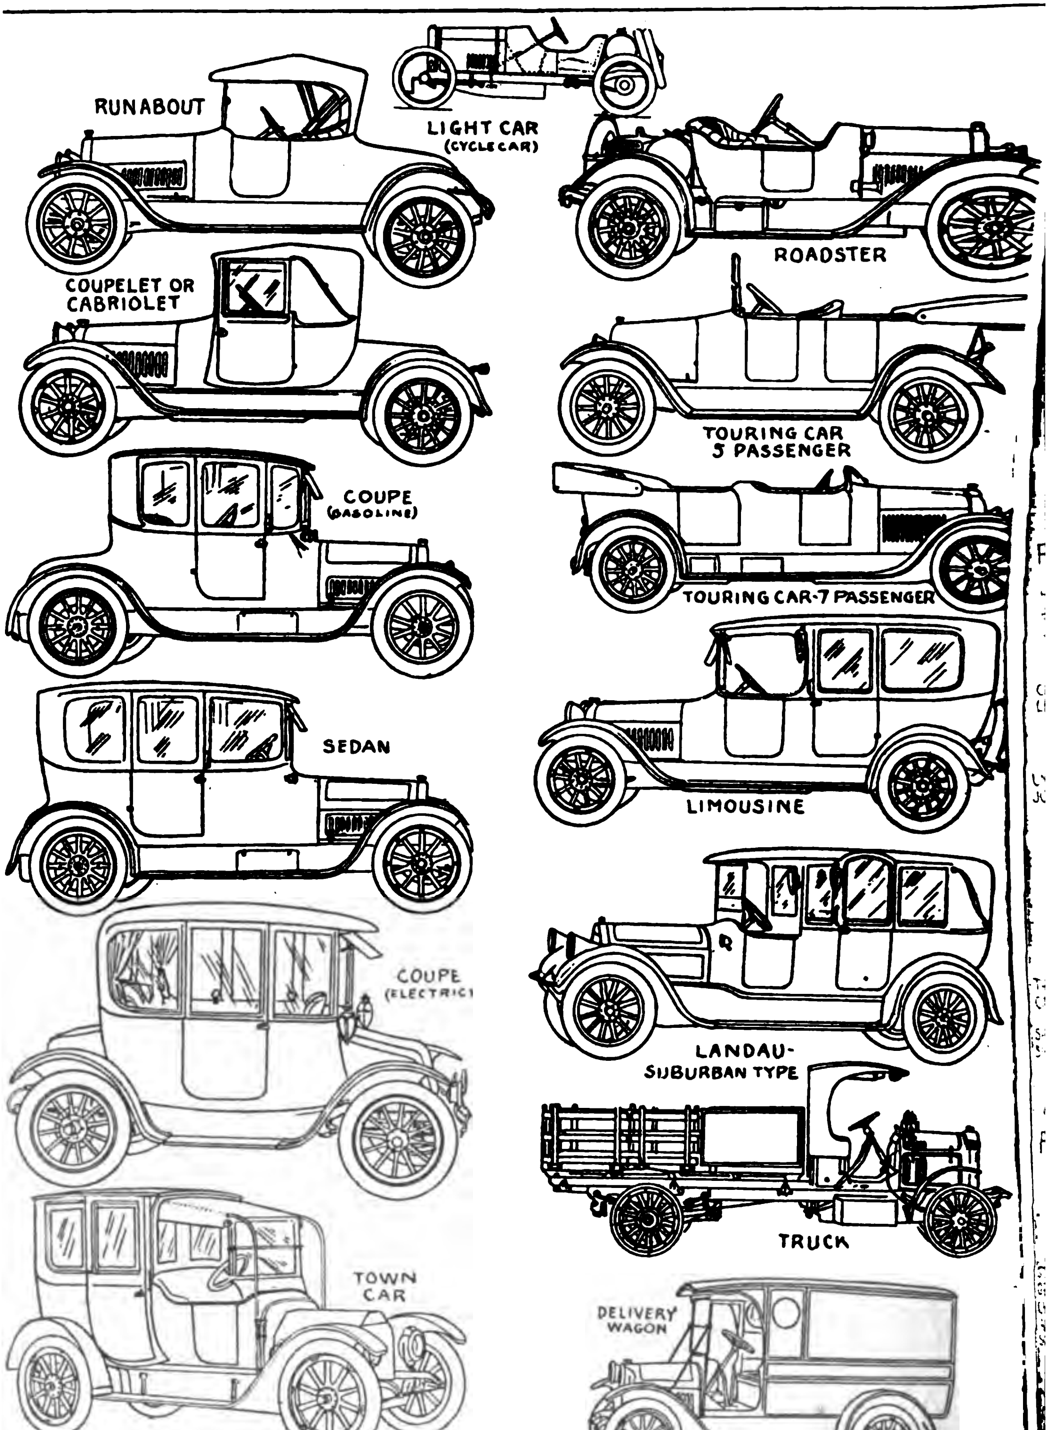


The wheels of an automobile are smaller in diameter than horse drawn vehicles, due principally to the fact that at the high speed the automobile travels, the wheels would have to be built entirely too heavy to sustain the strain. Automobile wheels must be very strong, because of the weight that they must support, and the strain that they are under. They are made of wood or wire (see illustration).

Wooden wheels are made with a wood felloe, over which fits a steel rim that holds the tire. It is called an artillery type wheel.

Wire wheels are light, easily repaired and are becoming very popular.

Mud guards or fenders are always fitted over the wheels, to protect the car and occupants from the mud thrown by the wheels.



Although there are many special makes of bodies which are given special names, the above illustrations will give the reader the names of the standard type of bodies.

Note the Cycle Car is now called a Light Car.

The Sedan differs from the Limousine in that the driver's seat in the Sedan is placed inside with other seats and would be termed a family car. The owner quite often drives this type of car.

The Limousine front seat is partitioned off from seats in the rear and is usually operated by a chauffeur.

The Town Car is a light, low, short wheel base, with chauffeur's seat in front. This type of car also used for Taxicab service.

The Landau is a type of car similar to the Limousine, but the rear part of top can be folded back.

The distinction between the Delivery wagon and Truck is in size and weight. The delivery wagon is usually a shaft driven pneumatic tired car, whereas the truck is a double chain or shaft driven solid tired heavy machine.

HART NO. 12—Types of Bodies.

FIG. 1

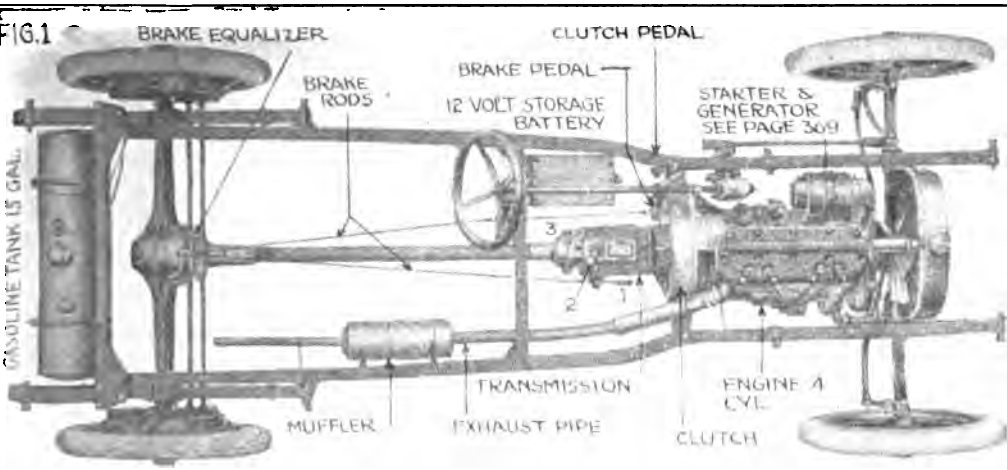


FIG. 2

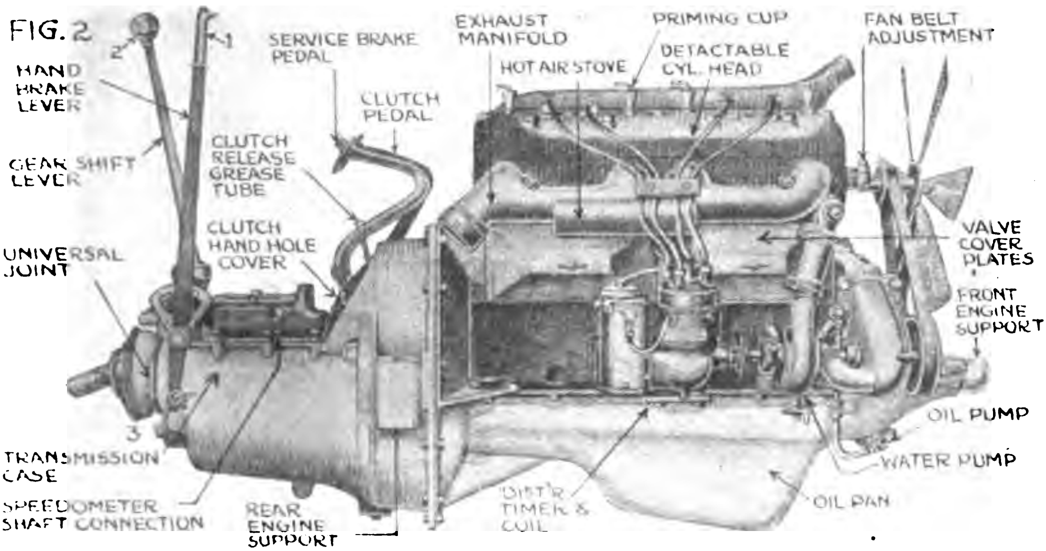

FIG. 3

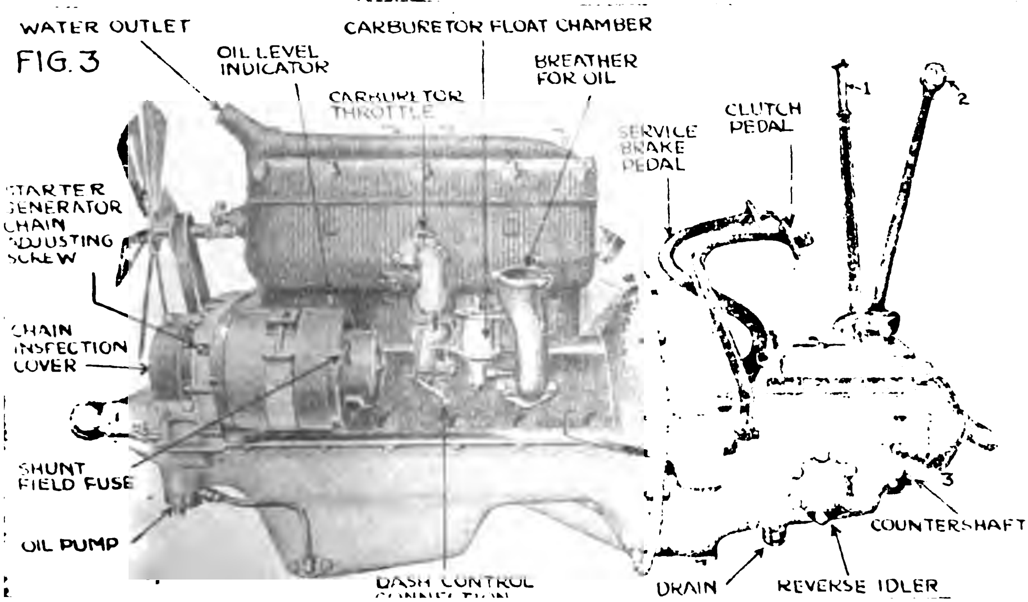
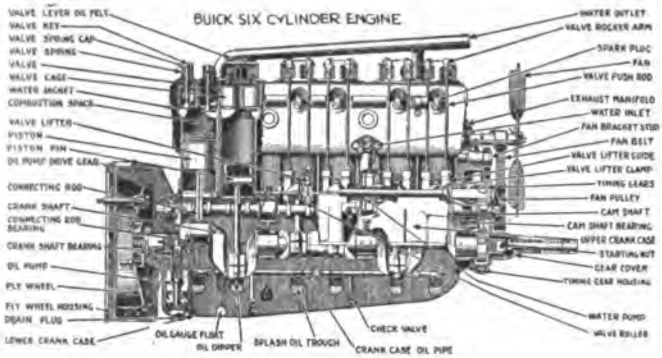
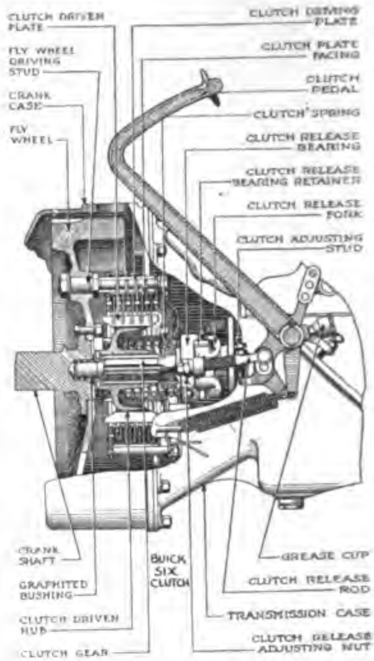
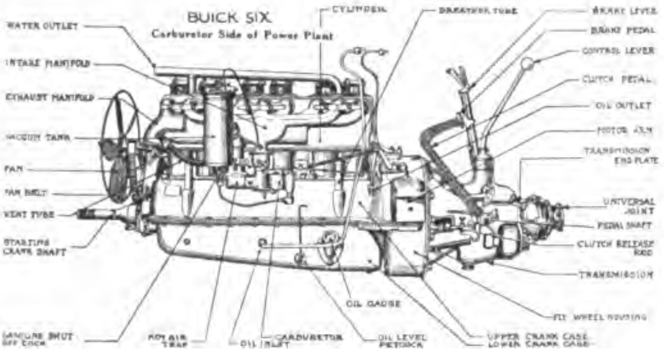
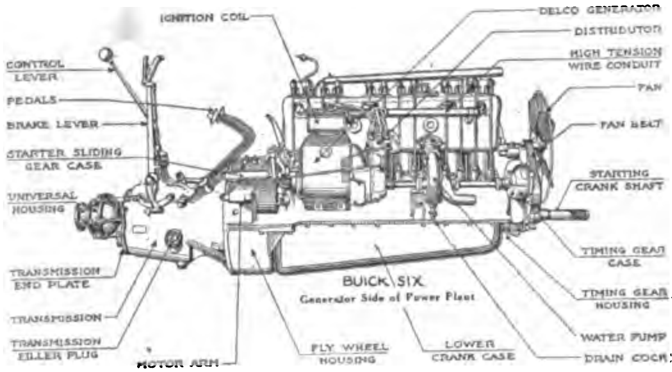
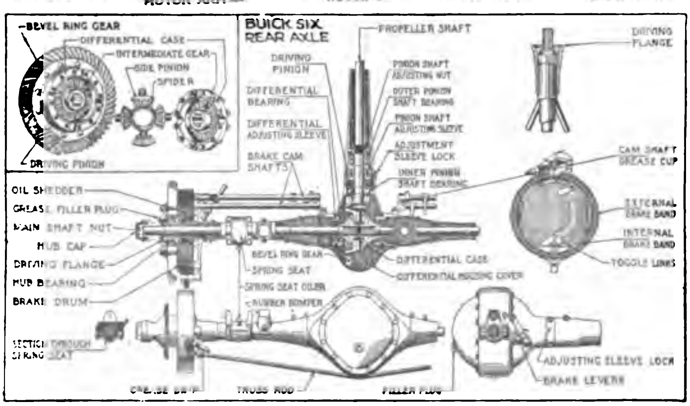












Buick Six.

The Buick 1918 line was composed of three models. Two sixes. The only material difference was in the wheel base, 118" and 124"—the engine being the same.

The 1920 Buick line is composed of six models of cars: Model K-six-44, a three-passenger roadster; model K-six-45, a five-passenger touring car; K-six-46, a touring coupe; K-six-47, a five-passenger touring sedan; K-six-49, a seven-passenger touring car; K-six-50, a seven-passenger sedan.

Engine on all models is the same six cylinder type with **valves-in-the-head,** 3⅜" bore by 4½" stroke, **semi-steel bloc castings. Valves are mounted in cages**—see page 109. **50 actual brake-horse-power. Cooling, centrifugal pump and cellular type radiator; lubrication, circulating splash operated by gear pump driven by spiral gears from cam shaft; carburetor is the Marvel shown on page 179, with** vacuum fuel feed system explained **on page 165; ignition, high tension jump spark system—Delco electric system,** Delco single wire. **Clutch, multiple disc,** dry plate; **transmission, 3 speed** and reverse, 3.36, 1.76 and 1 to 1 on first, second and third gears, **and 4.32** to 1 on reverse, selective **type—see** page 497 for gear shift; **rear axle, full floating type with 4 to 1 ratio on 118" wheel base and 4.615 to 1 on the 124" wheel base car—see page 557 for type of rim used.**

Buick Four.

This model was discontinued in 1917. The size of engine used on the Buick Four was 3¾x4¾" stroke. Pump cooled, splash lubrication — Delco electric system—cone clutch—¾ floating axle.

Lights.

Automobiles are required to carry **two lights in front,** and another, called the tail light, in the rear. The rear light is required for the benefit of the Fire Department—to avoid accidents of rear end collision. To make driving at night safe, there are usually head lights which burn acetylene gas or electricity.

Electric lights are the most popular; a storage battery supplies the electric current; when the battery runs down it is recharged from an outside source, but if car is equipped with an electric generator, run from engine, the battery is kept charged by the generator. (This subject treated further on).

Accessories.

Speedometers show the speed in miles per hour, and are operated by flexible shaft driven from the front wheel or transmission shaft.

Odometers show the number of miles traveled, either on one trip or during the entire season. Speedometers and odometers are often built in one case, for the sake of compactness, one cable driving both.

Grademeters show the per cent of grade the car is climbing.

The horn for automobiles is sounded by pressing a rubber bulb, and the tube from the bulb to the horn is long enough to have the former at the driver's seat, and the latter well forward. Another form of alarm is blown by the pressure of the exhaust from the engine, and it is sounded by pressing on a foot pedal. Exhaust whistles are the name of these horns, and the sound is very much like a locomotive whistle.

The electric horn is the most popular. It will be explained farther on.

Bumpers are placed in front of the car and sometimes in the rear. They protect the radiator and lamps and are well worth the investment (see fig. 10 page 26).

Wheel Base, Tread.

The wheel base of an automobile is the distance (in inches) between the rear axles and the front axles. The long wheel base rides easier than a short wheel base. The frame must be sufficiently stiff, however, to prevent sagging from the weight on same. The wheel bases vary from 80 inches on runabouts, to 144 inches on larger cars.

The tread (also called track) is the distance the two wheels are apart measured parallel with the axle. The standard tread is 56 inches, measured from center to center.

The treads of wagons and carriages vary in different parts of the country. In the Southern states it is 60 inches, in the West 48, and most of the other parts of the country 56 inches. Small, light cars are sometimes made with a smaller tread than 56 inches, but it is exceptional.

The clearance is the distance from the lowest point of the car to the road. For rough roads, a greater clearance is required than for smooth roads, as a high place in the road would strike parts of the machinery that hung too low. The front axle, which is solid and heavy, is usually curved down in the center, so that it will be the first part of the car to strike a high place, thereby protecting the delicate parts behind it.

INSTRUCTION No. 2.

DRIVE: Chain: Propeller or Shaft Drive. Worm Gear Drive. Radius Rods. Torsion Rods. Drive Reduction.

The power from the engine is transmitted through the transmission; and is applied to the propelling of the car by those parts called the drive.

There are three types of drive; one the **double chain** drive, requiring a dead rear axle, and the other the **single chain drive** (seldom used), and the **shaft or propeller shaft** drive, which requires a live rear axle. (see chart 13.)

***Double Chain Drive**—see chart 11.

The double chain drive is seldom used on pleasure cars, but is used quite extensively on trucks. †Trucks use chains, because trucks carry heavy loads and usually have solid dead axles.

When, as is usual in cars of this type of drive, the engine is in front, the crank shaft is parallel to the sides of the car, and therefore at right angles to the rear axle. The power developed at the crank shaft must therefore be turned at right angles in order to apply it to the wheels. (See fig. 1, chart 13.) This is done by means of bevel gears, which are in the transmission case.

The power is transmitted from the crank shaft of the engine to the square shaft of the change speed gear by gears, as explained farther on. The square shaft carries a bevel gear that meshes with another bevel gear carried on the jack shaft (see fig. 1).

The jack shaft passes across the car, running in bearings in the gear case and on the frame. It is held so rigidly that while it is free to revolve, its bevel gear is always in correct relation to the bevel gear on the square shaft of the transmission.

The jack shaft is in two sections, between the inner ends of which the differential is placed, the differential, of course, being in a housing to side of the bevel gear that drives the jack shaft.

At each end of the jack shaft, outside of the frame, is a sprocket which is in line with a corresponding sprocket on the rear wheel of that side (see fig. 2, chart 13). Over each pair of sprockets passes a chain that transmits the revolutions of the jack shaft to the wheels which run loose on the ends of the dead axle.

The chain most commonly used for automobiles is called a roller chain. It consists of side pieces in pairs, each pair being secured to the adjoining pairs by rivets passing from side to side. On these rivets are steel rollers which revolve as they touch the sprockets. These rollers fit the space between the teeth of the sprockets, and as the chain bends around the sprockets the rollers are stationary, while the rivets turn inside of them.

To give the best service, chain must run true; that is, the sprockets over which they run must be in line, the links of the chain must fit the teeth, and the sprockets must be exactly circular. If the sprockets are out of line, the chain will be forced to bend sideways. If the links do not fit the teeth, there will be a grinding that will cause rapid wear, and there will be danger of the

*For care and adjusting of chains, see instruction on trucks; also refer to this subject on double chain drive.

†The modern type of truck uses the worm gear drive.

chain jumping off. If the sprockets are not exactly circular, during one part of the revolution the chain will be slack, and during the other part will be drawn tight, stretching it.

The **double chain drive** has **advantages** on heavy cars. By its use the weight of the car is carried by a **solid** or "dead" axle, which is lighter than a divided "live" axle of the same strength can be. If a solid axle is bent, it can be straightened easily, while it requires an expert mechanic to straighten a bent live axle.

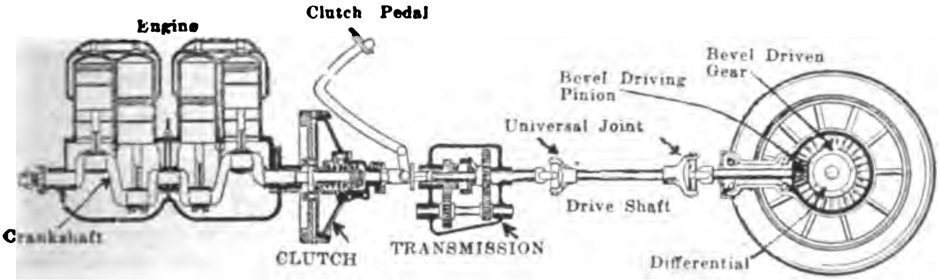
The **disadvantages** of a double chain drive are the difficulty of properly lubricating the chains, their rapid wear in consequence, and the liability of chains to stretch and jump off the sprockets.

The worm gear drive for trucks with substantial axles of the "live" type are now considered superior to the double chain drive.

Single Chain Drive—see chart 11.

This type of drive is now **seldom used,** and was formerly used only for cars with engines of small power, in which the engine is usually horizontal, with the crank shaft lying across the car and parallel to the rear axle.

A planetary change speed gear or transmission is usually used in a car of this type, and its sprocket is in line with the sprocket mounted on the differential on the "live" rear axle (see chart 11—also fig. 5, page 47).



The modern method for driving the rear axle is by means of a propeller type of drive shaft with a bevel driving pinion and bevel driven gear on differential on rear axle.
Commercial cars with shaft drive instead of double chain drive often use the worm drive, see page 21.

***Propeller or Shaft Drive**—see chart 11.

In this type, a shaft connects with the square main shaft of the differential and is extended to the rear axle, where it ends with a small bevel gear called the **axle drive bevel pinion.**

This driving pinion meshes with a bevel gear on the differential that is mounted between the inner ends of the two parts of the live rear axle, called the **axle drive bevel gear.**

The propeller or driving shaft, always has one, and often two, universal joints in between the gear box and drive pinion on rear end, so that the moving of the rear end as the axle receives the jolts of a rough road does not affect its driving.

The bevel gears are contained within a casing or housing that supports the bearings for the parts of the axle, and also the end of the driving shaft, so that the bevels are held in the same relation to each other, regardless of the moving of the axle.

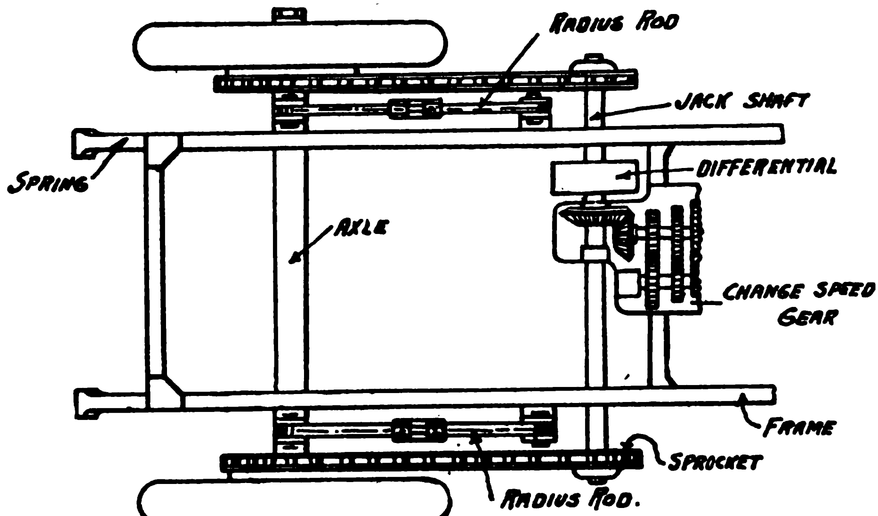


Fig. 1.

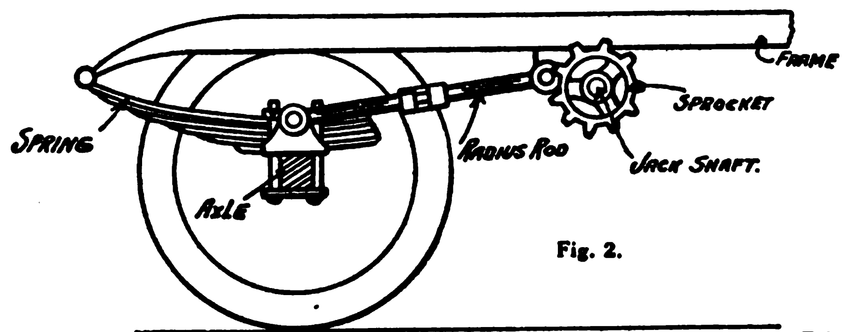

Fig. 2.

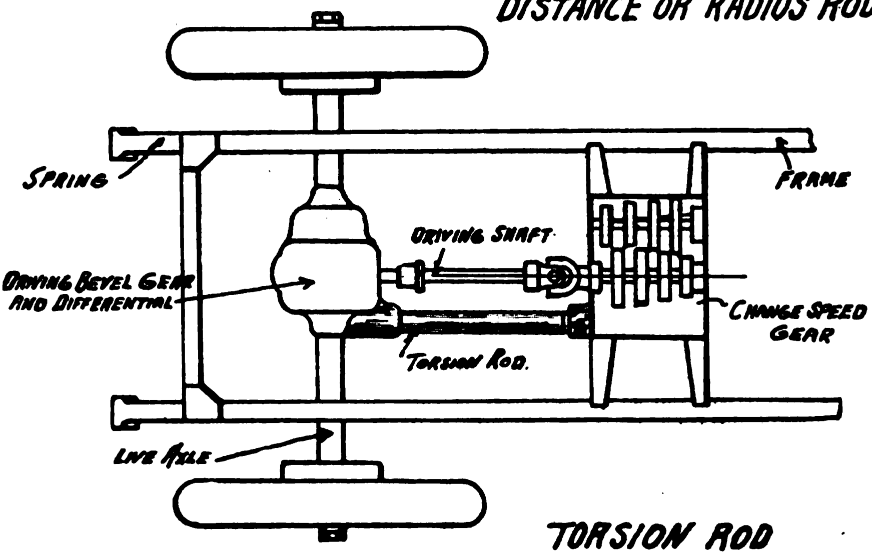
DISTANCE OR RADIUS RODS



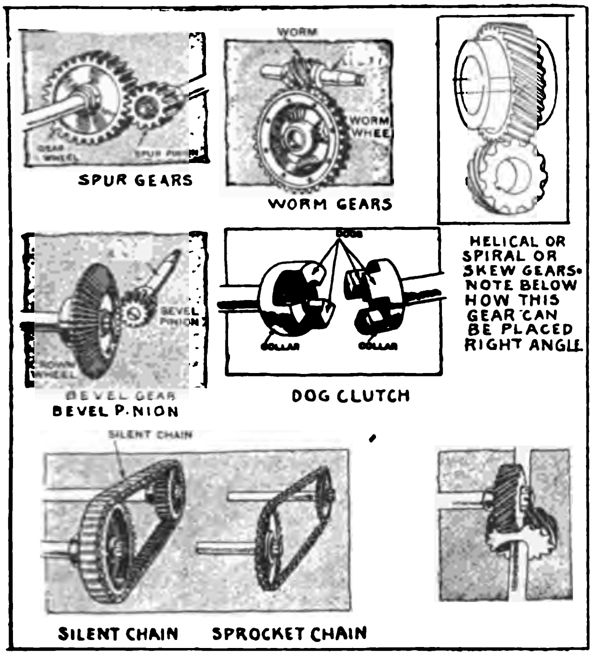
TORSION ROD

Fig. 3

CHART NO. 13—Explaining the Radius Rod, Torque Arm or Torsion Rod and Jack Shaft

The advantages of this type of drive are that all of the moving parts are enclosed and protected from dust, and run in grease or oil, which means perfect lubrication.

The disadvantages of a divided or split rear axle, are the difficulty of keeping the bevel gears in exactly the correct relation to each other, because of the bending or springing of the axle, and the troubles that may come from the general weakness of a live axle. (This trouble has now been overcome. During the early days it was a source of bother.)



Note the different methods of driving. Bevel gears are used extensively on rear axle drive systems. Worm gears are also used on rear axles. Helical gears, silent chains are used extensively for magneto, electric starter and generator drives. Spur gears and the dog clutch are used in the gear box.

†Gears.

Bevel gears must be cut more accurately, and meshed more carefully, than spur gears. They are used principally for driving the rear axle (see page 32).

To transmit power without more loss by friction than can be helped, there must be as little play as possible without having the teeth bind.

†The setting of bevel gears requires careful adjustment, for if incorrectly meshed they will be noisy, and will wear rapidly.

‡The worm drive gears are fast becoming popular for rear axle drives, especially on commercial cars (see illustration above).

The spiral bevel, which is often referred to as helical gear is similar to the worm. The worm gear makes a wiping contact and the helical more of a rolling contact (see page 35). The "skew" gear is the same as the helical gear. This type gear is also used to drive ignition systems, etc.

Silent chains are used principally for driving generators, magnetos, cam shafts, etc. (see index).

Sprocket chains are used to drive the rear wheels in chain driven cars.

***Radius rods**: are mostly used, on commercial cars using double chain drive. They extend from a point along side of the frame in line with the jack shaft, thence to rear axle. Therefore they keep the chain at the proper tension and the distance from sprocket to sprocket the same, no matter how rough the road. A turn buckle is provided to adjust (see fig. 2, chart 13).

Many manufacturers however, have now discarded the radius rods entirely.

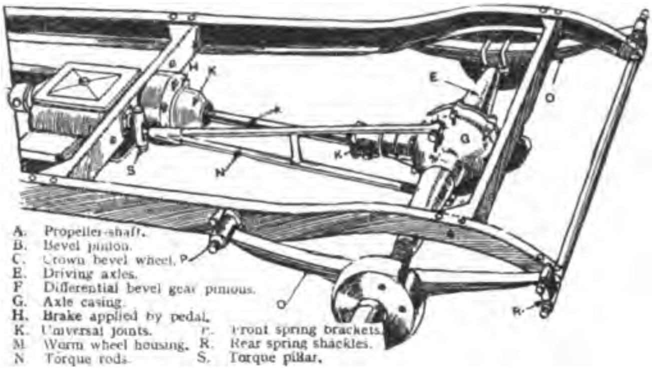
*Also called "strut" or "distance" rods. †See rear axles in repair subject and supplements.

†Bevel gears for final drive are of two types; the "ordinary bevel" and the "spiral bevel" (often referred to as the helical).

‡In principle the worm drive is a simple arrangement; the usual bevel gear and pinion are replaced by a specially-shaped hollow helical-toothed gearwheel and worm, the latter engaging in the teeth of the gearwheel, the axles of the two shafts being at right angles. When accurately made, worm gears run with great smoothness and silence. The worm may engage either from above or below the gearwheel. The angle of the worm and gear may be as much as 45 degrees. The worm (W) is made of hard steel and the wheel (B) of bronze.

The Torque Arm.

A torque arm ("torque" means turning movement or twist) is used on shaft driven cars. It extends from the cross member near the transmission to the housing on the rear axle, (construction varies).



A usual construction is shown in illustration. Note the arm (N), extending from the rear axle housing to a spring arrangement or torque pillar attached to a cross member, in line with the drive shaft (see illustration (S-N).

On the Hotchkiss drive the torque and drive is taken through the rear springs. The main leaf of each of these is made strong enough for this added duty, and the construction does away with torsion tubes, torque arms, and radius rods. On many cars the propeller shaft housing is made very heavy and acts as the torque arm.

If it were not for the torque arm, the revolving of the bevel gears would tend to revolve the rear axle housing, instead of revolving the axle shafts alone. While the construction of the rear axle would of course prevent this, there would be considerable play in the course of time, and the driving shaft might be strained and sprung out of line. The torque receives this strain, and protects the driving shaft. In other words it resists the torque of the rear axle when power or brakes are applied (see note on page 32).

Drive Reduction.

In all but racing cars, the speed of the crank shaft is reduced so that the road wheels turn once while the crank shaft revolves from three to four or four and one-half times with the high speed gear engaged.

On cars with single chain drive, this is done by having the transmission sprocket smaller than the axle sprocket.

If the reduction is to be three to one, that is, if the crank shaft revolves three times to once of the axle, the axle sprocket will have three times the number of teeth that the transmission sprocket has.

On shaft driven cars, the reduction is made at the axle drive gears. The gear on the axle is given as many more teeth than the pinion on the driving shaft as is necessary for the reduction that is required.

In the worm drive (see pages 32 and 35) the reduction is governed by the angularity of the teeth and not by the ratio. In other words the size of the worm could be changed without its changing the speed. (The angularity of course would have to be the same in both cases.)

To make the point clear as to just how the speed reduction is brought about in the worm drive, imagine the screw thread on a vise shaft which draws the jaws together. If that thread is coarse or has only a few to the inch, the jaws would move towards each other rapidly and of course would take some power to move it; if, on the other hand there were quite a number of threads to the inch the jaws would move slower but it would take less power to exert the same pressure.

The reduction on side chain cars is sometimes made at the bevel driving the jack, but usually at the sprockets.

Racing cars, or high powered touring cars for use over good roads, apply this reduction for the direct drive, but by the use of gears in the transmission may bring the speed of the wheels to the speed of the crank shaft, or even more.

When the "gear ratio" of a car is spoken of, it is this reduction that is meant. A car spoken of as having a "gear ratio of $3\frac{1}{2}$ to 1" is one in which the drive shaft makes $3\frac{1}{2}$ revolutions to one revolution of the road wheels on the high gear.

INSTRUCTION No. 3.

*STEERING, SPRINGS, BRAKES: Principle of Steering. Springs and Brakes.

**Steering.

The principle: Pulling on one of the reins swings the horse to that side, in steering a wagon. The shaft or pole is attached to the axle, and the axle is pivoted to the king pin, all swing with the horse.

If you go straight ahead, the front and rear wheels of any vehicle move in straight lines. To make a turn to one side or the other, the front wheels are swung so that they are at an angle with the rear wheels.

Whenever the front wheels stand at an angle with the rear wheels, the vehicle will turn, and it will continue to turn until the front wheels are swung back to a straight line again.

In a horse-drawn vehicle, the front wheels are square with the axle, for wheels and axle swing together. (See fig. 1, chart 14.)

In an automobile, the front axle does not swing, but each wheel swings on a pivot at the end of the axle.

It would not be practical to steer an automobile as a horse-drawn vehicle is steered, for the axle would have to be very heavy to support the weight, and besides, it would be so hard to swing it that steering would be difficult. Another reason is that the body would have to be raised up high so the wheels could go under it in making a short turn.

A fixed front axle is always used on automobiles. The pivots on which the front wheels swing must be as close to the hubs of the wheels as possible, for the closer they are the less leverage there will be to overcome, and the easier it will be to steer, also less liable to break.

When a wagon or automobile turns a corner, it moves in the arc of a circle.

In a horse-drawn vehicle, the front axle, because it swings on the king pin, always points to the center of the circle (see fig. 1.) Notice that both wheels and the axle are perpendicular to the same radius of the circle in fig. 1.

The front axle of an automobile is fixed and cannot turn, and therefore only its pivoted ends point to the center of the circle (fig. 2.) Notice in fig. 2, that the axle does not move, but that each wheel moves.

When running straight ahead, the front wheels of an automobile are square with the axle. When turning, the front wheels are not square with the axle, but at an angle with it.

Because each wheel is square with its axle end, and both axle ends point to the center of the circle, each wheel is square, or perpendicular to, a radius of the circle. If both were perpendicular to the same radius, which they are not, the wheels would be parallel with each other.

Thus while the front wheels of a horse-drawn vehicle are always parallel to each other, the front wheels of an automobile turning a corner are not parallel to each other on the same radius.

*See pages 684 to 691 for "adjusting brake" and pages 691 to 698, "adjusting steering."

Sometimes the driver will notice he can turn his front wheels farther to one side than the other. This is due to two causes: (1) the steering knuckle arms are not properly lined up; (2) the tire of wheel may strike the steering knuckle thrust arm.

It is also noticeable that an automobile has a tendency to travel to the curb when running on the side of streets. This is due to the oval surface of street or if wheels are "cambered" too much, see page 683.

**See also, page 691.

S—Sector.

Spark Lever (67) connects by a rod (which runs through the hollow steering post) and operates through bevel gears the Bell Crank (71), which in turn operates the timer on the engine or contact box on magneto, and advances or retards the spark in cylinders of engine.

Throttle Lever (68) connects by a rod, through bevel gears, and operates the bell crank (72), which in turn is connected by a rod with the throttle valve on the carburetor, and controls the speed of the engine by opening and closing a valve which admits or cuts off the gas supply.

CHART NO. 14—Explanation of Steering. Steering Gear, Parts and Connections. Spark and Throttle Lever System on the Steering Device.

The steering mechanism must be so arranged that the front wheels are parallel when the car is running straight ahead, but stand at an angle with each other when turning a corner.

Each of the pivoted axle ends (2), which are called **steering knuckles**, has a **steering arm** (3 and 4) projecting from it.

The ends of these two arms are connected by a rod called a **drag link or tie rod** (see fig. 5). When the drag link is moved endways, both wheels move with it.

The two steering arms are not parallel, but incline a little toward each other. If they were parallel, the two wheels would be parallel, no matter how the drag link was moved. As they are not parallel, moving the drag link moves one of the wheels through a greater angle than the other, depending on the direction the drag link is moved.

The old style of steering arrangement was a lever and rod running from the driver's seat to the steering knuckle. This old style arrangement would reverse and was unreliable. In striking stones or ruts in the road the wheels could be thrown from side to side, and the driver would be obliged to grasp the steering lever firmly to keep the car straight.

A bad place in the road might throw the handle out of his hand. While this is good enough for a light slow speed runabout or electric vehicle, it would be very serious with a large, heavy automobile.

A device must be used that will swing the front wheels when the steering wheel is turned, but that will keep the front wheels steady, and prevent their moving the steering wheel.

This is called an *irreversible steering gear, and while it is made in many ways, the chief types are the **worm-and-sector,** and the **screw-and-nut or worm-and-nut,** all shown in chart 14.

****The worm-and-sector type** consists of a worm (w), which is attached to the lower end of the rod moved by the steering wheel (64). Meshing with the worm is a sector wheel (s), so that turning the steering wheel turns the worm, and moves the sector wheel.

Attached to the sector is an arm (65), which is connected to the steering knuckle by the connecting arm or rod (6). The end of arm (65) and arm (7) are ball shaped, and fit in a socket on the end of rod (6) so that the fit is always tight, whatever the angle between the arm and the connecting rod may be. The socket is often movable, with strong springs on each side to hold the parts together, and to take up some of the shocks of the road.

The worm and sector are contained inside a metal case to protect them from dust, and to hold the grease in which they are packed.

****The worm-and-nut type steering gear** shown in chart 14, has a nut through which a worm passes. Instead of a "sector" the nut is used. The worm is fastened to steering rod. Turning the steering wheel moves the nut up and down.

One arm of a lever fits in a groove on the outside of the nut, and the other end is connected to the steering knuckle by a connecting rod. Steering gears are usually built so that wear can be taken up.

The breaking of any part of the steering connections is more likely to cause a wreck than the breaking of any other part of the car, and must be watched carefully. The parts must be kept tight enough to prevent play, but must not be so tight as to make steering hard. All parts must be kept lubricated, and the connecting rod, tie rod and knuckle joints are usually packed in grease and protected from dust by leather pockets that buckle over them.

***A steering gear is said to be irreversible** when an ordinary road wheel impact will be insufficient to turn the steering wheel. This is simply a question of reduction between the steering worm and gear, the greater the reduction, the less reversible the system and likewise the slower the motion of steering the road wheels in relation to the movement of the steering gear. Therefore a heavy car will be normally less reversible than the steering gear on a lighter car. **See also, page 691.

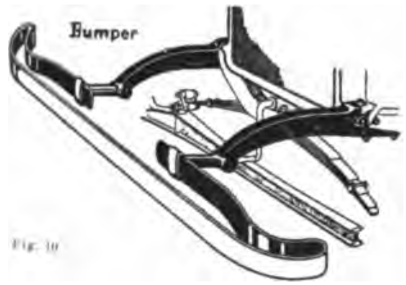

Fig. 10. Bumpers are placed on the front and quite often on the rear of the car to protect the radiator and lamps and rear of car. See also, page 736, 514.

Fig. 7. Air spring or plunger type shock absorber consists of an air chamber made up of two sections, one of which telescopes into the other. The outer section is attached to a bracket on the frame of the car (A). The inner section is attached to one end of one of the springs, (B).

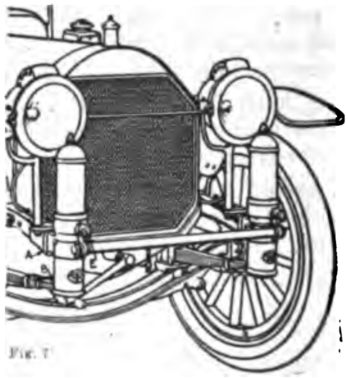

Fig. 7

The chamber is partly filled with oil, through the filling-plug hole under the cap (C). The filling-plug is fitted with an ordinary Schrader tire type of air valve through which the chamber may be charged with air at any desired pressure, by means of an ordinary tire pump.

The oil in the chamber seals the packings of the telescoping joint and prevents the air from leaking out.

The mechanism inside the chamber is a small oil pump which is worked automatically by the up and down flow of oil past the flat piston (D), whenever the air spring is compressed or extended. A trifling amount of oil which is always passing by the packings when in motion keeps them thoroughly lubricated The surplus drains into a collecting pocket, and the automatic oil pump delivers it back into the cushion chamber.

The oil passage surrounding the piston D is purposely restricted in order to retard the quick reaction of the spring, and thus prevent the disagreeable and dangerous catapult effect that is so apt to throw passengers from their seats when the car is passing over "thank-you-ma'ams," car tracks or other road obstructions.

All of the time that the spring is in action, air is being drawn in through filtering material in the "breather" E, and blown out through suitable **passages** in such a way as to **keep the** telescoping joint free of **dust** and dirt. (Westinghouse.)

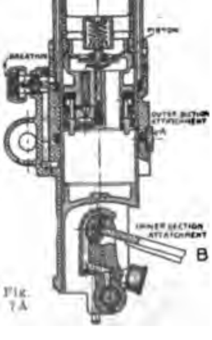

Fig. 7A

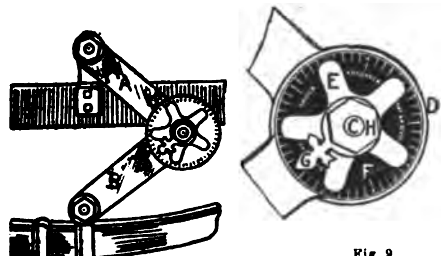

Fig. 9

Fig. 9. Friction type of shock absorber consists of a single arm, A, and a double arm, B, frictionally joined by bolt, C, and adjusting nut, H. Arm A works between the two members of arm B, giving a straight up-and-down movement, and the arm A being made of spring steel allows for any side-sway. The arm A carries a flanged cover, D, forming a cup-like space on each side. In these spaces are placed the friction plates, which are self-lubricating and highly impervious to wear. By screwing sufficiently on adjusting nut, H, any desired degree of friction may be obtained.

Adjustment dial, F, and indicator, G, provide means of securing the correct tension for the car. A spider compensating spring, E, takes up any little wear automatically, keeping the friction uniform after the adjustment has been made.

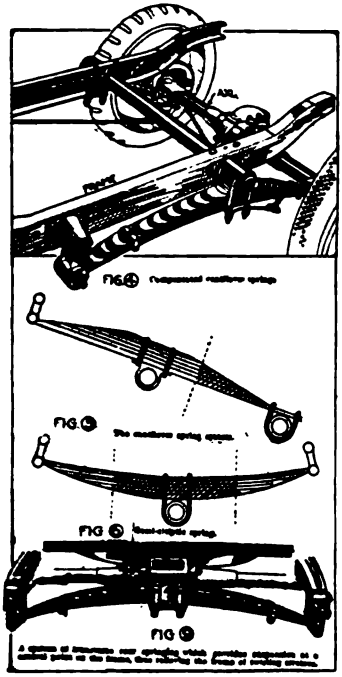
The arms A and B are joined to the frame and axle by two frictional joints, which also can be regulated. Above type is the "Hartford," see page 732 for the "Connecticut."

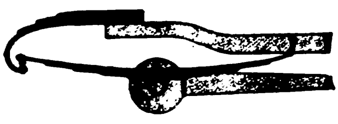
*Springs—see chart 15.

All vehicles intended to move at more than a very slow speed must be provided with springs. Springs not only protect the occupants from the vibrations of a rough road, but also keep the machinery from being shaken to pieces.

The size and strength of the springs depend on the weight of the vehicle. Springs that are too weak will not give sufficient protection and if they are too strong they will not have enough resiliency.

Types of springs in general use are: Full elliptic, three-quarter elliptic, half elliptic and cantilever.





The three-quarter elliptic rear spring. A type seldom used.

The full-elliptic was formerly used on a great many cars for the rear, as per fig. 1. In some instances it was used in front.

Other types of rear spring suspension are shown in figs. 1, 2 and 3, also the cantilever, fig. 4.

The cantilever spring system (fig. 4) is probably the most popular present day practice. The illustration shows how it compares with the ordinary half-elliptic principle shown in fig. 3.

In the cantilever spring the forward end is shackeled and the axle attached to the rear end. The center of the spring is attached to a trunion or bearing on the frame. Thus the spring has a certain amount of movement about its center. One good feature of this form of spring is that it reduces the unsprung weight of axle. The shaded parts of the respective springs show the comparative amount of unsprung weight. In the cantilever form of spring the heaviest part of it is supported by the frame.

The half-elliptic spring (upper fig. 8) is used to a great extent for the front.

*Breakage of a spring means breakage of one or more of the leaves. Breakage almost always occurs in the expansion that follows a heavy compression, and not during the compression. In other words, it is the rebound that breaks the spring.

Because the leaves slide on each other, they will wear and squeak if not properly lubricated.

To lubricate between the leaves it is necessary to relieve them of the weight they carry. This may be done by jacking up the body, or taking the springs apart, and spreading heavy grease or graphite on the leaves. This is quite a job and is seldom done (also see index "lubricating springs.")

Shock Absorbers—see chart 15.

As breakage will come during a rebound, devices called shock or jolt absorbers are attached to the springs to check their up movement, also to prevent jolting on rough roads.

There are two types of shock absorbers in general use; the friction type and the air or plunger type.

The friction type is shown in fig. 9. All these movable frictional parts offer a constant resistance to the vibration of the spring both ways, and it is easy to see that when the wheel strikes an obstruction, the arms come together, but instead of the flying back, as does the free spring, it is retarded by the friction and moves gradually to its normal position, since the friction is always the same, while the tension of the spring diminishes as it approaches its normal position. See also, page 732.

The air or plunger type is shown in fig. 7 chart 15. There are other types of plunger type shock absorbers, but the two mentioned are most popular.

*See repair subject for repairing springs.

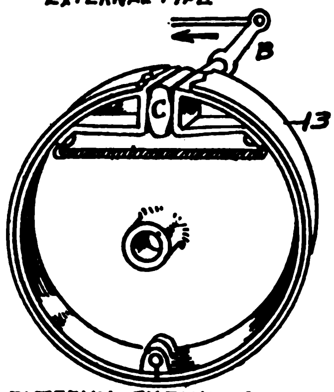

FIG 3. INTERNAL EXPANDING DOUBLE ACTING, BAND BRAKE.

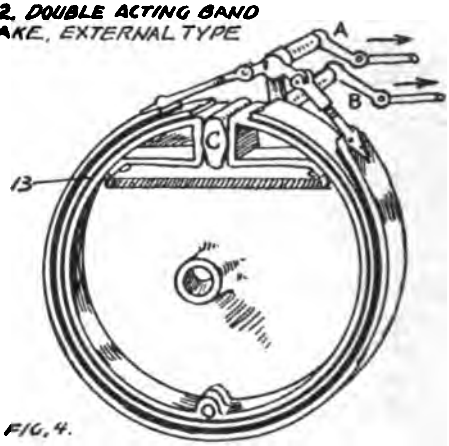

FIG. 4. COMBINATION OF INTERNAL AND EXTERNAL, DOUBLE ACTING. BAND BRAKE.

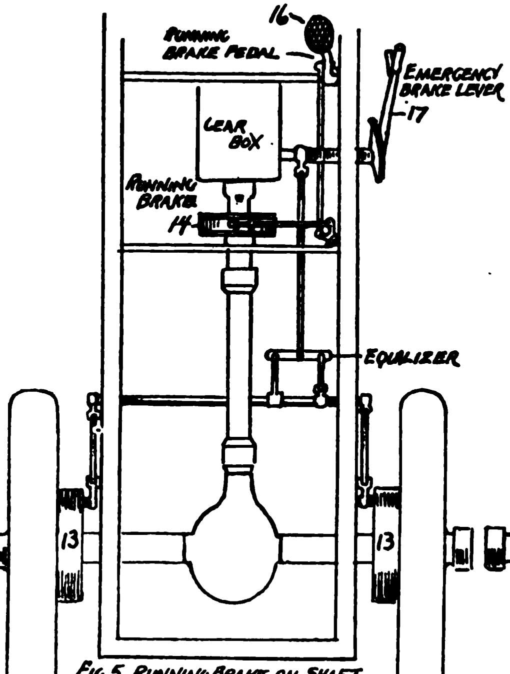

FIG.5. RUNNING BRAKE ON SHAFT INTERNAL D.A. EMERGENCY BRAKE ON REAR AXLE. INTERNAL DA.

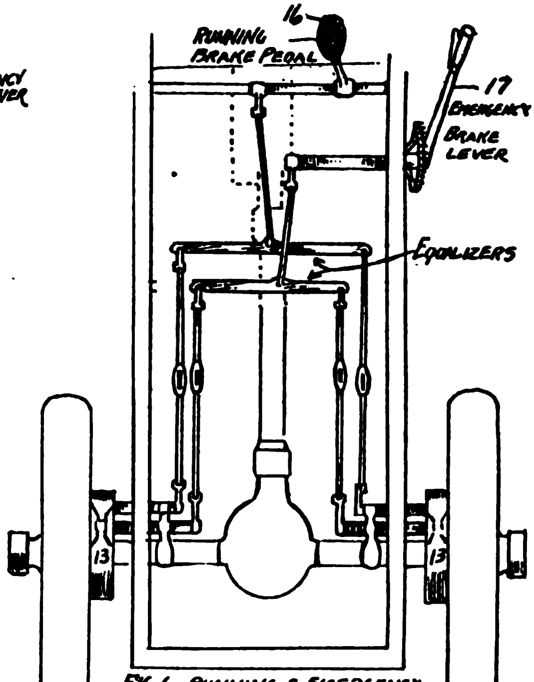

FIG.6 RUNNING & EMERGENCY BRAKES. COMBINATION, BOTH ON REAR WHEELS

CHART NO. 10—Brakes and Brake Systems. Explanation of the "Running" or Foot Brake and the "Emergency" or Hand Brake. The hand brake usually operates the internal brake inside of the rear brake drums or the brake on transmission shaft. The foot brake operates the external band brake on the outside of rear drums. This is modern practice.

***Brakes**—see chart 16.

An automobile is equipped with brakes, **usually on drums on the rear wheels,** so that its motion may be checked or stopped when running or so that it may be held on the side of a hill.

In a horse-drawn vehicle with steel tires, the brake shoes press directly on the tires, but as this would quickly ruin rubber tires, brakes for automobiles are of other types.

Because of the weight of an automobile, its brakes must be powerful in order that it may be stopped suddenly when necessary.

Practically all **automobiles are fitted with two sets of brakes,** called the running service or foot brake and the emergency or hand brake.

***The foot brake** is applied by pressing on a foot pedal (16) and is the one most in use because of its convenience, and because it is used most when running. The foot brake is also called the **service** brake.

The usual method of connecting the running, service or foot brake is by a contracting band on the **outside** of the brake drum on rear wheel hubs called the external contracting band brake.

The emergency or hand brake is usually applied by a lever (17) at the side (or center) of the driver's seat, so placed that he may apply his whole force to it. The emergency brake is seldom used while running. It is usually applied when the car is left standing, in order to keep the car from rolling down an incline. It connects in almost every instance with the internal expanding brake **inside** of the brake drum on rear wheel hubs, but occasionally will be found connected by a contracting band over a drum mounted on the main transmission shaft.

The foot brake pedal is the right pedal on most all cars, see "operating a car."

Types of Brakes.

Therefore summing up the types of brakes we might say there are but two distinct types in general use; the **external contracting** and the **internal expanding** type.

The external band brake is a flexible steel band faced with an asbestos composition—called Raybestos or Multibestos.

Setting the brake causes friction between the brake drum and the linings, hence the use of asbestos composition.

Band brakes are of two kinds: Single acting and **double acting,** the latter being an improvement over the former.

The single acting band brake (fig. 1, chart 16) only binds when the drum is revolving in one direction, having very little grip when the drum is revolving in the same direction in which the band is being pulled. This form is going out of use for automobiles, for it cannot be depended on to hold the car from running down hill backward.

The double acting band brake (fig. 2), is taking its place, for it holds with the drum revolving in either direction. In this form, both ends of the brake are attached to the lever or pedal, and so arranged that while one end is being pulled in one direction, the other end is being pulled in the opposite direction. This binds on the drum so tightly that it may be depended on to hold the car in any position.

*The running brake is now known as the "foot brake." The emergency brake is now properly called the "hand brake."

See page 685 for "adjusting of brakes."

The brake shoe is a band that may either be drawn around the outside of the drum, called the **external band brake,** or expanded within it so that it bears against the inside wall of the drum, called the **internal expanding brake.** Sometimes the internal brake is made of **metal.**

The external type of brake is usually of the **double acting** band brake type, and is always placed on the outside of the brake drum attached to hub of rear wheels.

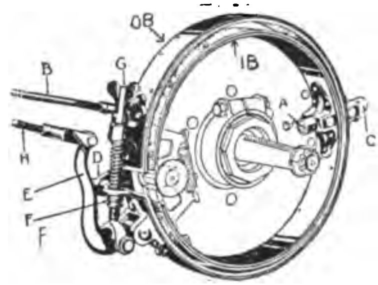

Fig. 7.—A combination of an internal expanding and external contracting brake system on brake drum of rear wheel hub. OB is the outer or external and 1B is the inner or internal. B is the hand brake rod operating the internal brake. H, foot brake rod operating external brake. **Adjustment of external brake is made at F, G and C. Adjustment of internal** or hand **brake is at A.** It is turned up or lowered so as to have 1-64 inch clearance between brake drum and brake. (See page 691 for "adjusting brakes" for further information.)

The internal expanding brake acts on the inside of drum (1B, fig. 7) and may be a metal shoe or metal faced with asbestos composition, but more frequently a **band** faced with an asbestos friction composition.

The internal band brake formerly consisted of two shoes of metal, but the modern form is shown in fig. 4, chart 16. When the lever (B) is raised the wedge (C) forces the internal brake against the inside of the drum. This brake shoe is lined with Raybestos or some similar material.

A combination of internal expanding and external contracting brakes are shown in fig. 4, chart 16. Lever (A) operates the external brake and lever (B) the internal brake. (See also fig. 7 this page, and page 689).

Brake Connections.

There are two methods usually employed for the **hand brake;** (1) by connecting hand lever with the brake on transmission shaft; (2) by connecting with the internal expanding brake inside of drums on the rear hubs. This latter method being the one in general use.

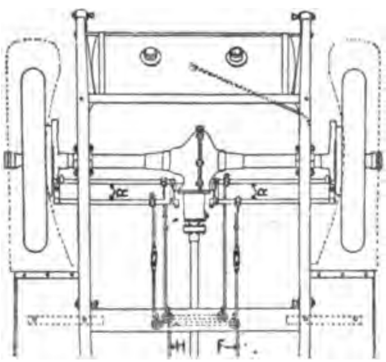

Fig. 8.—Note modern method of connecting the two brakes in rear.

The **foot brake** on most all cars connects with the external band brake on rear brake drums. It is used most and requires more attention.

Brake Equalizers.

When the foot brake pedal or hand brake lever is applied, the pull should be the the same on each brake on each wheel. If one brake rod is longer than the other the brake effect is not equal on both wheels, and this has a tendency to make the car skid.

To overcome this, a brake **equalizer** is used, the principle of which is shown in **figs.** 5 and 6, chart 16, and **page** 204. This is a rather crude illustration in chart 16, but it clearly explains the principle. In chart 100 the idea is more clearly explained. The brake equalizer, however, has been greatly improved as shown in illustration, fig. 8. Also page 32. Instead of an equalizer, the rods (R) are placed in bearings and the rod (F) connects with foot brake and rod (H) with the hand brake.

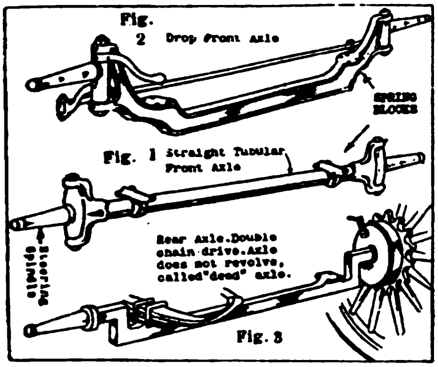
If a brake squeaks, it is an indication that it is dirty and needs cleaning The dirt clogs the pores in the surface of the lining and glazes it over. Gasoline or, better, kerosene will remove the dirt. The wheel should be removed and the linings cleaned with a stiff brush, such as a tooth or nail brush.

INSTRUCTION No. 4.

AXLES, DIFFERENTIAL OR COMPENSATING GEARS, BEARINGS: Front Axles. Rear Axles. The Differential: principle and application; the bevel and spur gear. Bearings: ball and roller.

Front Axles.

The front axle of a modern car carries most of the weight of the engine, and must at the same time withstand the shocks and jars that it receives through the steering wheels; it must therefore be strong and stiff.



Front axles are of two types: tubular and **solid** (figs. 1 and 2). Formerly axles were made of heavy steel tubes, but steel drop forgings with a cross-section of the form of the letter I, is considered to give better results.

The center of the axle is usually bent down, so that it is the lowest point of the car except the wheels; this is done in order to protect the mechanism from being struck by high spots in the road. A rock or stump standing up high enough to hit the fly wheel, will first strike the axle, which is strong enough to withstand a blow that could easily damage the engine.

The steering spindles are that part of the front axle on which the front wheels revolve and are made of nickel steel, heat treated. The steering spindles are sometimes fitted with either roller or ball bearings. The **steering knuckle** is that part which fits into the yoke of the axle. The steering arm (65) of the device (page 24) connects with the steering knuckle thrust arm (7), and movement of steering wheel, then guides the direction of the wheels.

*Rear Axles.

There are two types of rear axles; the dead axle and the live axle.

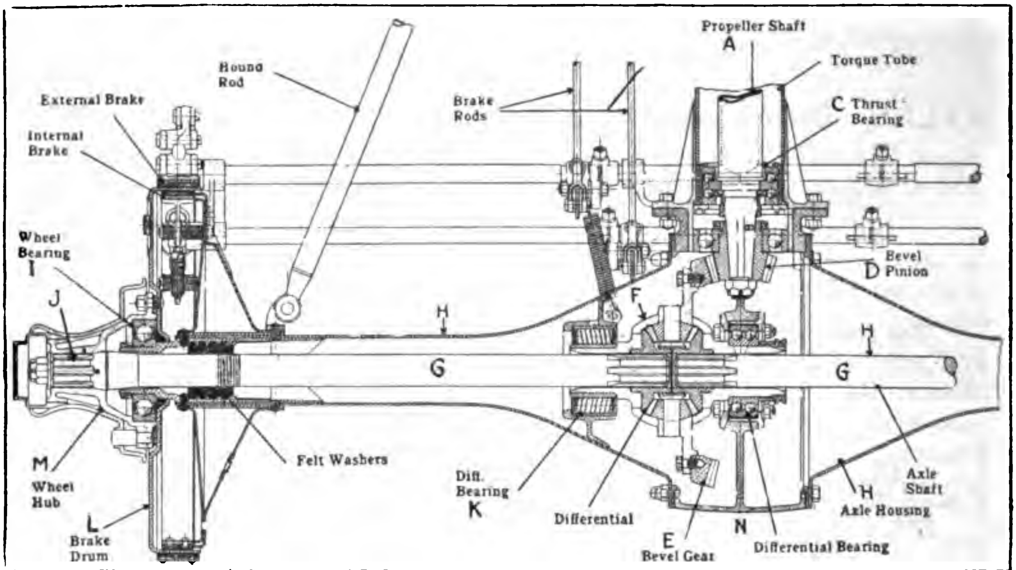
Dead axles are stationary, with the wheels running free on the end of axle, and are usually made as shown in fig. 3. The wheels are usually revolved by chain and sprocket (see charts 11 and 13), and there is no provision in axle itself for driving wheels.

Live rear axles is the name given to axles that revolve with the wheels, and are known as **plain** live axle, **semi-floating** axle, **three-quarter floating** axle, **full-floating** axle.

A live axle on any type is made in **two sections**, the differential being placed between its inner ends, this makes it necessary to support the axle parts in a strong housing and to brace it, in order that the parts of the axle do not sag or get out of line.

The axle is contained in a housing which is a metal cover entirely surrounding it; the differential gear, which is in a smaller housing of its own, being also inside of the axle housing. The housing extends to the wheels,

*See pages 544 to 546 for make of axles used on leading cars and page 669 for "rear axle pointers."



Construction of a Rear Axle—(Marmon).

Illustrating rear axle complete with bevel driving gear (E). Differential (bevel pinion type). The actual driving axles do not support any dead weight. The road wheels run on ball bearings (I) carried on the outer sleeve or casing of the axle. The details are as follows:—(A) propeller shaft connection. (B) driving pinion shaft. (C) ball thrust bearings. (D) bevel driving pinion. (E) large bevel. (F) differential gear. (G) half of driving axle. (H) tubular outer casing or sleeve. (I) ball bearing for wheels. (J) driving ends of axle (squared or keyed). (K) roller bearings in differential case. (L) drum of internal and external brake. (M) hub of detachable wire wheel. (N) casing enclosing bevel gear and differential.

Note—The power is transmitted from driving bevel (D) to large gear (E)—this being bolted to the case of the differential (F)—thence by the inside pinions to each half of driving axle. It is usual to "anchor" the outer casing enclosing the differential gear to the chassis by means of torque or hound rods bolted to the upper and lower points of the gearcase which counteract the tendency for the whole casing to twist round from the reaction of the driving effort. On some cars the rear springs are made to serve as torque rods.

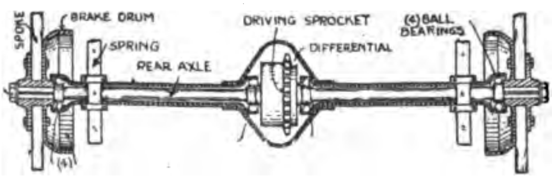


Fig. 3—A single chain driven live rear axle—now obsolete.

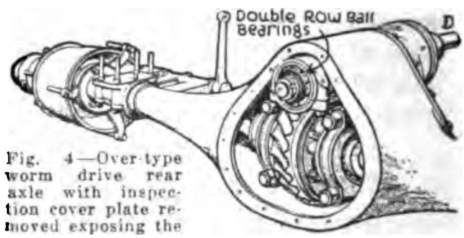

Fig. 4—Over-type worm drive rear axle with inspection cover plate removed exposing the gear.

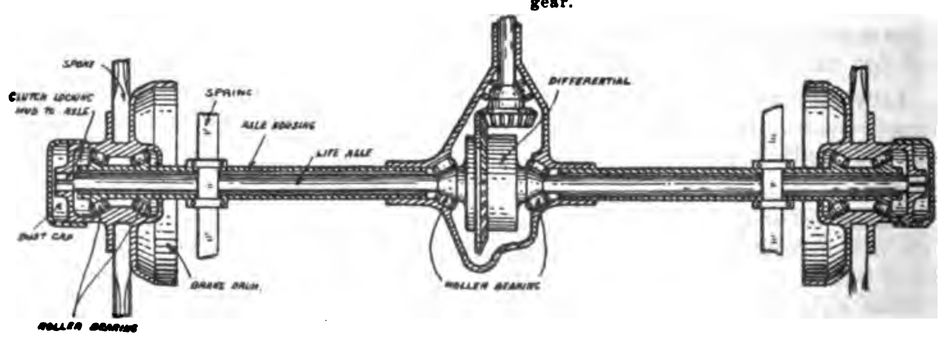

Fig. 2—Full floating live rear axle with roller bearings.

CHART NO. 17—Rear Axles.

and is enlarged at those points to take the ball or roller bearings. These bearings run between the axle and the inner side of the housing, or as shown in figs. 5, 6 and 7.

There are also bearings at the inner ends of the two parts of the axle, close to the differential. The axle housing of this type must be heavy, as it supports the weight of the car.

Types of Rear Axles Explained.

Plain live axles: have shafts supported directly in the bearings at center and at ends, carrying a differential and road wheels. This type is now practically extinct.

***Full floating type of rear axle:** the weight is taken from the axle, and supported on the housing through which the axle passes (fig. 5).

The hubs of the wheels are outside of the housing, and the bearings are between the inside of the hub and the outside of the housing (fig. 5).

The axle passes through the housing, and the ends that project are square; over these square ends fit caps that screw or are bolted to the outside of the hub. Thus when the axle revolves, the caps transmit the movement to the wheels. As the wheels run on the housing, the housing supports the weight, the axle serving only to turn the wheels. By removing the caps, the parts of the axle may be drawn out without removing the wheels, which hold up the car whether or not the axle is in place.

By jacking up the car to take the weight from the wheels, they may be drawn off the housing. The live axle is not continuous, but is divided in the center (see chart 18).

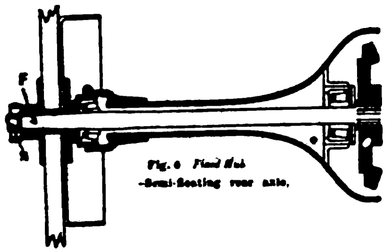

Fig. 6 Fixed Hub -Semi-floating rear axle.

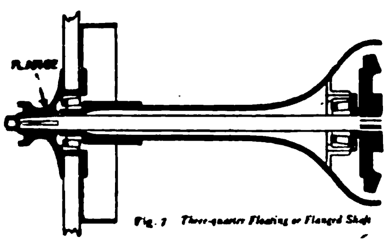

Fig. 7 Three-quarter Floating or Flanged Shaft

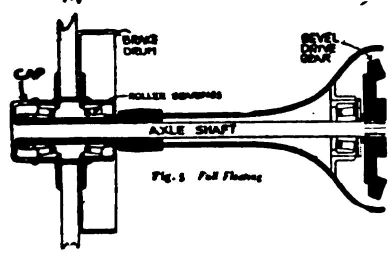

Fig. 5 Full Floating

In the "semi-floating" type, more properly called the "fixed hub" type (see figure 6), the driving shafts turn freely within the housing. At their outer ends they are fixed in the hubs of the wheels and carry the bending stresses as well as the torque. The hub of wheel in fig. 6 is fitted to shaft (F) with Woodruff keys and nut (N) which serve to secure wheel to shaft. Hub cap is merely a protection to end of hub.

In the "three quarter floating" (figure 7) or better the "flanged shaft" type, the housing extends into the hubs of the wheels as in the "full floating" type, but the ends of the driving shafts are connected rigidly by flanges with the wheels so that the shafts take almost all the bending stresses and all the torque. In the flanged shaft axle, especially when only one bearing is used under the center of the wheel, the stresses are quite similar to those in the fixed hub type.

In the "full floating" type of axle (figure 5) all the bending stress due to static force and skidding force is carried by the housing. The driving shafts turn freely within the housing and bear only the "torque" or stress of turning the wheels. The shafts are said to float within the housing.

In the full floating axle the shafts can be more easily removed for repairs. This is an advantage. It is necessary to make the full floating somewhat heavier than the fixed hub type for the same capacity.

*See also index for "axles, full floating;" and "removing axles." see pages 669 and 932.

In the full floating axle the entire differential can be removed by unscrewing 4 bolts (after cover plate is removed). In the ¾ floating, two gears must be removed first, before differential can be taken out, and in the semi-floating, the entire housing must be removed from car, see page 669.

*Bearings.

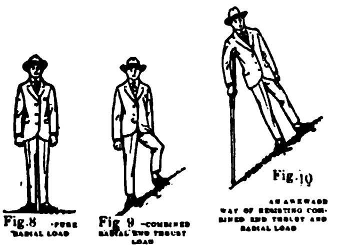
Every part of the car that moves with a rotary, sliding or other motion is supported in bearings, which together with proper lubrication reduce wear and friction.

There are three different types of bearings in general use; the **plain, roller** and **ball** bearings.

Bearings are called upon to do two kinds of work; to take a **radial** load or a **thrust** load or a **combination** of both.

A radial load is load or pressure perpendicular to the shaft supporting the load. For instance, the wheel bearings of an automobile, when running on a perfectly level road are subject to radial loads.

Thrust load is a load or pressure parallel to or in direction of the shaft. When the automobile strikes a curve a thrust load is imposed on the bearings in the wheels—that is, to the side or endwise.

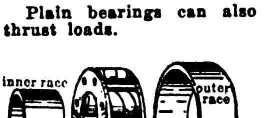


†**We might illustrate the relation between thrust and radial loads in this way:** A man could be considered as being subjected to pure radial load when walking on an absolutely level surface, fig. 8, but when this man walks along a hillside, without either ascending or descending the hill, as illustrated in fig. 9, he is subjected to a combination of radial and thrust load; the thrust load having a tendency to push him down the hill.

If a straight roller were called upon to take a thrust load as well as a radial load, it might be compared to the man in fig. 10, he would need a crutch to prevent his toppling over. Therefore a ball thrust bearing (fig. 7) would be necessary at end of the straight roller bearing, per fig. 12.

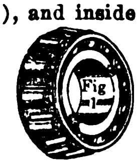
Plain bearings are usually on the main crank shaft, cam shaft and connecting rods of an engine and take a radial load.

Plain bearings can also be designed to take thrust loads.

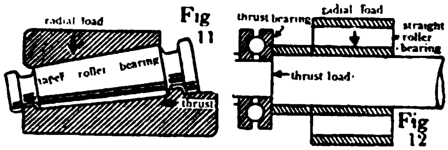


Roller bearings are used in the wheels, rear axle, transmission and other places and when **straight**, as per fig. 2, they can only take a radial load. The roller itself runs over an inner race and inside of an outer race, case hardened.

When a roller is tapered, it runs over a cone type hardened race (fig. 1), and inside of a outer race, arranged as per fig. 11 and page 687. This type of roller bearing will take a radial and a thrust load without the use of a separate thrust bearing.

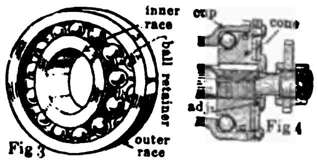


The groove in the race and roller, fig. 11, take the thrust load as well as the cone shape of race.



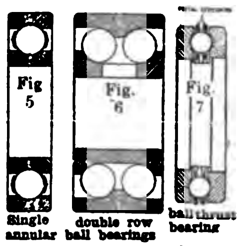
A straight roller bearing, to take a thrust load as well as a radial load, would require a separate thrust bearing, fig. 12 and fig. 9, page 676.

Ball bearings are also used on the wheels, rear axle, transmission and other places.



They are divided into three general classes; **cup and cone, annular** and **thrust.**

The cup and cone bearing is shown in fig. 4, and is used on many cars in the front wheels. This type of bearing is used extensively on bicycles. It is designed for radial loads but is capable of withstanding considerable thrust also. It is adjustable.



The annular ball bearing is a bearing with an inner and outer race, which is grooved and hardened. They are not adjustable. This type can be a "single row" of balls, per fig. 3 and 5, or "double row," fig. 6. The single row takes a radial load.

The races of the double row are so shaped, that it will withstand considerable thrust as well as a radial load. It is used where space would not permit the use of a separate radial and thrust bearing.

An example of where a bearing of this type is used is shown in fig. 4, page 82. Note the double row bearing is shown on the rear end of the worm taking the thrust (which is considerable), and also takes a radial load.

The ball thrust bearing is shown in fig. 7. This bearing can be used only where the load or stress is strictly a thrust or end to end load.

This type is often used in clutches and is extensively used on the propeller shaft driving the propellers of motor boats.

The two parts the balls touch are called races. The one or two balls at the lower side support the entire weight and must be strong enough to hold up without being crushed. In automobiles, the **balls** are large and run in size up to 1 in. di. hardened and polished.

Sometimes balls wear flat or crack; if so a click will be heard and must be replaced with perfect balls at once.

*See page 681 "adjusting front axle bearings" and page 669, "removing rear axle shafts."
†From Automobile Digest.

INSTRUCTION No. 5.

*CLUTCHES: Cone, Disk and Plate Clutch. Universal Joints.

Purpose of the Clutch.

The word "clutch" as used in connection with automobiles, indicates a device attached to cars having change speed gears of the sliding type, **which permits the engine to be connected with, or disconnected from, the transmission,** so that the car may or may not move while the engine is running.

The clutch is connected and disconnected from fly wheel of engine by a foot lever.

When disconnected from flywheel of engine then there is no connection between the engine and rear axle.

When clutch is connected with flywheel of engine then the power of engine is connected with rear axle—**if** the gears of transmission are not in "**neutral**" position.

If gears are in neutral position then the power of engine would end at the end of the secondary shaft of transmission (see page 38).

While other types of transmissions require clutches, they are of special kinds, and will not be referred to in this lesson. (The Ford, for instance, uses a different principle.)

Because a steam engine has behind it the pressure of the boiler, it can be called on to supply much more than its regular horse power for short intervals.

A gasoline engine has no reserve power to call on, and cannot deliver more than a fixed horse power.

When the gasoline engine is required to start the car, it must overcome the inertia of the car. This might be greater than the power of the engine could accomplish, and the engine might be stopped instead of the car being started.

If the clutch made an immediate connection between the engine and the drive, the power of the engine would have to instantly overcome the inertia of the standing car.

The power of the engine coming from the revolving of the fly wheel, and the explosion that might be occurring in one of the cylinders, it would probably be stopped instead of the car being started.

If, however, the clutch is made so that the engine takes hold **gradually,** the inertia of the car will be overcome, and it will move faster and faster as the clutch permits the engine to apply its power more and more.

This is done by making the clutch in such a way that when it is applied, it **slips,** instead of instantly making a connection between the engine and the drive.

When the clutch is "let in," it connects the crank shaft of engine through the fly wheel with the transmission through the clutch shaft, and if the gears are in the "neutral" (gears out of mesh) position, the counter or secondary shaft in the gear case of transmission will revolve without moving the car. See illustration page 50.

Clutches have two chief parts; one part (usually the flywheel, see chart 19, fig. 1), is attached to the crank shaft of the engine, the other part (cone or disk or plate) is attached to the clutch or main shaft of the transmission (see page 48, fig. 1). (134.)

When the two parts are separated, that is to say "clutch thrown out" by the clutch pedal, they are independent of each other and the engine can run without moving the car.

*See Dyke's working model of the clutch and gear box. For repairing clutches, see index. For make of clutch on different cars, see "Specifications of Leading Cars"—page 543.

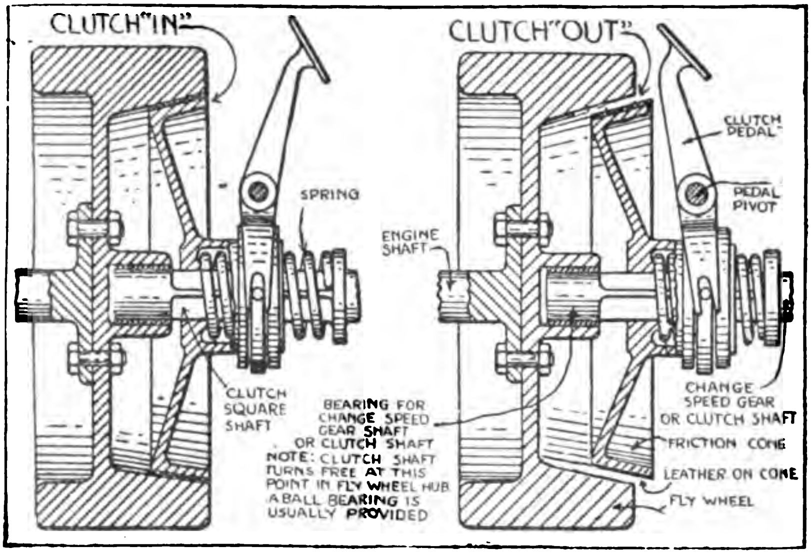


Fig. 1—Illustrates how the cone type of clutch is fitted into the fly wheel.

Illustration shows same in section as if cut in half. The cone is perfectly circular, but cone shaped and fitted with leather which grips the inner surface of the fly wheel rim when clutch is "in," which it always is, unless thrown "out" by the clutch foot pedal.

Note in illustration position of cone when clutch is "in" and "out." Also note clutch shaft runs free in hub of fly wheel, usually on a ball bearing as per (CE), page 50.

By pressing clutch pedal the pivot causes lower part of pedal to throw clutch out. At all other times clutch is held in by tension of clutch spring.

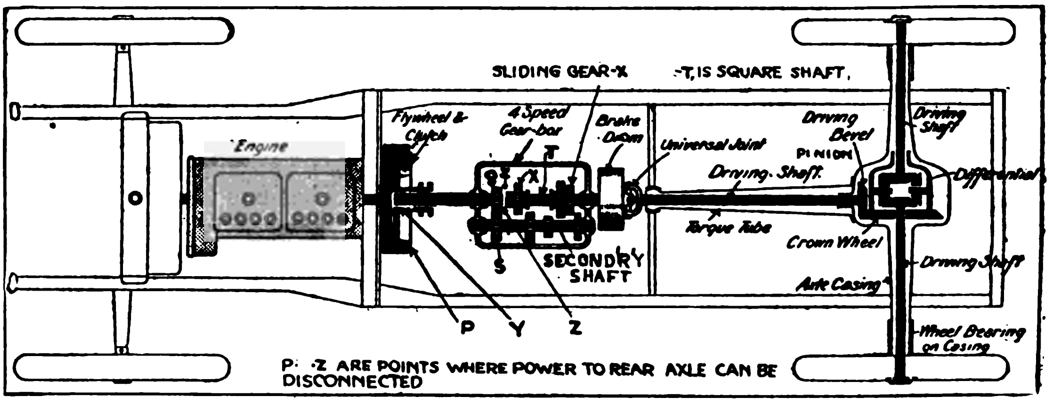

Fig. 2—Illustration explains how the power **is transmitted from engine to clutch, thence to secondary or counter shaft. Note drive parts are** flywheel, clutch, clutch shaft, drive gear (O), secondary shaft gear (S) and gears on secondary shaft. The **driven gears** are the sliding gears (X) on square shaft (T). Note power to rear axle is disconnected at point (P) when clutch is "out," at which time the clutch and clutch shaft turn free from flywheel. and at (Z) when the **drive** and **driven gears are in "neutral"** or not in mesh. (This end of square shaft (T) runs free in end of clutch shaft, as per fig. 3, page 48, and is not actually separated as shown above.)

Clutch action: Note the power from engine is transmitted to the clutch shaft **only through the clutch** when **in** the rim of the fly wheel (if disk or plate type, then by the disks or plates as explained under that type of clutch).

Observe that clutch shaft does not connect with engine, but runs **free** at all times in hub of fly wheel. The cone part of clutch is connected with the clutch shaft so that when cone turns, clutch shaft must also turn. But observe that the cone slides on the square part of clutch shaft so that it can be pushed **out** by pedal or **in** by the spring.

When friction part of cone is **out** of fly wheel—**power ends at the fly wheel.**

When clutch is **in,** then **power ends at the end of the secondary or countershaft—if gears** are in "**neutral,**" which position they are in above.

Turn to page 48 and study the meaning of "neutral" and see in figs. 1, 2 and 3 **how the rear axle is made to revolve.**

HART NO. 19—Explaining the Purpose of a Clutch and how the engine can run yet not drive the .r. Explanation of "clutch out" and "clutch in."

When the two parts are connected, that is, when the clutch is "let in" by releasing the clutch pedal, the part on the transmission shaft is forced into a frictional contact with the part on the crank shaft or flywheel by means of a powerful spring and held there. The two parts being thus connected forces the transmission to revolve with the engine and so drive the car, if gears are not in "neutral" as has been explained.

The part on the crank shaft does not grip the part on the clutch or transmission shaft immediately, unless they are moving at the same speed.

If they are moving at different speeds, which is usually the case, or when the part on the transmission is stationary, the two parts slip. This slipping continues until the two parts revolve at the same speed, when they bind together firmly. When "thrown out" they must separate instantly.

A disk or any other type of clutch used with the gear type of transmission is placed in the same relative position; **back of fly wheel,** between the fly wheel and gear case. Although the construction may vary, the reader will note that the **clutch principle is necessary on all cars.**

Clutch pedals—The **left** foot pedal on all cars of standard design, is the **clutch** pedal and on the **right** the foot **brake** pedal. See "operating a car."

Types of Clutches.

There are four types of clutches in general use; the cone, disk, plate, and **†expanding** type.

The disk clutch (formerly called the multiple disk) is a clutch with more than three disks and can be a **lubricated** disk clutch or **dry** disk clutch. A **plate clutch** is one wherein one plate is clamped between two others.

*The Cone Clutch—see chart 19.

This type of clutch is built into the fly wheel, and the fly wheel forms one of its parts. The rim of the fly wheel is broad, and the inside of the rim is made slightly funnel-shaped, forming the surface against which the other part of the clutch presses (fig. 1, chart 19).

The cone; the other part, called the "cone," is, as its name indicates cone-shaped, and fits into the funnel formed inside the fly wheel rim. The surface of the cone that bears against the fly wheel is often covered with **leather** to give good grip (one large manufacturer uses fabric running in oil).

The hub of the cone has a **square** hole, so that while it may slide on the **square** part of the clutch shaft which connects to the transmission sleeve (see 134, fig. 1, page 48), still the cone and shaft must revolve together. The forward end of the clutch shaft rests in a bearing formed in the hub of the wheel, so that it is supported, and yet may revolve independently of the fly wheel.

A heavy spring presses the cone against the seat formed in the rim of the fly wheel.

When the clutch pedal is pressed forward, the cone slides on the shaft away from the fly wheel, and separates from it, the spring being compressed (see fig. 1, page 38).

When the clutch pedal is released, the spring presses the cone against its seat, and if the crank shaft and sleeve are not making the same number of revolutions, the cone will slip. This friction makes the cone act as a brake on the crank shaft, slowing it, and at the same time the cone and sleeve are speeded up, so that the cone and fly wheel come to the same speed.

Clutch Operation—cone type as an example.

Fig. 2, page 38 (also page 50)—note the power from crank shaft of engine is transmitted to the clutch through friction connection with fly wheel, thence through gears, thence to drive shaft to bevel gear drive on the rear axle.

If engine is running, clutch could be "**in**" if gears are in "**neutral**" (not in mesh). If gears are in mesh with engine running then rear axle would revolve—unless clutch was "out."

*See repair subject for adjusting clutches.

†The expanding shoe clutch is very seldom used. As has been previously stated, a successful clutch must be fairly light at the rim, but with the expanding clutch, owing to its method of operation, this is almost impossible.

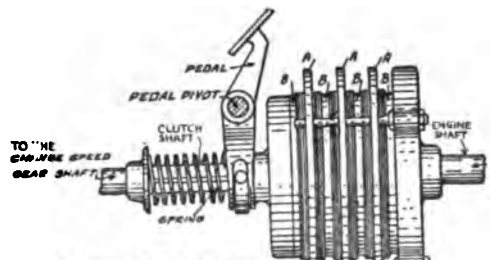

Fig. 1. One Type of a Multiple Disc Clutch.

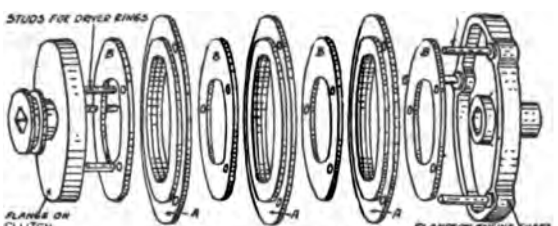

Fig. 2. Parts of above Multiple Disc Clutch. A—Driving Rings. B—Driven Rings.

Principle; Disk Clutch Lubricated Type.

Parts: Fig. 2 shows the parts of the clutch separated from each other. The disks (A) are attached to the flange on engine shaft, the smaller disks (B) are attached to the transmission shaft. The large disks (A) and small disks (B) are placed alternating.

The two flanges have pins extending from them, the disks having holes so that they may be slipped on the pins.

The small disks on their studs fit inside of the studs on the large flange, and the openings in the large disks permit the studs or pins on the small flange to pass through them. Thus the outer edges of the small disks come in contact with the inner edges of the large disks.

Assembled clutch: as will be seen from figure 1, which is the clutch assembled, the two flanges are connected only by the friction between the large and small disks, when the spring presses the parts together. The entire clutch is placed inside a casing, and runs in oil.

When the clutch pedal is pressed forward, the clutch is "thrown out," the oil then flows between the disks, and when the clutch is "in" and the spring presses the disks together, the oil is squeezed out from between them. While it is being squeezed out the clutch is slipping, and it begins to bind when the pressure has squeezed it out and the disks in consequence feel the effect of the friction. When the clutch is "thrown out," one set of disks may revolve independently of the other, for they are not connected in any way.

Hele-Shaw Disk Clutch.

In the Hele-Shaw disk clutch (fig. 4) a similar principle is adopted. The plates consist of a number of alternate bronze and steel disks much thinner. They are corrugated to increase the grip.

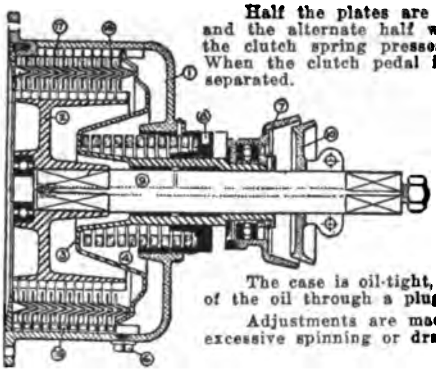

Fig. 4—The Hele-Shaw corrugated disk clutch-lubricated type.

Half the plates are rotably connected by grooves with the driving member, and the alternate half with the driven member. When the clutch pedal is released, the clutch spring presses these disks together, and they all rotate as a solid mass. When the clutch pedal is depressed, the spring pressure is removed and the plates separated.

Referring to the illustration (fig. 4) the outer oil-tight case (1), to which the driving bronze plates (16) are keyed, is bolted to the flywheel of the engine. The inner core (2) is keyed directly to the clutch shaft and to it are keyed driven steel plates (17).

The clutch is shown engaged as normally held by the spring (4) which actuates the ring (7) and the sliding presser (8). To facilitate quick disengagement, small springs (26) are fitted between the disks.

The case is oil-tight, provision being made for the replenishment of the oil through a plug (6) for the purpose.

Adjustments are made by means of an adjusting nut (8), and excessive spinning or dragging is prevented by a cone brake (10).

Cadillac—Dry Disk Clutch.

Fig. 5—The driving disks "A" are covered on both sides with a friction material, composed largely of asbestos, and are driven by six keys in the clutch ring "H" which is bolted to the engine fly wheel "G."

The driven disks "B" are not covered. These disks are carried on the clutch hub "E" and drive it through six keys on the hub. The clutch hub is keyed to the transmission shaft "F."

When the clutch is engaged by allowing the clutch pedal to come towards you, the spring "C" forces all of the disks together. The resulting friction between the disks "A" and "B" drives the transmission shaft "F" and the car, when the transmission control lever is in other than the neutral position.

There are no adjustments. The clutch pedal should be adjusted occasionally to compensate for wear on the facing of the clutch disks.

There is one point "D" on the clutch for lubrication.

There are 17 steel plates, having 9 driven disks and 8 driving disks. The coil spring is held under 300 lbs. compression.

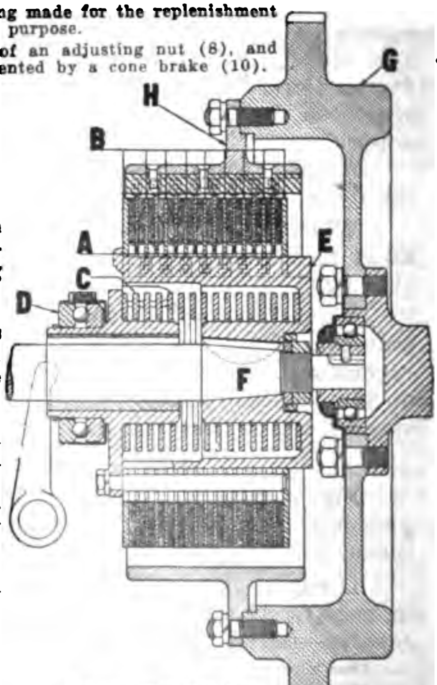

Fig. 5—The Cadillac disk clutch — dry type.

CHART NO. 20—Disk Clutches; lubricated and dry types.

Therefore there are three methods of cutting off the power to rear axle; (1) stopping engine, (2) by throwing "out" clutch, (3) by having gears in "neutral."

The usual method to stop car and engine—is to "throw out" clutch, shift gears to "neutral" and apply foot brake. After **car** stops **then** turn off ignition switch and stop engine.

When starting engine the gears are placed in "neutral" position by the hand gear shift lever. (Note fig. 2, chart 19; also page 50. Gears are now in "neutral" position.) Engine can then be started without car moving.

To start car after engine is started; throw "out" clutch with foot pedal—shift gears in mesh (usually to lowest gear set), then gradually let clutch "in."

The term "clutch in" means, the clutch is allowed to press into the fly wheel by tension of spring.

The term "clutch out" means it is held out by foot clutch pedal. If car was running and you desired to coast, "throw out" clutch or disengage gears.

When stopping—throw "clutch out" by movement of foot pedal. (Usually left foot pedal.) Apply running brakes (usually right foot pedal.) Shift gears into "neutral" and then let "clutch in."

The clutch is used more than any other control on car—therefore **study the meaning of "clutch in," "clutch out," "gears in neutral."**

When the change speed gear is to be moved to a higher speed after starting or at any time when car is in motion or engine running, the clutch must first be "thrown out," for the gears could not be meshed with the countershaft revolving and the square shaft stationary; "throwing out" the clutch leaves the countershaft free to move as necessary to mesh the gears.

The cone clutch adjustments are simple. Examples are shown in the repair subject. See index. The "grabbing" feature is being done away with by insertion of springs, usually about 6 inserted under the leather. Slipping is overcome by clutch springs within the spider. See Buick clutch adjustment in repair subject.

The Disk Clutch—see chart 20.

The disk clutch (formerly termed multiple disk), consists of a number of disks which are pressed together when the clutch is "**in**," the friction between them causing one to drive the other. This type of clutch is very compact, and is frequently built inside of a metal housing cast to the engine frame.

To illustrate the principle of the disk clutch, place a silver dollar between two silver half-dollars, and squeeze them together between the thumb and forefinger of one hand. With the other hand, try to revolve the dollar not moving the halves. It requires only a slight squeeze to produce sufficient friction to make it impossible to move the dollar.

Multiple disk clutches are of two general types; those that operate in an oil bath and those that run dry; called **lubricated** and **dry** types

The lubricated disk clutch **runs in oil**; its disks are usually alternate steel and bronze or all steel disks, and the type that **runs dry** is usually of steel disks, one set of which is faced with a friction material of woven asbestos fabric.

The lubricated and dry types are described in chart 20.

The Plate Clutch.

The S. A. E. term the disk clutch (formerly called the multiple disk); a clutch with more than three disks. **The plate clutch** is where one plate is clamped between two others.

The single plate clutch is a popular type of clutch. It is a variation of the disk type, the latter comprising a large number of narrow disks, while the other usually consists of but three broad disks or plates, the ordinary type having two **driving** plates and one **driven** plate.

An example of a single plate clutch is described in detail in the following matter. In this type the clutch effect is created by **wedging** the plate. The type which will now be described is the Borg and Beck make (chart 20A, and page 43).

24—Shaft, Brake and Universal Connection (not shown).
25—Adjustment-Incline—take-up seat for roller.
60—Bell-Crank Pivot—mounts thrust-lever.

Borg & Beck Single Plate Clutch.

Principle: This type of clutch runs dry. The action is best understood when it is kept in mind that among the revolving parts, only the **driven** group; disk 11, shaft 13 and brake collar 20, can stand still when fly wheel is running; and all other parts being "anchored" to fly wheel must always revolve and drive with the latter.

When clutch is "in:" The asbestos friction rings 10, though not positively attached to either the driving or the driven parts, will, in practice, "freeze" to the unpolished faces of the inner case of fly wheel and thrust ring 8; and thus always run bodily with the fly wheel.

When clutch is "out:" The foot lever is applied which telescopes the coil spring (14) back, by action of the throw out sleeve (16) which causes the roller (7) to withdraw a sufficient distance from face of thrust ring (8), to permit the latter, with its companion friction ring (10), to "back-away" bodily, from friction disk (11), thus releasing the disk from the friction-grip, and permitting it and other driven parts to come to a stop, while fly wheel and parts anchored to it revolve.

CHART NO. 20-A—Principle and Construction of a Modern Single Plate Clutch—dry type. (The **Borg** and Beck Co., Moline, Ill.)—see also pages 668 and 842.

See index for "Specifications of Leading Cars," for cars using this clutch.

†**Adjusting the Single Plate Dry Clutch**—per chart 20-A.

Take up action: The roller seat face of the thrust ring (8), is formed on three, equal succeeding, takeup "inclines" (25); the ring being ¼ inch thicker, at the high end of each "incline" (25), than at the beginning, or low end. The three thrust-levers (6), are mounted upon, and equally spaced by, the adjustment ring (5); and this ring is adjustably mounted against the inner face of the cover (2), by means of the adjustment—bolts (4) of which there are two, through slots (3) in the cover.

When the bolts (4), are "slacked," and shifted in their cover-slots (3), they control and shift with them the ring (5), the latter carrying with it the levers and rollers (6 and 7)—thus shifting all the rollers to new seats against the non-shifting thrust-ring; and, these seats being further up the ring "inclines" (25), where the inclines are thicker in cross section, the ring is necessarily thrust so much further toward the other friction parts, to compensate for any friction wear, and to maintain, at all times, a perfect friction grip.

Therefore to adjust clutch, the clutch is held entirely out.

With the clutch thus held "out," it is only necessary to "slack" the adjustment-bolts (4), tap either of them "**clockwise,**" in the slot (3) on cover, a **quarter or half inch,** or any other distance required, thus shifting the ring (5), carrying the levers and rollers to new seats, upon thicker sections of the thrust-ring; and thus compensating for the friction-wear which made the adjustment necessary.

If too much oil gets into clutch and causes slipping: In this case it will be necessary to unscrew the bolts (4) about three turns, have some one hold out clutch and let oil drain out. It is also desirable to squirt gasoline into interior of clutch to wash out the oil. If slipping continues the trouble is due to oil working into clutch housing and must be separated from main oil supply of oil pan of engine.

Removing clutch: First remove transmission. Mark clutch cover that bolts to flywheel with punch and corresponding mark on flywheel, in order that it is put back in same position. Cover plate must not be turned.

Replacing clutch: There are two asbestos fabric rings; one lays against face of fly wheel (10), next to this comes the driven plate (11), then other friction washer (10). The cast thrust ring (8) comes next, but before installing, make sure the driving pins (9) are in place in the inside of the fly wheel rim. Drop thrust ring (8) in position so that the three slots fit over pins (9). The adjustment ring (5) with its parts assembled to it should now be installed. The adjusting ring (5) fastened to the cover plate by means of two cap screws and cover plate bolts to fly wheel.

Clutch brake is provided which comes into action when the clutch pedal is pushed all the way down. Purpose is to stop spinning of transmission gears when clutch is disengaged. The throw out collar (15) presses against the brake collar (20). The clutch brake is mounted on the transmission shaft and is faced with asbestos fabric.

If worn, trouble will be experienced when shifting gears into first speed when car is standing. Clutch will appear to drag and will continue to drive transmission gears when fully disengaged, so it will be difficult to mesh gears.

To remedy, remove oil pan, have some one hold out clutch, while throw-out clutch and collar are examined; to see if collar (20) actually touches brake or not. If it does not, the transmission should be removed and if brake friction facing is in good condition no need of installing a new one. See that the throw-out is not coming in contact with brake flange and should be adjusted so that these two points form a contact.

Note—always remember to drive with **foot off the clutch pedal.** Make sure clutch pedal does **not strike or press against toe board.**

*Universal Joints.

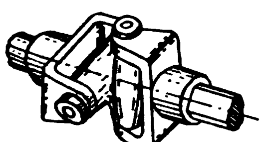

Fig. 2. Universal Joint, also called Cardan Joint—note straight line.

A universal joint is a flexible connection between two shafts, which permits one to drive the other, although they may not be in line. Refer to figs. 2, 3 and 5 and study the principle. Universal joints are usually placed forward and rear of the drive shaft (see page 50).

Universal joints are necessary on automobiles with shaft drive, for while one end of the driving shaft is attached to the transmission shaft, which is on the frame, the other end is connected to the axle, and constantly moving up and down as the wheels follow the roughness of the road.

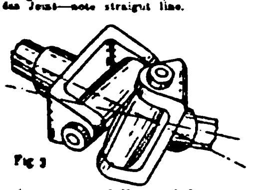

Fig 3

Another view of Universal Joint—note it is now out of line

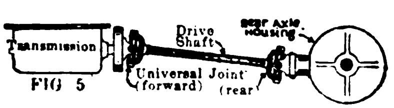

FIG 5

If no universal joints were used, the shaft would jam in its bearings from the up and down movement of one end of it.

*Universal joints are also called cardan joints. See pages 680, 681 for construction of "universal joints." †See pages 668 and 842 for other adjustments on Borg and Beck clutch. See foot note page 662. why gears of transmission are sometimes difficult to shift.

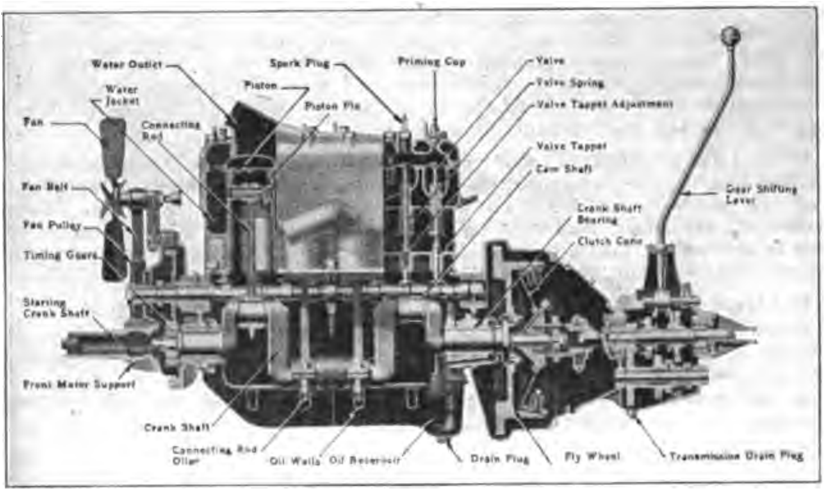

Fig. 1: A modern unit power plant, the Dort.

The engine of this unit power plant has "L" head cylinders cast in block; valves on side, poppet type; detachable cylinder head (see index, "cylinder head, replacing of.")

Transmission: selective type, 3 speeds ahead and reverse. **Clutch;** cone type. **Gear shift lever;** ball and socket type.

Left, foot clutch pedal and right, foot brake pedal.

Power is transmitted to rear axle from end of transmission shaft (upper one).

INSTRUCTION No. 6.

TRANSMISSION: Principle of Operation, Location, Different Types.

Principle of a Transmission.

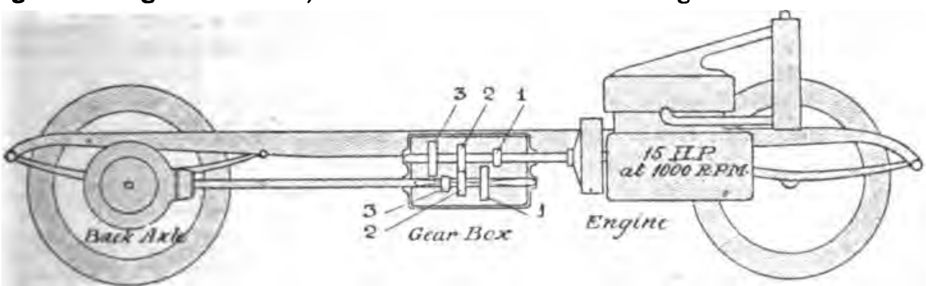
When a bicyclist wants to race on a level track, he gears up his wheel with a larger sprocket so that one revolution of the crank takes him farther. Yet if he takes this wheel with this large sprocket on the pedal shaft, out on the road where there are hills, he must get off and walk or exert an extra lot of power. This clearly shows that if a bicyclist wants to speed while on the level and yet take all hills, he must change the drive sprocket.

The same principle applies to the automobile—therefore the automobile is provided with not only two changes of gears (instead of sprockets), but it has three and sometimes four changes of gears, which gears are contained in a gear box usually placed back of the clutch. (See page 38).

The principle upon which all change-speed gears work is the fact that when two cog-wheels or spur gears are meshed together the larger wheel turns more slowly than the smaller wheel.

As an example, a cog-wheel with 10 cogs, in mesh with a second wheel having 20, would revolve twice as fast as the latter, the explanation being, that when the 10 cogs of the smaller wheel have moved round once they will have engaged with only 10 cogs of the larger wheel, and therefore will have turned the larger wheel through only half a revolution, that is, that it will be necessary for the smaller wheel to revolve twice in order that the larger one may revolve once.

*With this piece of elementary information, we will observe that in the gear-box (see below) there are two shafts—the upper one coming from the engine through the clutch, and the lower one continuing to the back axle.



Each shaft is fitted with three different sized cog-wheels numbered in the illustration 1, 2 and 3; those on the upper shaft are fixed to the shaft itself, but those on the lower shaft are able to slide on a keyway, to right and left along the shaft. The shaft is not round like the upper one, but is **squared,** so that although the sleeve of cog-wheels can slide backward and forward, they cannot revolve independently of the lower shaft.

In order now to vary the speed of the car, it is only necessary to slide the cog-wheels (gears) along the lower shaft until the correct two gears come into mesh to form the gearing required.

The illustration, for instance, shows intermediate speed gear in mesh, but were we to move **the gears to the right** so that wheels 1 and 1 come into mesh, we should put the car on its **first speed,** that is its **lowest speed,** so that with the engine running normally the car would be moving very **slowly,** the driving gear being much smaller than the driven gear.

When, however the sleeve is moved to the left so that gears 3 and 3 mesh, the effect is reversed. Now we have the **driving** gear much larger than that **driven,** and the result will be that when the engine runs normally the car will be traveling at a very high speed.

*This illustration is intended to simplify the explanation. In actual practice the arrangement is slightly different (see page 46); the sliding gears are usually above, clutch shaft and transmission shaft are not continuous as shown and drive shaft connects with transmission main shaft instead of counter shaft.

The number of revolutions made by the engine to one of the wheels is different with different manufacturers, but as a general thing, when on the low speed the engine makes from twelve to eighteen revolutions to one of the road wheels, and on high speed from one and a half to four revolutions to one of the road wheels.

The sides of the teeth of the gears are usually made like the point of a chisel, so that when two gears are brought together they will mesh easily. If the sides of the teeth were flat, as in ordinary gears, it would be difficult to slide them into mesh. (Mesh means the teeth of two gear wheels engaged.)

When sliding the gears from one speed to another, the main clutch in fly wheel must always be thrown out.

With the main clutch in the fly wheel thrown out, the sliding gear on the square shaft is free to move and its speed may easily be changed. If the change were to be made with the engine driving the upper shaft, changing the speed of the gear would require the speed of the engine to be changed; or changing the speed of the gear on the square shaft would require the speed of the car to be changed.

Neutral—means that the gears are not meshed or in engagement at all. Therefore power to rear axle is cut off, yet engine is free to run although the clutch is in engagement with fly wheel.

When running it is always necessary in shifting gears, to **first throw clutch out** of engagement with fly wheel, then bring gears to **neutral** position and then shift from a **lower to higher gear,** unless car is gradually slowing down, then a shift to lower gear would be in order. But never shift to a lower gear when running at fast speed, as there is a liability of stripping the teeth from the gears, or if the teeth were strong enough to stand it, the car would be badly jolted. Therefore, **always throw out the clutch in the fly wheel before changing gears and let car slow down if shifting to a lower gear.** It is seldom, however, a shift to lower gear is made unless car slows down, and it is unnecessary to slow car down.

****To reverse motion of car** the reverse gear must never be used until the car is at a **dead stand still.**

The location of the transmission may be either in front; adjoining the clutch, or on the rear axle housing; see chart 24, figs. 2 and 7. The modern method is the **"unit power plant,"** where the transmission and clutch are connected to the engine as one unit. See pages 44 and 50.

Types of Transmissions.

There are three types: the sliding gear, planetary and friction disk type.

The **planetary** type is used on the Ford (see Ford instruction). The **friction disk type** is used on light cars to a certain extent as cycle cars, etc., see fig. 4, chart 24 for principle.

There are two types of sliding gear systems; the old style **progressive** type (fig. 2) and the modern **selective** gear type, pages 48 and 50.

The progressive type was discarded because it was necessary to pass one gear through another which made a clashing noise and difficult at times to operate.

With the selective type it is not necessary for the sliding gear to pass through another gear. It is easier and quicker to operate and considerably less noisy. It is with this type we shall deal.

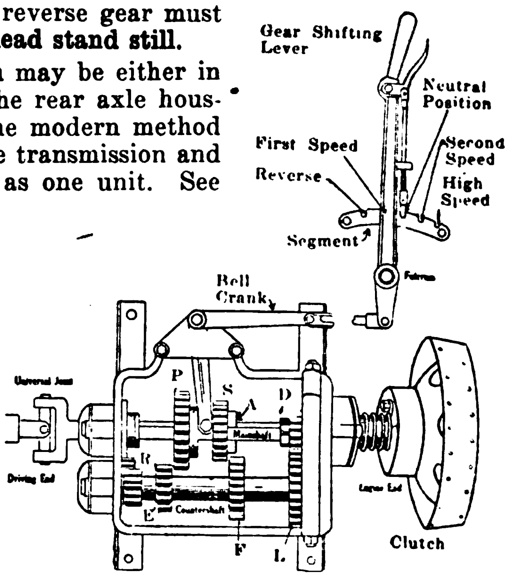


Fig. 2.—A three speed progressive type of transmission, showing the lever and gears in "neutral" position; an obsolete method.

By referring to fig. 2—note in order for dog (A) to reach dog (D) which would be high gear or direct drive, it would be necessary for the sliding gear (S) to pass through gear (F). Or if to reach reverse, by gear (P) being meshed with (R), it would be necessary for gear (P) to pass through gear (E).

*Transmissions are also called change speed gears or gear boxes. **See pages 48 and 50.

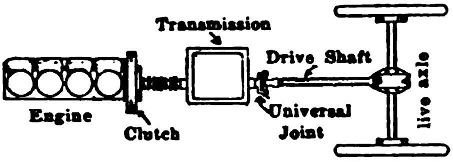

Fig. 2. Shaft drive type of transmission. Transmission mounted on frame directly back of clutch and is of the gear type. This type used to great extent on pleasure cars. Transmission of the gear type.

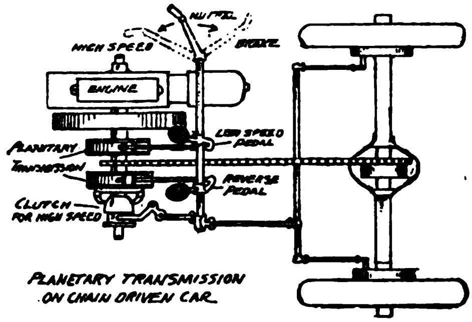

Fig. 5. Single chain drive type of planetary transmission. The transmission is mounted to the side of the engine. The type of transmission is the planetary type. This system is now seldom used.

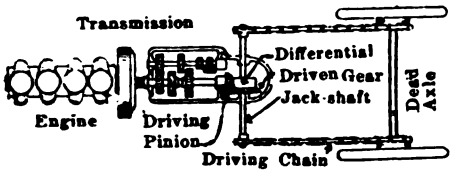

Fig. 3. Double chain drive type of transmission. Transmission is mounted on frame and is connected by bevel gears to a jack shaft. This type used to a great extent on trucks. Transmission of the gear type.

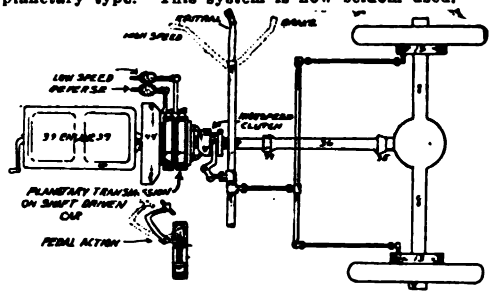

Fig. 6. Shaft drive type of planetary transmission as used on the Ford. (See Ford Instruction.)

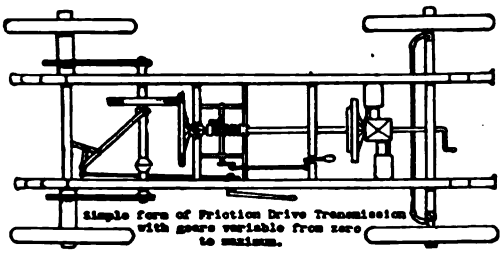

Fig. 4. The friction disc type of drive of transmission used on the Carter Car. It is extensively used on Cycle Cars.

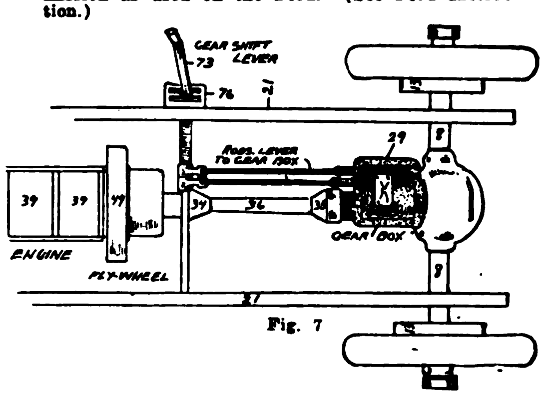

Fig. 7

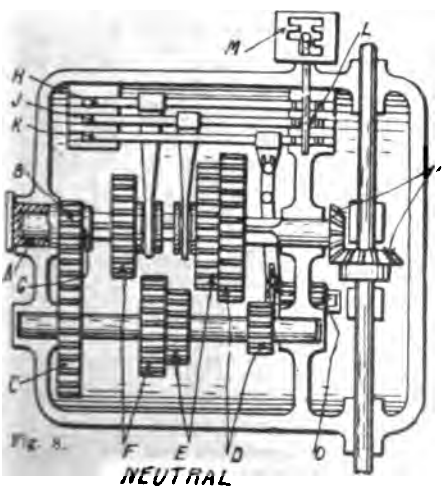

Fig. 7—The method of placing the gear type transmission on the rear axle. See also page 204.

***Fig. 8**—Four speed selective type of transmission for a double chain driven drive car.

The only difference between this type and the one in (Chart 23), is that a jackshaft with bevel gears (N), is employed. (See fig. 3 above.)

When there are four changes of speeds, note that there are three shifting forks (H, J and K). The drive gear (B) is attached to the sleeve (A), which connects with engine drive shaft through the clutch.

A—Sleeve driven by engine.
B—Gear on sleeve.
C—Gear on countershaft.
D—Low speed gears.
E—Second speed gears.
F—Third speed gears.
G—Clutch for high speed.
H—Rod and arm for third and high speed.
J—Rod and arm for low and second speed.
K—Rod and arm for reverse.
L—Finger in groove.
M—Guide plate for selective lever, also called a "gate."
N—Bevel gears to jack shaft.
O—Idler for reverse.

CHART NO. 24—Location of Gear Box (Transmission) Four Speed Selective Type Transmission.

(Chart 22 is on page 50). *See page 51 (footnote) for 4 speed ratio of gearing.

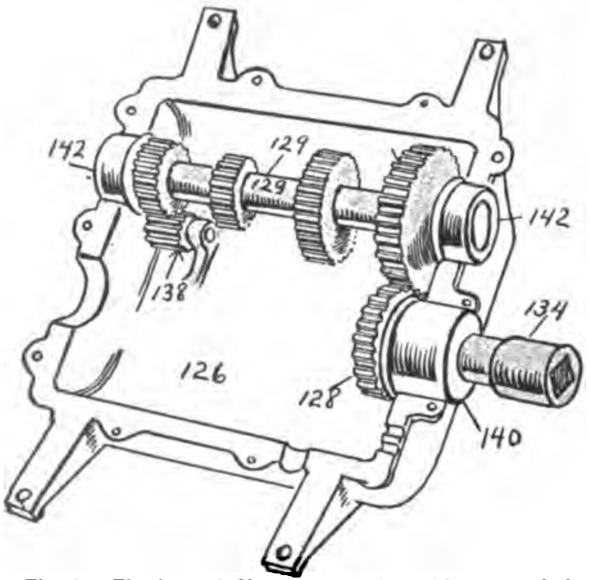

Fig. 1: The lower half of transmission with countershaft (129) and its gears which are permanently attached thereto. Idler gear (138), clutch or main drive gear (128), clutch shaft (134) are also illustrated.

Note:—When clutch and transmission are in one unit, the shaft (134) has no square hole—see page 50. Gear (128). countershaft drive gear and its shaft (129) always turn together.

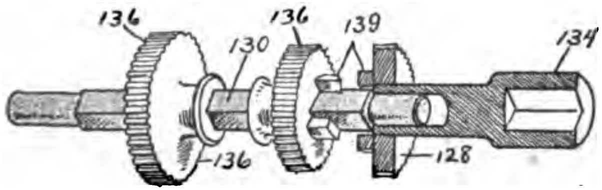

Fig. 3: Transmission square drive shaft (130) and sliding gears (136). Note forward end of square shaft (130) runs free into end of clutch gear and shaft. If dogs (139) are brought together by sliding gear (SG-1, fig. 2) forward, then square shaft (130) would revolve with clutch shaft (134)—this would be "direct" or "high" gear drive.

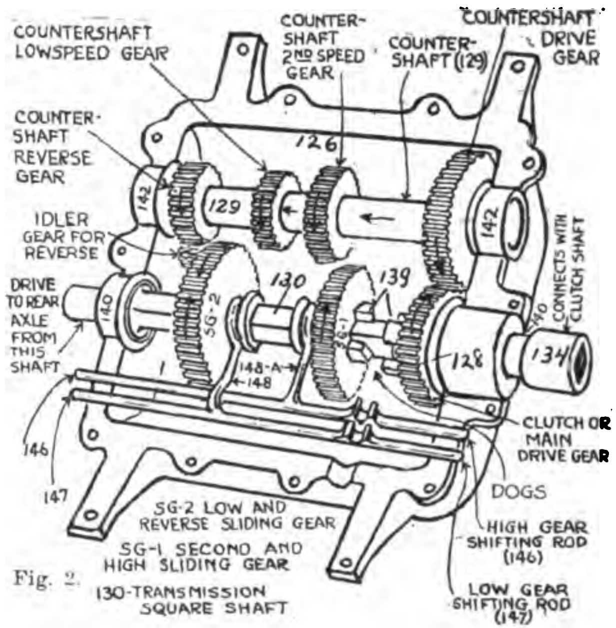

Fig. 2.

Fig. 2: How the change of gears are obtained. Note in fig. 3 the square shaft (130) is independent of the clutch shaft (134). Also note in fig. 2 that gear (128) and drive gear on *countershaft and the countershaft itself (129), always turn together, therefore, power from engine would end at shaft 129 providing sliding gears (SG-1 & SG-2) were in position shown, which is "neutral" position.

Neutral, means the sliding gear is not in mesh with the gear that drives it, therefore with present position as illustrated in fig. 2 we could not drive the rear axle, even though the engine was running and clutch "in."

First or low speed would be obtained by shifting gear (SG-2) in mesh with countershaft low speed gear. **Second speed,** would be obtained by shifting sliding gear (SG-1) in mesh with countershaft second speed gear. **Third or high speed,** would be obtained by shifting (SG-1) forward so dogs (139) would grip, then the drive would be **direct** to rear axle, but countershaft and its gears would also turn, but not being in mesh with the driven gears it would make no difference. **Reverse** would be obtained by shifting (SG-2) back until it meshes with idler gear which would reverse the direction of drive shaft (130).

Remember—gears cannot be shifted until lever is brought to "**neutral**" position. Also see pages 50 and 51, and foot note page 662.

CHART NO. 23—Simplified Illustrations Explaining the Principle of Operation and the Change of Gears in a Selective Type of Transmission with Three Speeds Forward and Reverse. Note—in modern transmissions the transmission shaft (130) sets horizontally over the countershaft as per page 44. Another change made in some transmissions, is the elimination of dogs (139); the gear (128) fits internally into the main drive gear (SG-1). See page 50.

*Also called "secondary shaft."

The Selective Gear Type Transmission.

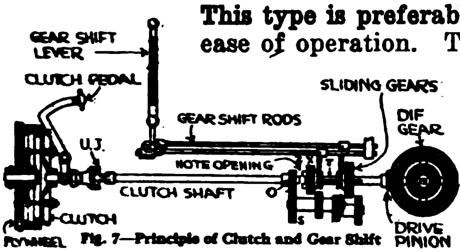

Fig. 7—Principle of Clutch and Gear Shift

This type is preferable, due to absence of noise of gears and ease of operation. The gear change ratio or gear desired, is "selected" by movement of the gear shift lever and the shift can be made without one gear passing through another.

Relation of the gears to the clutch is shown in fig. 7, and fig. 2, page 38. Principle of the selective type transmission is shown on pages 48 and 50.

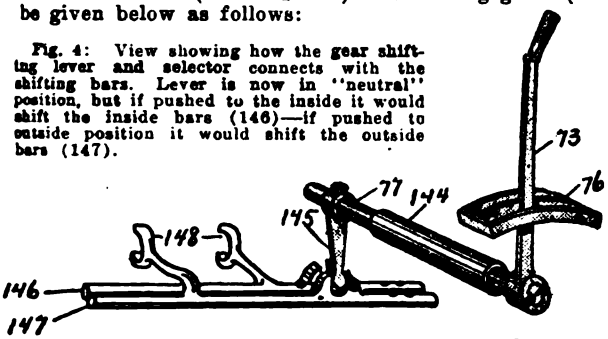
Referring to fig. 7, note power is transmitted from fly wheel to clutch, thence clutch shaft to gear O and S, through sliding gear for 1st or 2nd speed. For high speed, small dog clutches on sliding gear X, on square shaft (T), mesh with dogs on gear O, which makes the drive direct to rear axle, see fig. 3, page 48.

Operation of the Gear Shift Lever.

There are two types of gear shift levers; the "gate" principle as per figs. 4 and 2 below, and the "**ball and socket**" type shown in fig. 1. The latter being used more than any other type.

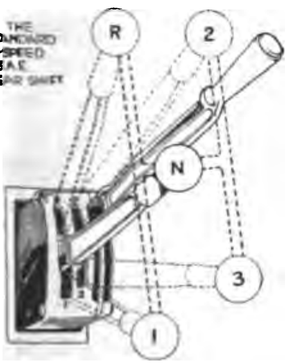
A simplified explanation of how the parts operate is shown in fig. 4. If the reader will first refer to page 48 he will understand just how the shift lever operates in relation to the shift bars (146 and 147) and shifting gears (SG-1 and SG-2). Further detail will be given below as follows:

Fig. 4: View showing how the gear shifting lever and selector connects with the shifting bars. Lever is now in "neutral" position, but if pushed to the inside it would shift the inside bars (146)—if pushed to outside position it would shift the outside bars (147).



By moving lever (73) in, to the left, the arm (145) engages with gear shift bar (146). Then by moving it (73) **forward** or **backwards,** the sliding gear (SG-1) is moved to "**second**" or "**high**" speed engagement.

By moving (73) out, to the right, this action causes arm (145) to engage shifting bar (147) which shifts sliding gear (SG-2) **forward; forward** movement of lever (73) throws sliding gear (SG-2) in mesh with "**reverse**" speed gear on counter shaft, while a **backward** movement throws (SG-2) in mesh with "low" speed gear.



†**Fig. 2.—Gate type** of gear shift lever is now in "neutral" position (N). The hand or emergency brake lever to the right is "set" until ready to start car. (1) is "low speed" position; (2), "second or intermediate;" (3) is "high" speed; (R) reverse. Movements vary on different cars. (See index "gear shifts of leading cars.")

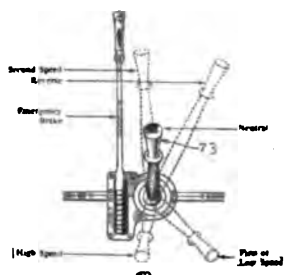
When lever (73) is erect and in between the two slots as shown in illustration fig. 4, the slots which (145) work in are in line and all gears are out of mesh, or in "**neutral**" as it is called. For instance, the gears in fig. 2, page 48 are out of mesh, and slots on shifting bars are in line, therefore gears are in neutral.

Gate type: by studying the illustration fig. 2 on page 48 and figs. 4 and 2 on this page, the reader will readily see how the gears are shifted.

The lever (73), the gate or selector (76), and the other parts are numbered and named.

Note this lever moves **sidewise** as well as forward and backward (see figs. 4 and 2).

The ball and socket type of gear shift lever is identically the same principle except the movement of lever (73), fig. 1, is in a ball and socket instead of a gate. Note arm (145) serves the same purpose as arm (145), fig. 4, above. This type is the type in general use.



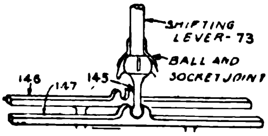


Fig. 1.—Ball and socket type of gear shift lever (73) is now standing upright in center of the socket and is in "neutral" position.

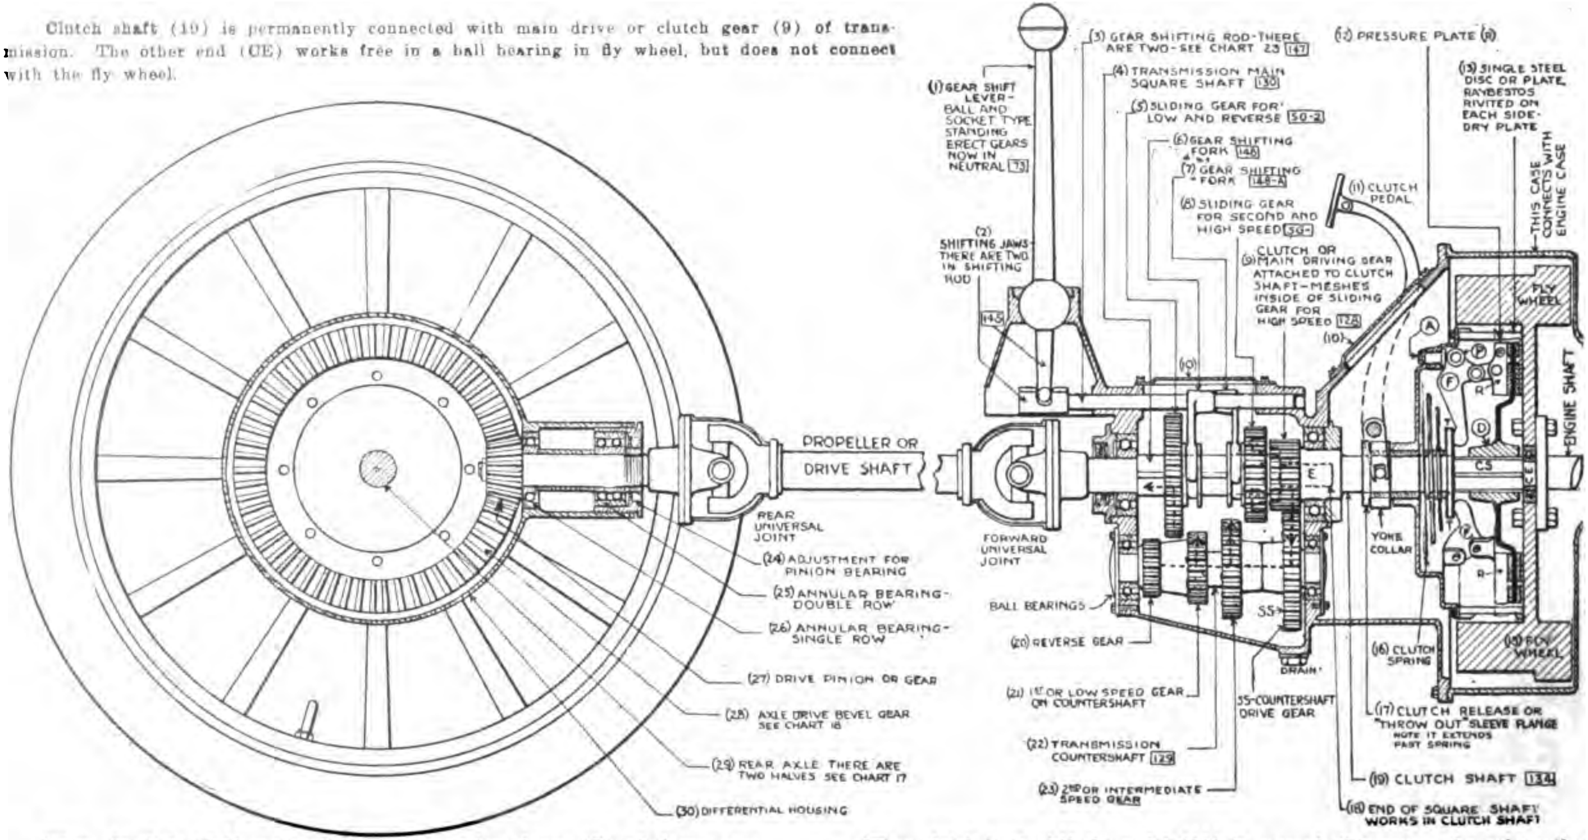
*Note the movement of gear shift lever in fig. 2. This is the type used on the Overland model 85.

The movement of lever (73) in fig. 4 varies slightly from movement of lever in fig. 2 this page. For instance, if lever (73) in fig. 4, is shifted in to the left and back, we would have 3rd or **high speed;** if to the left forward, **2nd speed;** if to the right side and backwards, 1st or low speed and if to **the right side, forward, reverse speed.** (See fig. 4 this page and fig. 2, page 48).

†This is the standard S. A. E. three speed gear shift. Illustration is that of the Overland, see pages 490, 497 and 358.

Clutch shaft (10) is permanently connected with main drive or clutch gear (9) of transmission. The other end (CE) works free in a ball bearing in fly wheel, but does not connect with the fly wheel.



When clutch is "in" spring (16) presses against flange (T) of sleeve, causing the three fingers working on pivots (F) to apply pressure through pressure plate (R) (which is a ring), this in turn applies pressure against the single plate. The single plate (13) is fitted with Raybestos riveted on each side. This friction material clutches the fly wheel. Drive is then through driven plate (13) to plate hub (D), then square section of clutch shaft (CS) to main drive gear (9). Note (CS) part of clutch shaft is squared and clutch plate hub (D) slides thereon.

When clutch is "out," the pedal (11) is pressed, this causes the yoke collar to press against flange (17) of the sleeve. This action causes flange (T) on other end of sleeve to relieve pressure against fingers (F). This releases pressure against the single plate (13).

The adjustment of fingers (F) or pressure against plate is at (A). This type clutch runs without oil.

Note.—Figures in the square at end of wording compare with reference figures on transmission in chart 28.

CHART NO. 22—Principle and Operation of a Single Plate Clutch (see page 42), Selective Type of Transmission and Method of Driving Rear Axle. A modern Unit Power Plant. The clutch may be of any one of three types; cone, disk or plate. The transmission is a three speed and reverse type.

Chart 28 is on page 48).

How the Various Speeds are Obtained By Shifting Gears.

NOTE—**The clutch is always engaged** or **in**—unless held out by clutch **pedal.** Therefore gears must be **out** of mesh or in **neutral** before **starting engine.**

When shifting gears, engine is supposed to be running, therefore always hold clutch **out** while moving the change or shift.

Never shift from high to low gear, unless car is slowed down to a **very** low speed.

Obtaining Various Speeds.

Before describing the operation of changing speeds, it is **most important to notice** in chart 22, that the main shaft of the transmission (4) is **not square continuously** right through the gear box. One end (E) works free into end of clutch shaft, so when gears are in "neutral" or not in mesh, there is no connection between clutch and transmission. A study of fig. 3, chart 23, will assist the reader in understanding this. Also note remarks under "clutch shaft" in chart 22.

"**Neutral**;" by observing the position of gears, it will be noticed that none of the gears are in mesh except the main clutch drive gear (9) (called clutch gear), connected with the clutch shaft and the gear (SS) on the countershaft. If we then follow the dotted lines and arrows it will be noticed that the countershaft (22) and gears (23, 21, 20) thereon are free to revolve.

Low or 1st speed: the gear shift lever (1) is brought to the center, and then drawn sidewise until the lower end of lever engages with shift bar which oprates (6). This gear (5) is then moved into mesh with gear (21). The power then is from gear (9) to (SS), thence (21) to gear (5), thence square shaft to propeller or drive shaft.

Intermediate or 2nd speed—is obtained by returning the gear shifting lever to "neutral" (straight up and down, position illustration shows lever now); then putting end of shift lever (1) in shift bar which connects with (7). Push lever forward, this will slide gear (8) into mesh with gear (23). Note dotted lines then for the transmission of power.

High or 3rd speed—also called "direct" drive: Pull lever (1) straight back. This will shift sliding gear (8) **over** gear (9).

The drive is then direct through gear (9) and gear (8), through square shaft to rear axle. The action causes gear (9) to partially mesh inside of gear (8), as gear (8) is fitted wiht internal teeth. The former method was by means of "dogs" (139), fig. 2, chart 23.

The engagement of these two gears cause the top transmission or square shaft to be engaged direct with the clutch shaft and continuous right through to rear axle.

During the time that the direct drive is on, it will be noticed that the countershaft or secondary shaft (22) although doing no work, is still running. In a few instances, makers have arranged that this should be thrown out of action as soon as direct drive is on, but owing to the difficulty in connecting it up again when the second speed is wanted, it is now generally allowed to remain in mesh.

***Reverse**: When the "reverse speed" is required the gear shift lever is brought to "neutral," then pushed forward to mesh gears (5 and 20). There are now five gears in operation instead of only four, as for first and second speeds, and the result is that the square shaft (4) turns backwards.

***The reverse pinion** is set lower down in the transmission case and slightly under the countershaft, hence it is not possible to see it. **Changing gears,** see pages 486, 488.

The Locomobile and Pierce Arrow use a four speed transmission. The direct or high gear drive **is on the *fourth* speed. On the model 22 and 22A** Winton the direct drive was on the third speed and **the *fourth* speed was geared slightly higher** than direct drive--see page 583

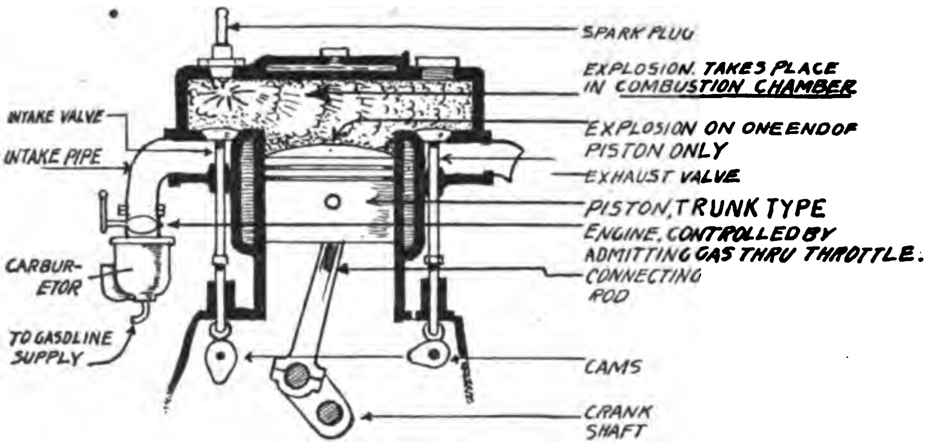


Fig. 1—The Gasoline Engine; an **internal** combustion type.

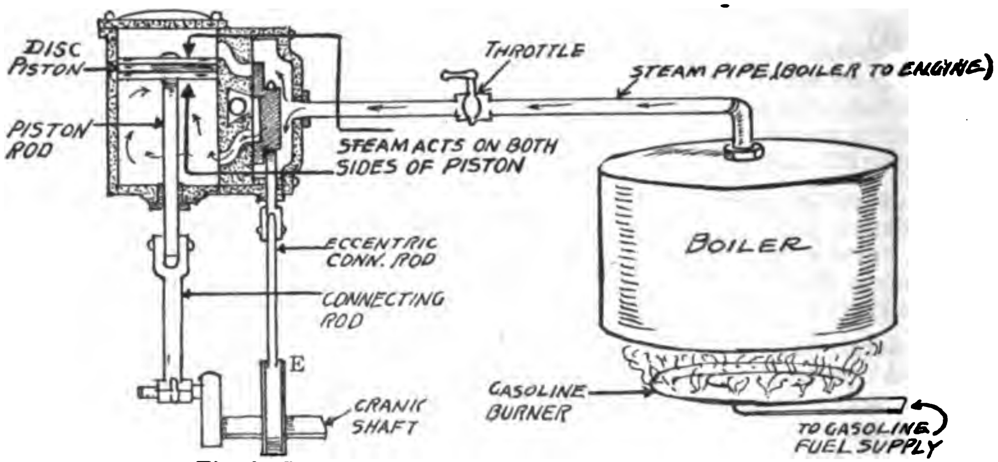

Fig. 2—Steam Engine; an **external** combustion type.

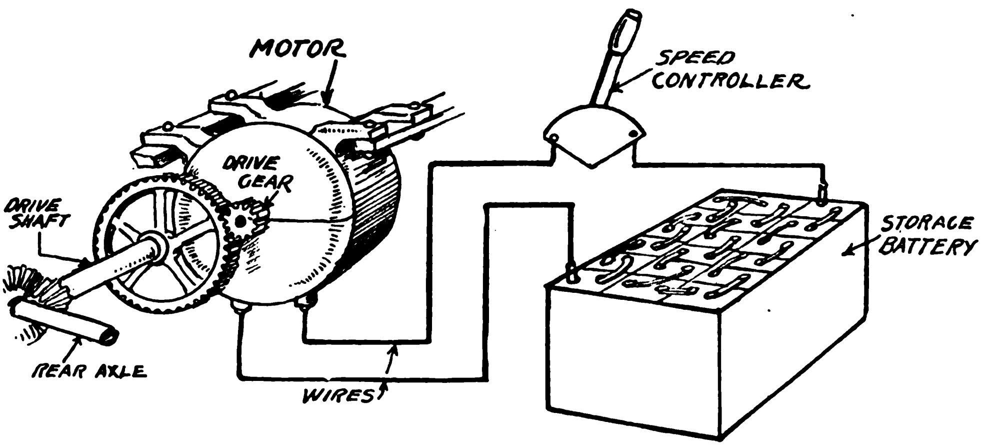

Fig. 3—The Electric Motor and its source of electric supply; the storage battery.

CHART NO. 25—The Three Motive Powers; Gasoline Engine, Steam Engine, Electric Motor.

Note—An eccentric (E) on a steam engine is for the same purpose as a cam on a gasoline engine: i. e. to open the valve. Although, the word "explosion" is used, under fig. 1, the correct term is "combustion"—see seventh paragraph, page 53.

INSTRUCTION No. 7.

*THE GASOLINE ENGINE: General Explanation. Cycle Principle Explained. Construction of the Gasoline Engine. Assembling a Four Cylinder Engine. Speed Control of Engine.

General Explanation.

There are three motive powers for automobiles. (1) the **gasoline engine, also** called **an **internal combustion type of engine** in which the fuel combusts **inside** of the engine, between cylinder head and piston or the combustion **chamber.** This type of engine could use either gasoline, kerosene or alcohol, but in this treatise we will deal with gasoline as a fuel. (2) **the steam engine is an** external combustion type. The combustion taking place under the boiler, separate from the engine. (3) **the electric motor** (shown in chart 25), derives its power from an electric storage battery.

Gasoline engines: We will deal with the gasoline engine type of automobile. The gasoline engine furnishes the motive power to drive the automobile.

Engines for small cars are sometimes made with but one, or perhaps two cylinders (now obsolete). A few motor cars formerly had engines of three cylinders. The majority have four, six and eight. Five-cylinder engines hardly exist. Seven-cylinder engines exist in a special form for flying machine, as the Gnome revolving cylinder type. The †twelve-cylinder engine is also coming into prominence; motor boats indulge in engines with as many as 12 to 24 cylinders. But whether the engine has 1 or 24 cylinders, the explanation of how it works or the principle, always remains the same.

All gasoline engines work on practically the same principle. It must be a four cycle or a two cycle type (four cycle is dealt with in this instruction). The valve arrangement may be different, but we describe the various types of valves further on in this instruction. The ignition may be different, but we cover all forms of ignition. We mention this so that when you see an engine with a different ignition or a different valve arrangement, remember the principle is just the same on all engines (except the two cycle type, which have no valves. The principle of combustion and ignition is similar, however).

Gasoline engines belong to the class known as **internal combustion** type of engine. This name is used to distinguish them from **steam engines,** which are of the **external combustion** class, for the heat that a steam engine turns into power is produced **outside** the engine, under a boiler.

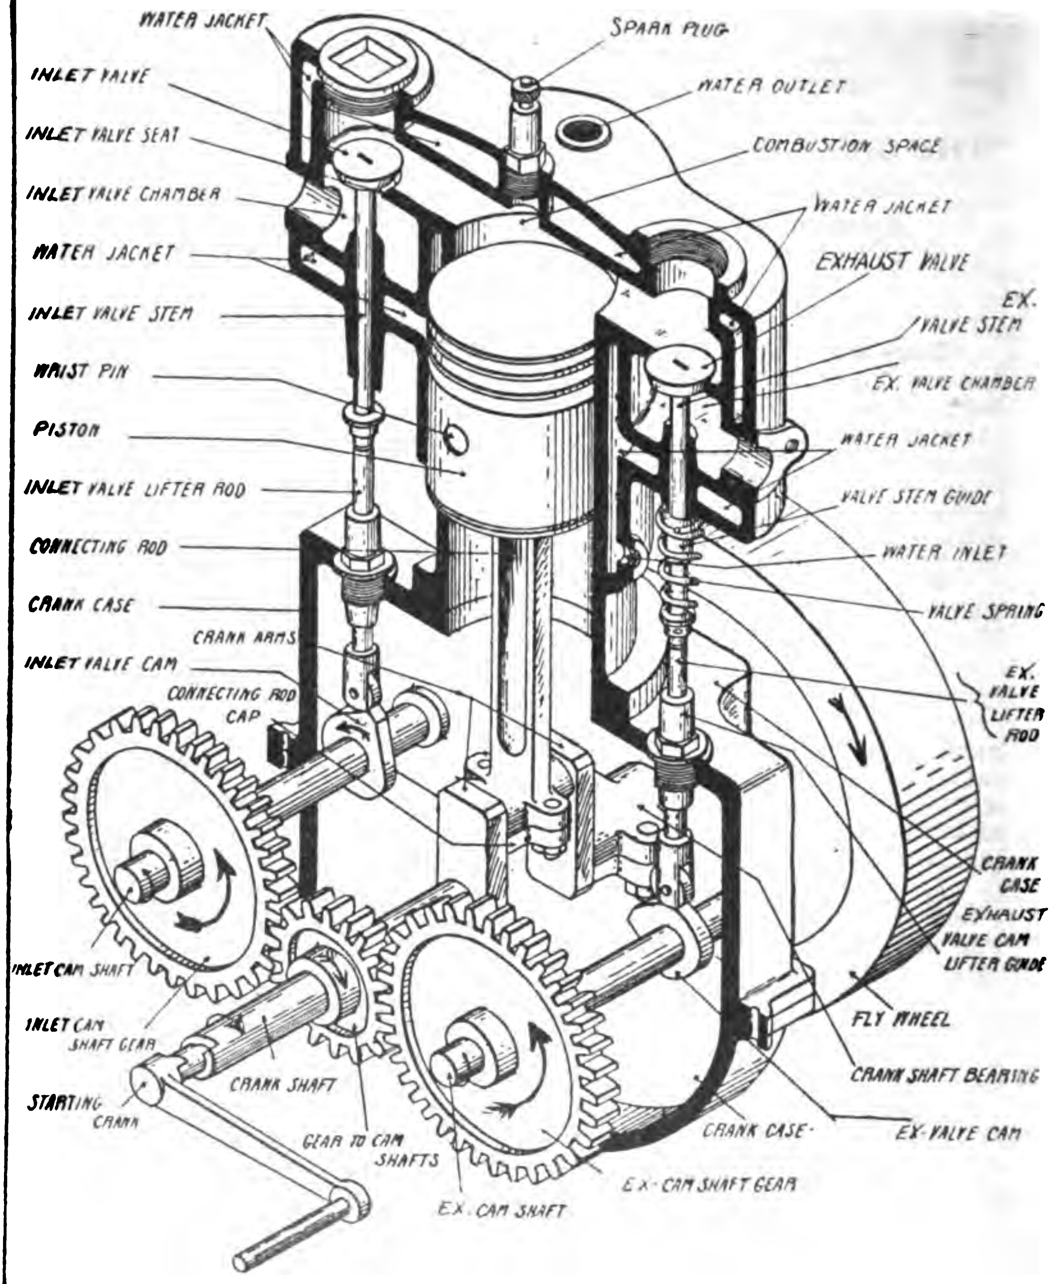
In a gasoline engine, the combustion, or in other words, the burning of the fuel, takes place **inside of the** cylinder of the engine, the fuel being gasoline.

When a mixture of gasoline vapor and air is set on fire, it burns with great rapidity and produces intense heat, which expands and develops the pressure against the head of the piston, which operates the crankshaft of the engine. This combustion is so rapid that it is usually spoken of as an **explosion**; and that word is often used, although the word **combustion** is more correct.

*For engine repairs and adjustments, see subject of repairing. **The gasoline engine is also called a "hydrocarbon" type of engine.

†The "twelve" cylinder engine was formerly referred to as the type used on motor boats, where the twelve cylinders were in line. The "twin six" is referred to as the type used on automobiles, with cylinders placed "V" type. However, both terms are used. "Twelve or eight cylinders 'V' type" would be the proper term.

*Note—**The word motor is often used to designate the engine,** but if one wishes to be technical and correct it should always be referred to as engine. The word "motor," however (owing to the popular practice), is used in many instances in the book.



The Four Cycle Gasoline Engine and Its Parts

When in doubt as to the names of any parts of the engine refer to this chart

The type of valves (both intake and exhaust) on this engine are called "mechanically operated valves."

The type of cylinder is the "T-Head type," with the exhaust valves on one side and the intake valves on the opposite.

CHART NO. 26—A Four Cycle Gasoline Engine Showing a Sectional View T-head type cylinder, valves are of the poppet type and are mechanically operated. With the T-head type of cylinder the intake valves are placed on one side and the exhaust valves on the other side—therefore two cam shafts and two cam gears are required.

*See index for Two Cycle Engines.

The difference is that an explosion is instantaneous, while the combustion of gasoline vapor and air, although very rapid, is not instantaneous. The combustion takes place within the cylinder of the engine.

One end of the cylinder is **closed**, and the other is **open**, the closed end being called the **cylinder head.** Within the cylinder is a **piston**, sliding back and forth.

The space between the piston and the cylinder head is called the **combustion chamber.**

The back-and-forth motion of the piston in the cylinder is called **reciprocating motion.** In order that it may turn the wheels, this reciprocating motion must be changed to the motion of a wheel revolving on its axle, which is called **rotary motion.** The reciprocating motion of the piston is changed to the rotary motion of the wheels by means of a **crank shaft.**

The piston is connected to the crank shaft by a **connecting rod**, so that it moves in and out as the crank shaft revolves. One complete turn of the crank shaft, by which the piston is moved from one end of the cylinder to the other, and back again, is called a **revolution.** One-half of a revolution of the crank shaft moves the piston from one end of the cylinder to the other, and this is called a **stroke.**

It must be remembered that **there are two strokes of the piston to every revolution of the crank shaft**; one **down**-stroke and one **up**-stroke.

A steam engine is called double-acting, because the pressure of the steam acts on both sides of the piston.

A gasoline engine is called single acting, because the pressure acts on only one side of the piston; on the top or side nearest to the cylinder head.

The combustion that causes the pressure that operates the engine, takes place between the cylinder head and the piston, in the combustion chamber. The combustion should be timed to occur so that the greatest pressure is exerted when the piston is nearest the cylinder head. The pressure causes the piston to slide the length of the cylinder, from the head toward the open end.

In a steam engine, the pressure of the steam forces the piston to slide first one way and then the other.

In a gasoline automobile engine the pressure from the combustion acts on only one side of the piston, forcing it to slide only one way. After being forced downward, the piston must be brought upward again, and this is done by a heavy ***fly wheel** attached to the crank shaft. With the downward motion of the piston, the fly wheel starts revolving. When once started, the fly wheel continues to revolve until friction or some other resistance stops it, but before this can happen the pressure is again exerted, keeping it going.

†The fly wheel being attached to the crank shaft, they revolve together, and because the piston is connected to the crank shaft by the connecting rod it moves with them. The piston moved downward by the pressure, starts the crank shaft and fly wheel, and then the fly wheel in continuing to revolve moves the crank shaft and piston.

Because a gasoline engine does not operate with continuous pressure, during its action the piston first moves the crank shaft and fly wheel, and then the fly wheel and crank shaft move the piston.

Before there can be a combustion of mixture in the cylinder, the mixture must be drawn into the cylinder, through the **inlet** valve.

When in the cylinder, the mixture must be prepared, so that it **ignites,** burns and expands with the greatest possible rapidity and heat.

*Larger fly wheels are used on single cylinder engines than on multiple cylinder engines, because there are not as many firing impulses to two revolutions of crankshaft on a single cylinder engine.

†The fly wheel is usually fitted securely to tapered end of crankshaft and flange, per (92) page 62. It must be secure, else a knock would occur, per page 638.

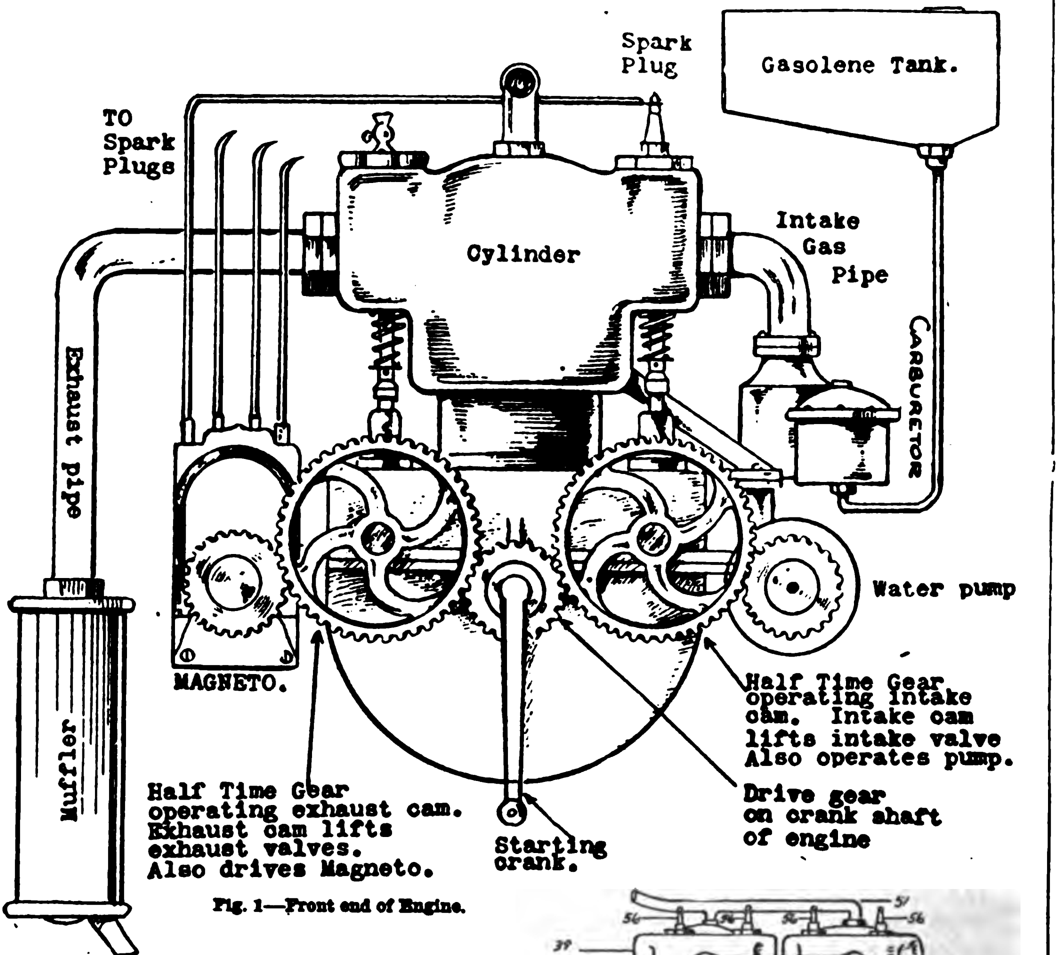


Fig. 1—Front end of Engine.

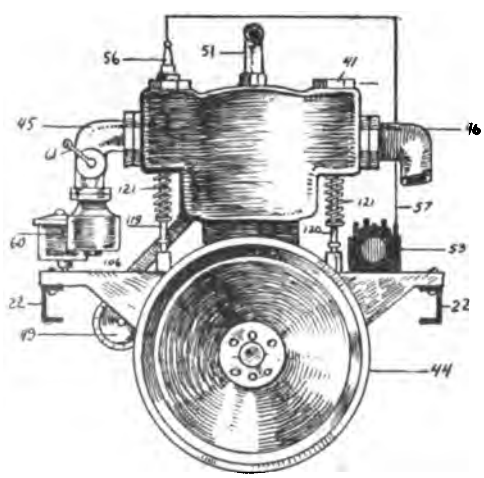

FIG. 2 FLY WHEEL END OF ENGINE

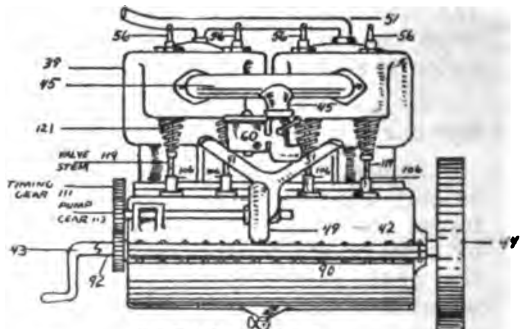

FIG 3 INTAKE SIDE

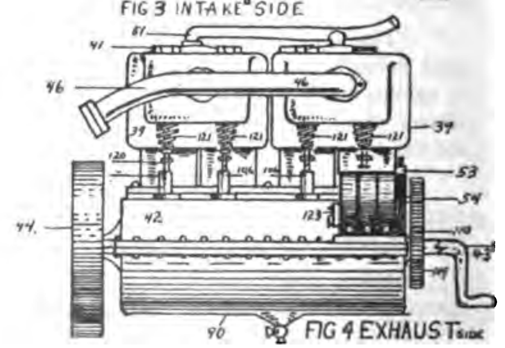

FIG 4 EXHAUST SIDE

HART NO. 27—Different Views of the Outside of a Four Cylinder Gasoline Engine with cylinders cast in pairs. Valves are mechanically operated. Exhaust valves on one side and the intake valves on the other side. Ignition by magneto. Water circulation by pump.

)TE—This "T" head type of engine could be constructed with the inlet and exhaust reversed if necessary. For instance, inlet could be on the right side of engine and exhaust on the left side, as shown in chart 26. Chart No. 28 on page 60).

After the mixture has been burned, the useless gases must be removed, **or exhausted** from the cylinder, to make room for a fresh charge of the mixture.

These successive events must occur in their proper order, for if any one **of them** fails, or it is not performed properly, the following event cannot **occur,** and the engine will stop running. ***These events are called a cycle.**

The Four Cycle Principle.

There are two distinct cycle principles; generally spoken of as "four stroke cycle" and "two stroke cycle" principles. The two cycle engine is generally a small marine type of engine and will be dealt with under marine engine instruction.

The four cycle engine is the type used for automobile work, therefore we will deal with this type throughout the automobile instruction.

The cycle is thus composed of: **1st,** the drawing into the cylinder of the mixture; **2d,** the compression of the mixture; **3d,** the burning or ignition of the mixture and the forcing downward of the piston by the pressure produced by the burning of the mixture; **4th,** the removal of the burned and useless gases left after the combustion.

The cycle is performed during two revolutions of the crank shaft, or, what is the same thing, **four strokes of the piston.**

The first event occurs while the piston makes a **downward stroke,** during which the cylinder is sucked full of the mixture, just as a similar stroke of a pump or syringe sucks in a liquid: this is called the **inlet stroke** or **suction stroke.**

The next stroke of the piston is an upward stroke, during which the mixture sucked into the cylinder is prepared by being compressed, and at the end or top of this stroke it is set on fire, or ignited: this is called the **compression stroke.**

When the compressed gas is ignited the pressure from the combustion forces the piston to make a **downward stroke;** this is called the **power stroke.**

The next upward movement of the piston pushes the burned and useless gases out of the cylinder: this is called the **exhaust stroke.**

In principle the gasoline engine is like a gun. In a gun the shot is fired by exploding powder behind it—in a gasoline engine we explode gasoline behind the piston in exactly the same way.

There are some differences, of course When the charge goes out of the gun, that is the end of it. But in a gasoline engine, after the explosion drives the piston before it, in order to get any work out of the machine, this piston must come back and a new charge must be exploded behind it. The burnt gases and heat must be disposed of and all of these things must be done over and over again very quickly at exactly the right time.

Valves are arranged to open and close at the proper time **to admit fresh gas and to let out the burned gas,** and the positions of the piston, valves and **cams** for each function are shown on chart 29. Note the direction in which **the cams** are turned by the cam gears.

Explanation of The Four Strokes.

Fig. 1: In the first diagram, chart 29, the piston is at the beginning of **the down stroke** on **suction,** and the arrows show the direction in which it is moving.

Fig. 2: In the second diagram, the piston has completed its **suction stroke** and is now starting **up** on its **compression stroke.**

*The word Cycle really refers to the complete operation of the four strokes of piston to complete the cycle evolution. Therefore to distinguish the engine with four movements of piston, from the engine with two movements of pistons to complete the cycle evolution, we will call them: "four cycle" and "two cycle" types of engines.

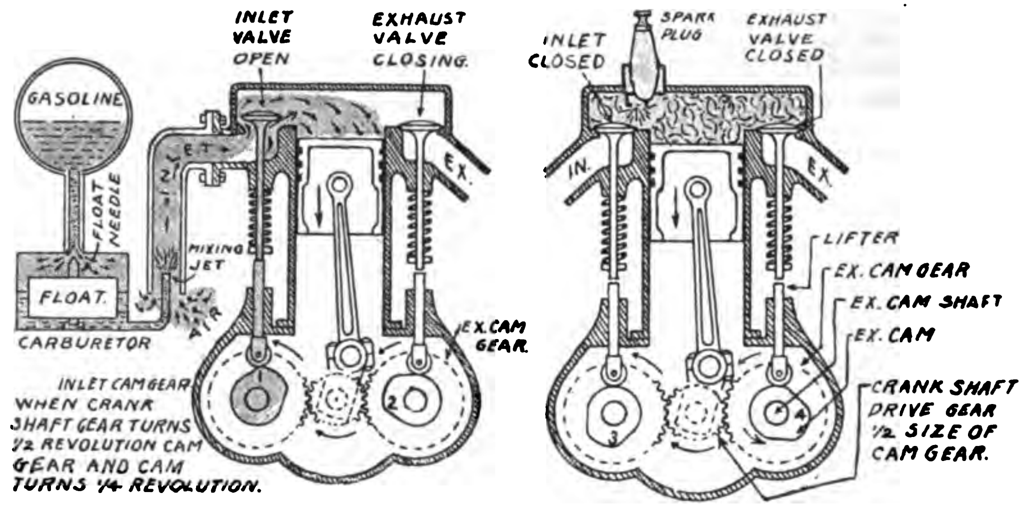

FIG 1. SUCTION STROKE DOWN **FIG 3. POWER STROKE DOWN.**

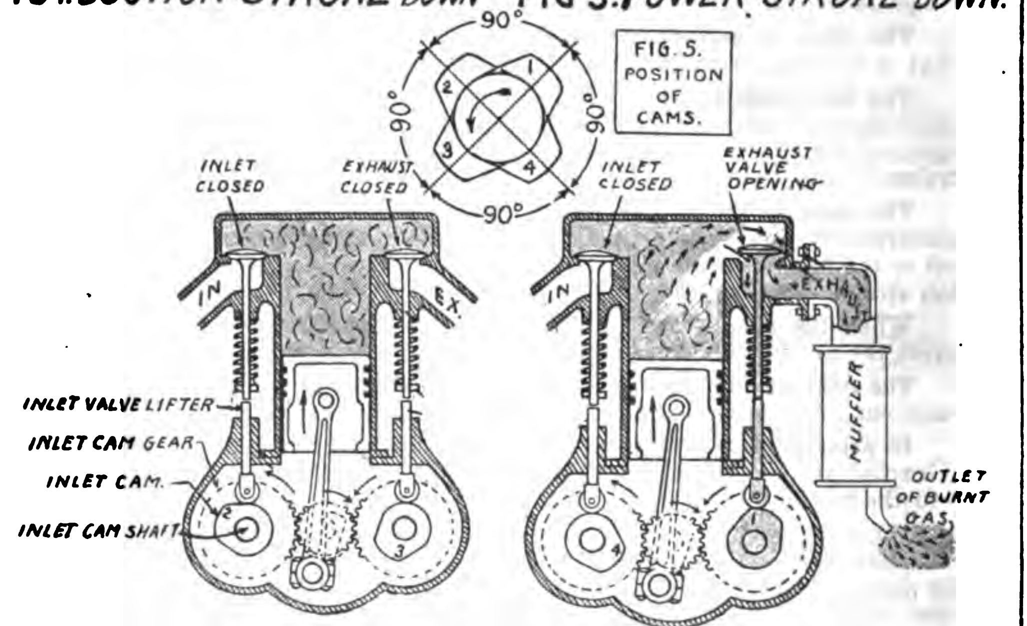

FIG.2 COMPRESSION STROKE UP **FIG 4. EXHAUST STROKE UP.**

Fig. 1. Suction stroke; note charge of gas being taken into cylinder from carburetor by the suction of piston through the open inlet valve.

Note inlet valve opened by inlet cam. Note direction of travel of cam, also note this stroke is also called "admission" or "inlet" stroke.

Fig. 2. Compression stroke; note both valves are closed because nose of cam is not raising either of the valves. Note travel of cam.

Fig. 3. Power stroke; note the spark is now occurring, therefore the compressed gas is combusting. (See page 61, note in actual practice, spark occurs before combustion takes place.) Both valves are closed. This stroke is also called "explosion" or "working" stroke.

Fig. 4. Exhaust stroke; note the exhaust valve cam is now raising the exhaust valve. The burnt gas is being forced out the exhaust pipe through muffler. This stroke is also called "scavening" stroke.

When piston reaches top of exhaust stroke the piston will have completed the four strokes, or two crank revolutions, and cam shaft one revolution.

The next stroke is the suction stroke again. These four strokes are repeated over and over again as long as engine runs.

The above explanation of the four strokes is explained with a "T" head type of engine, supposed to be cut in half and standing in front of engine.

The "L" head uses but one cam shaft, there is but one inlet and one exhaust cam for each cylinder. Just the same as a "T" or "round" head cylinder or any type of four cycle engine. The principle is identically the same.

Fig. 5, illustrates the movement of the cam; note the cam moves 90 degrees or one-fourth revolution, each time the crank moves 180 degrees or one-half revolution.

CHART NO. 29—The Four Cycle or Four Stroke Principle Explained. See index for "two cycle" engines.

(Chart No. 28 on page 60. Chart 30 on page 70).

Fig. 3: The piston has now completed its compression stroke and the compressed gas is being **ignited** by the spark at spark plug gap. This **ignition** of the gas causes the **combustion** to take place and piston travels down with **force,** the amount of force being governed by the amount of compressed gas which was admitted to cylinder by throttle of carburetor. This **down** stroke is called the **power stroke.**

Fig. 4: The piston has now completed it's power stroke and is coming up on **exhaust stroke,** pushing burned and useless gas out exhaust valve.

Note the inlet valve is raised to admit the **suction of gas** (fig. 1) and **exhaust valve** is raised to permit the burned **gas to be discharged.** During the other two strokes (compression and power strokes), the valves are closed.

†**The reason for first cranking an engine to start it** is due to the fact that a charge of gas must first be drawn into cylinder by the suction stroke, then compressed. After the gas is ignited, then the force of the power stroke, **will give** more turn **to the fly wheel which carries** the piston **through the other three strokes** until power stroke is reached again. (See page 116.)

Therefore, during three strokes (suction, compression and exhaust), the **engine is not developing power.** There being only one power stroke out of the four.

In starting the engine with the starting crank, the spark lever (chart 33) must be **retarded** so that combustion occurs when the piston has begun to move downward on the power stroke, otherwise it will fire before piston reaches the top and run backwards for half a revolution termed "kicking or back firing."

Additional Explanations of the Four Strokes.

As explained four events, called the cycle, occur in the cylinder of a gasoline engine during every two revolutions of the crank, or, what is the same thing, during every four strokes.

The strokes of the piston during the events of the cycle (as stated previously), are called the:

1st—"Inlet" or suction" or "admission" or "inspiration" stroke, fig. 1, chart 29. **2d**—"Compression" stroke, fig. 2. **3d**—"Power" or "firing" or "working" or "explosion" stroke, fig. 3. **4th**—"Exhaust" or "scavenge" stroke, fig. 4. These will be described in their proper order.

***Suction stroke**; the inlet stroke is a **downward** stroke of the piston, sucks in the explosive mixture. Note fig. 1, chart 29.

The speed of the engine is governed by the amount of gas drawn into cylinder through the throttle valve of carburetor (page 66). If high speed is desired, it is necessary that all of the mixture possible may be sucked in, for it is clear that if the cylinder is only partly filled not as much power will be developed as would result from a full charge. There must be no obstruction in the inlet pipe to prevent the mixture from entering the cylinder easily, and the inlet valve must open wide enough to admit the full charge. (See chart 28, 33 and 106.)

As the inlet valve is mechanically operated, the cam must be adjusted (by having the inlet cam gear properly meshed with the crank shaft gear) so that it will open the valve promptly as soon as the sucking action of the piston commences, which it is just beginning to do in fig. 1, chart 29. Note the cam is just starting to raise the inlet valve.

If all the openings into the cylinder, as the exhaust valve, the spark plug, piston rings, relief cock, etc.—are not tight, air or gas will be sucked into the cylinder through them at the same time that the charge enters through the inlet valve, and this would destroy the proportions of the mixture.

If the inlet valve does not open **soon enough,** the piston will have made part of its stroke before the charge begins to enter; if it opens too soon, part of the burned gases from the previous power stroke will be pushed into the carburetor.

*See Dyke's working model No. 1, of the "T" head type of gasoline engine, and the four cylinder engine model for the "L" head type of engine.

†The piston of a steam engine moves as soon as steam is admitted to the cylinder—because pressure exists in boiler—therefore it is self-starting. There is no pressure in a gasoline engine until it is running—therefore it is not self-starting. The crank shaft must be turned by hand or an electrical or mechanical device.

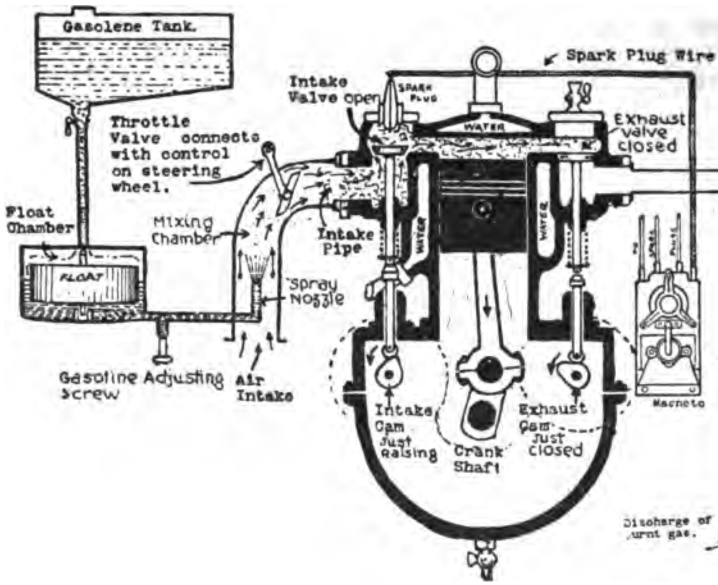

Fig. 1. In this view we are looking at the end of the engine. Imagine end cylinder cut **in half.**

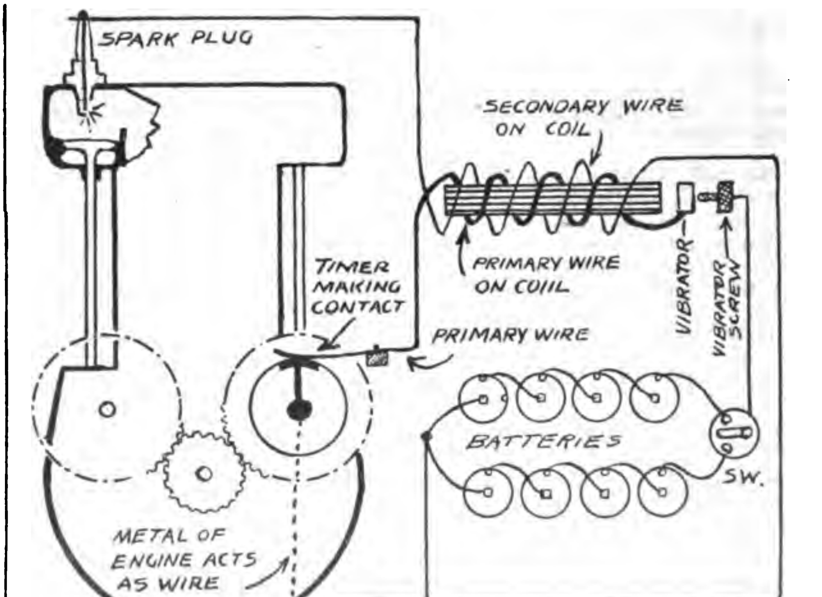
The object is to illustrate how the gasoline from the tank flows to the carburetor and fills the float chamber until the float needle cuts off the flow. The gas, mixed with air, is then drawn **into** the cylinder by the suction of the piston on the **suction stroke.** During this suction stroke the **intake** valve must be opened by cam (nose shaped **affair** at bottom of valve lifter) to permit gas to enter **cylinder.**

After the cylinder is filled with gas, which is the purpose of the **suction stroke,** the intake **and exhaust** valves are closed and the piston on its up stroke (**compression stroke**) compresses the **gas. At** the highest point of compression the gas is **ignited** by the spark at the point of the spark **plug and** the piston is forced down with considerable force; this is called the **explosion stroke.** As the **piston** travels up again the **burnt gas** is expelled through the exhaust valve which should open at **this time,** and permit the burnt **gas** to pass out through the exhaust pipe and muffler, this fourth and **last stroke to** complete the operation, is called the **exhaust stroke.**



The spark occurs at spark plug when piston is almost at the top of compression stroke. (See Fig. 3, Chart 29).

This spark is caused to occur by a coil and battery being connected together at the **right** time by a "timer or commutator" contact.

The timer arm is revolved by the cam shaft to which it is attached. Therefore it revolves once and makes one contact during two revolutions of crank shaft, if a single cylinder engine. If a four cylinder, there would be four contact segments for arm to touch during one revolution.

If a magneto is used for igniton, as in Fig. 1, then the magneto is run from cam shaft and contact is made by an "interrupter" arm at the right time. See Chart 33.

CHART NO. 28—Elementary Principle of Carburetion and Ignition; explaining how the gas is sucked into Cylinder by down motion of Piston and how the Spark is made to occur at the correct time.

(Chart 29 on page 58)

If it closes too soon, the cylinder will not get a full charge; if it closes too late, part of the mixture will be pushed out of the cylinder on the compression stroke.

†**Compression stroke.** The next stroke up of the piston is the compression stroke. As the piston travels up, the mixture cannot escape, therefore it is compressed until it occupies only the space between the inside head of cylinder and head of piston.

Power or explosion stroke; at this instant the spark should occur, which ignites the compressed gas causing the piston to be forced down with considerable force. This force or pressure is governed by the amount of gas and compression space in top of cylinder when piston is at its extreme up position.

Too poor or too rich mixture will not burn as rapidly as a proper mixture, and must therefore be ignited sooner.

In getting the proper time for the **ignition of the mixture**, it must be remembered that it is necessary for the spark to occur at such a time that all of the mixture is to be burned just as the piston is at the top of its stroke—when the gas is compressed to the highest point.

The contact on timer or commutator, or the magneto contract breaker in the ignition circuit, is so arranged (see chart 33), that it may be moved, in order that the spark may occur in the cylinder at the instant desired by the driver; that is, the spark can be made to occur **early** or **late** by movement of the hand spark lever. **Advancing** the spark is to move the timer or contact breaker, so that the spark will ignite the mixture (early) before the piston reaches its upmost point in the cylinder. **Retarding the spark** is to move the timer so that the spark occurs later in the stroke, in some cases as the piston reaches its upmost position, or even a trifle after.

If the spark is advanced too much, all of the mixture will have been burned before the piston reaches its upmost point, so that it will be necessary for the fly wheel to force the piston upward against the pressure until it gets to its upmost point. This strains the engine, and causes a sound that is called an ignition knock; a hard, metallic sound that may be prevented by retarding the spark.

It is seen from the foregoing that the **speed of the engine may be also controlled** (in addition to the gas throttle lever; see chart 33) by **advancing or retarding the spark**, the speed of the car changing accordingly.

Exhaust stroke: during the exhaust stroke, the cylinder is cleared of the burned and useless gases that are left from the power stroke.

Toward the end of the power stroke, there is still pressure in the cylinder, and when the exhaust valve is opened this pressure will cause the gases to begin to escape.

As the exhaust stroke is an **upward stroke** of the piston, the piston will push out through the exhaust valve all of the burned gases that do not escape by their own pressure.

Back pressure, caused by the muffler or obstructions in the exhaust pipe, will prevent the burned gases from escaping as freely as they otherwise would, and all may not be pushed out by the time that the exhaust valve closes.

If all the burned gases are not pushed out of the cylinder, it will prevent a full charge of fresh gas from being drawn in, which will cause a weak mixture and a weak explosion.

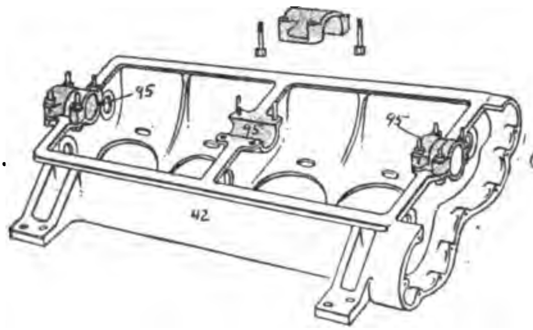
The exhaust valve closes as the piston reaches its upmost point, or a little after it, the inlet valve opening as it closes.

The exhaust valve and its seat are exposed to the full heat and flame of the burning mixture, and are more liable to warp or pit than the inlet valve.

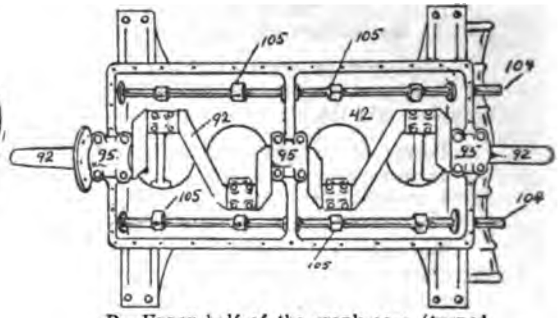
It must be watched, and if there does not seem to be perfect compression when the engine is cranked the probability is that it needs grinding to seat it properly.

A proper mixture will be entirely burned before the exhaust valve opens. An **improper mixture** that burns slowly, may still be burning when the exhaust valve opens, and will heat the exhaust pipe and muffler so that the pipe may become red hot. Such a mixture wastes fuel, and may result in a fire. It may be corrected by **making a correct adjustment of the carburetor and spark**, which will be explained later on.

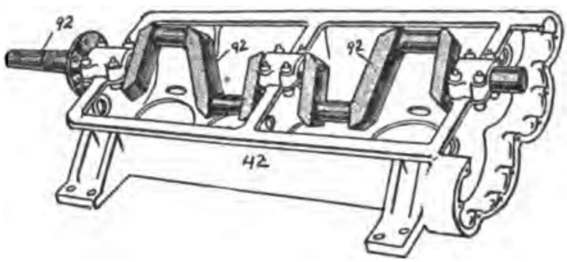
†**Note on word "compression"**—the word "compression" as used by motorists in such terms as "good compression" or "weak compression" refers rather to the compressibility of the engine than to the amount of pressure actually obtained in the cylinder, which, of course, varies very much with the amount of gas admitted to the cylinder during the suction stroke and also to condition of the piston rings and other parts which might leak and cause the pressure to decrease.



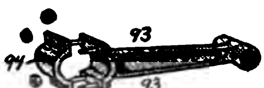
A—Upper half of crank case (42), (turned upside down) showing the main bearings (95). Note lower half of one of the main bearings at top of illustration.



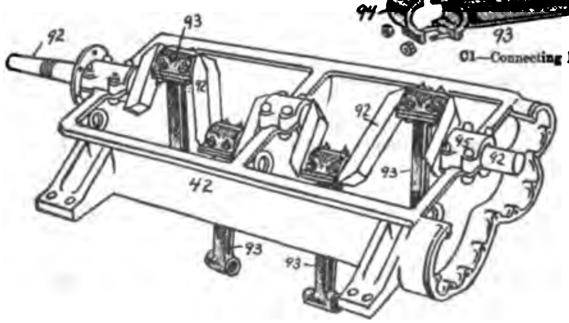
D—Upper half of the crank case (turned upside down) showing cam shafts (104) and cams (105). Continued on page 64.



B—Upper half of the crank case (turned upside down) showing the crank shaft (92) in place in the main bearings.



C1—Connecting Rod.



C—Upper half of the crank case (turned upside down) showing the connecting rods (93) fitted to the crank shaft (92).

Key to Engine Parts.

Crank Case—
- Upper half (upside down) 42
- Crank case—lower half 90
- Crank shaft (4 cylinder) 92
- Fly wheel 44
- Starting crank 43

Pump—(Water circulating) 49
- Intake water connection 118

Valves—(Mechanically operated)—
- Intake gas valves 119
- Exhaust valves 120
- Valve springs 121

Manifold—
- Inlet gas pipe (supports carburetor and passage of gas to cylinders)... 45
- Exhaust pipe (passes to muffler and through muffler the burnt gas is discharged) 47

Ignition—
- Magneto, supplies electric current for igniting the gas—run by gear..... 53
- Magneto distributor 122
- Contact breaker on magneto 223
- Spark plugs 56

CHART NO. 31—Explaining how a Four Cycle, Four Cylinder Gasoline Engine is Constructed. If the reader will start with illustration (A) and study each carefully he will note different parts are added until the engine is completed.

NOTE:—The S. A. E. now designate the lower part of crank case as the "oil pan" when containing no bearings. If it contains bearings, it is termed lower crank case. S. A. E. further designate crank cases of the "split type" and the "barrel type."—In the barrel type the crank shaft is removed from one end of crank case. The bearing caps being removed through hand hole plates. Type shown here and most used, is the "split type" with the bearings completely in the upper half as at (A).

(Chart 30, see page 70.)

Types of Engines.

As previously mentioned there are several types of engines, all of which work on the four cycle principle. In order that the reader may more clearly understand we will give an outline illustration of some of the different types of engines in general use, see pages 70 and 71.

The type of engine used more than any other type for automobile work, is the four and six, the eight and twelve V cylinder type of engines are also popular. We will confine our attention, however, principally to the four.

Building a Four Cylinder Engine—showing the construction, step by step.

Before the reader can thoroughly grasp the meaning and purpose of the parts, we will build up a four cylinder T-head type of engine as shown in charts 31 and 32. We shall then describe what each part is for, and the various constructions of the different parts by different manufacturers.

***Crank case**: by referring to fig. A, we have an aluminum crank case, upper half part, which we lay on the floor, upside down, so that we can see the bearings (95).

The bearings are made in two halves. The bearings are usually made of bronze or white metal and are termed "bushings" instead of bearings when removable or renewable. The bushings are fitted into bearing caps.

Shims (thin paper or metal strips) are placed between the two halves of the bearing so that when wear occurs a "shim" can be taken out and the lost motion taken up. See index.

The crank shaft (92, fig. B), will now be fitted in the bearings. The bolts are tightened so that there is no lost motion.

The connecting rods (93, fig. C), will now be fitted to the crank shaft. The lower half of the large end of the connecting rod, called the connecting rod cap, is removed, so that it can be fitted to the crank shaft. It is then tightened carefully, and shims inserted so that it works free on the crank shaft, but good and tight, so that there will be no lost motion. If there was lost motion a knock or pound, which would cause wear, would be the result.

The cam shaft (104, fig. D), with the four cams (105, nose shaped) are now fitted to its bearings. In this engine there are two cam shafts; one with four cams for raising the four inlet valves, and the other one, with its four cams (105) to raise the four exhaust valves.

The nose of the cams are so placed that they are divided equi-distance apart so that when they revolve they will raise the valves, by pushing them up with their nose, at a certain given time. The timing gears which operate the cam shafts, will be explained further on.

The crank case, is now turned right side up, after having fitted the lower half of the crank case (90) (oil pan). This lower half holds the oil, which the crank shaft splashes in (lubrication systems explained farther on).

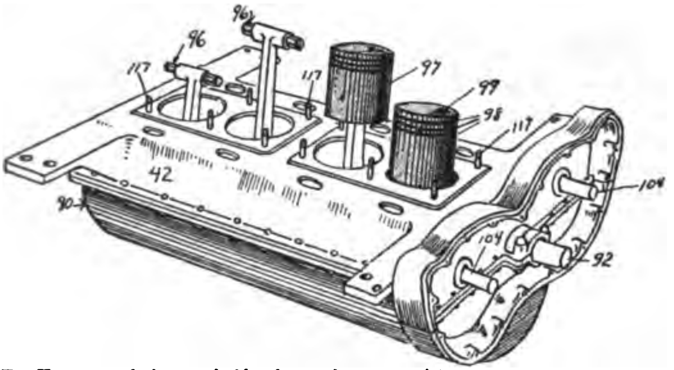
The piston or wrist pin (96, fig. E), in small end of connecting rod, is shown in the next illustration. This holds the piston to the end of the connecting rod (details of each part will be explained further on).

After the four pistons are fitted to the connecting rods, the cylinders (39, fig. F), are fitted down over the pistons, being careful not to break the piston rings (98, fig. E). (Treated under repair section.)

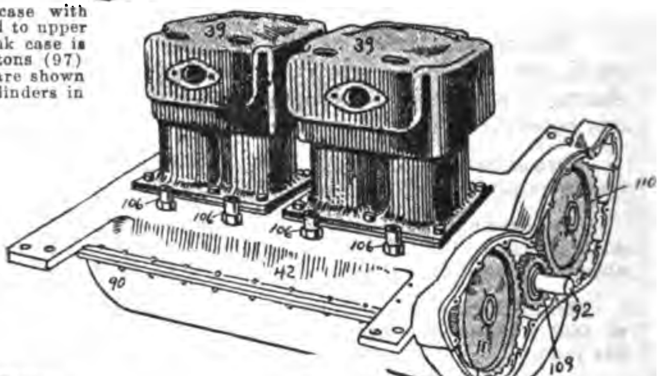
The cylinders (39, fig. F) are bolted to the crank case by nuts fastening to studs (117, fig. E).

The valve lifter guides (106, fig. F) are fitted in holes in each side of the crank case that they will come in line with the exhaust valves on one side of the cylinders, and the inlet valves on the other side.

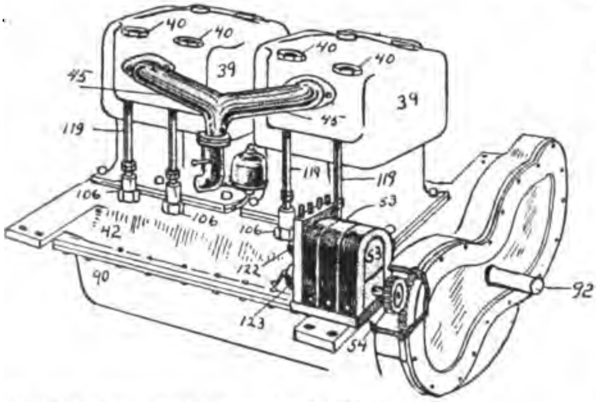
*Technically the term "crank case lower half" should be "oil pan" and as the term "crank case lower half" is used only when it contains the bearings, whereas in this and most engines the lower half is merely an oil pan.



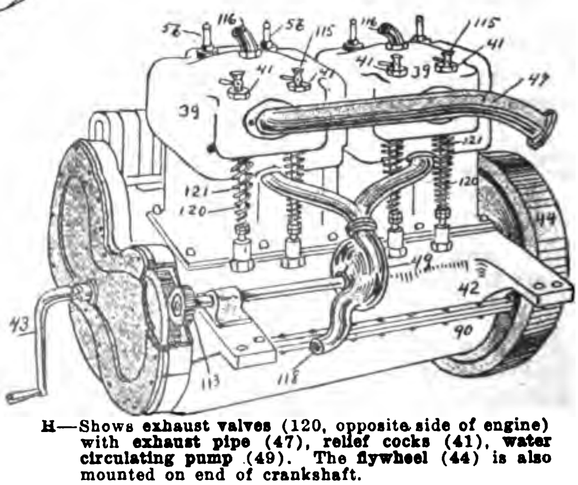
E—Upper and lower **half of** crank case with **lower half of crank case** (90) bolted to upper half (42). The upper half of crank case is now turned right side up. The **pistons** (97) and **piston pin** or **wrist pins** (96) are shown —also the **studs** (117), to hold cylinders in place.



F—The cylinders (39, cast in pairs—"T" head type) are now bolted to crank case. The **valve plunger guides** (106) are also fitted. The **crankshaft drive gear** (109) is fitted to crankshaft (92). The **two camshaft gears** (110) are next applied to the camshaft (104).



G—This view shows the intake valves (119) in cylinders, **intake pipe** (45) with **carburetor**, fitted to cylinders, also **magneto** (53), mounted and geared to one of the cam gears.



H—Shows **exhaust valves** (120, opposite side of engine) with **exhaust pipe** (47), **relief cocks** (41), **water circulating pump** (49). The **flywheel** (44) is also mounted on end of crankshaft.

CHART NO. 32—Construction of a Four Cycle, Four Cylinder Gasoline Engine, Continued. Carburetor, ignition and water circulating system added.

Valve lifters are now fitted through these valve lifter guides (see chart 26), which raise the valves through the action of the cams.

The gear for driving the timing gears, called the crank shaft timing gear (109), is keyed or threaded to end of the crank shaft (92); this gear drives the two timing gears (110 and 111).

***The cam shaft timing gears** are keyed to the cam shaft (104), one gear and shaft to operate the inlet valves (119), fig. G, and the other gear and shaft to operate the exhaust valves (120), fig. H. The gear case is filled with grease and a cover is placed over the gears. (On modern engines the gears run in oil.)

The inlet valves are placed in their seat by passing them through the inlet valve cap holes (40).

The exhaust valves are placed in position, on the opposite side of the cylinders, in the same manner.

The inlet manifold (45) fig. G, is now bolted to the inlet valve side of the cylinders, and the carburetor is connected to it.

The exhaust manifold (47) fig. H, is bolted to the exhaust side of the cylinders, and is connected with muffler (48) at rear of car, by the exhaust pipe (47); see chart 5.

The exhaust valve caps (41) and the inlet valve caps on the opposite side are now screwed in place—tightly.

The priming cups also known as compression or relief cocks (115) fig. H, are screwed into the exhaust valve caps.

The spark plugs (56) are screwed into inlet valve caps or in center of each cylinder as per page 54, but usually over inlet valves.

The fly wheel and starting crank (44-43) are fitted to each end of the crank shaft. By referring to fig C-92, the reader will note the end of crank shaft tapers, and a flange is also turned on this crank shaft. The fly wheel fits to this taper and bolts to the flange, as there positively must not be any lost motion.

The magneto (53) fig. G, is bolted in place on a brass base provided for it, on the side of the engine. An extra gear (which will be explained further on) is operated by the cam shaft and drives the magneto, which generates electricity. The electricity is distributed to the four spark plugs (56) at certain periodical times by the distributor on magneto (122) fig. G.

We now connect our wires through switch (55, see chart 1) to magneto. This switch is to cut off or turn on the electric ignition.

The circulating pump (49) is connected to the water jacket of cylinders. The gear (113) driven by the cam gear, drives the pump, and keeps the water in constant circulation, which keeps the cylinders from getting too hot, not over 170 to 180 degrees Fahr. We now connect rubber hose (51) to metal pipes on radiator (50), see chart 1, and also to our pump (49) and belt up our fan (52), which is run from the same shaft. **The radiator** is filled with water by unscrewing cap (50, chart 1).

We now connect the gasoline fuel pipe (62) from gasoline or fuel tank (58, see chart 1) with carburetor.

†Starting the Engine.

We now have our engine ready to run (we will presume it has been fitted to car as shown in chart 1).

We now put the gear shift lever in "neutral" position, so the car will not move when the engine begins to run.

The starting crank is revolved, which turns the crank shaft, timing gear and moves the pistons, (see chart 26). The crank shaft timing gear revolves the cam gears which in turn revolve the cam shaft, and which in turn revolves the cams.

When the cams turn, one of them with its nose pushes up one of the eight valves in one of the four cylinders. (There is one intake and one exhaust valve for each cylinder.) **We will suppose that this valve being raised is the inlet valve of No. 1 cylinder.** As this valve is raised the piston will be going down on the suction or intake stroke, as explained in fig. 1, chart 29, **and draws in a charge of gas.**

*The gears are timed as shown under valve timing.

†See page 59 why it is necessary to start a gasoline engine.

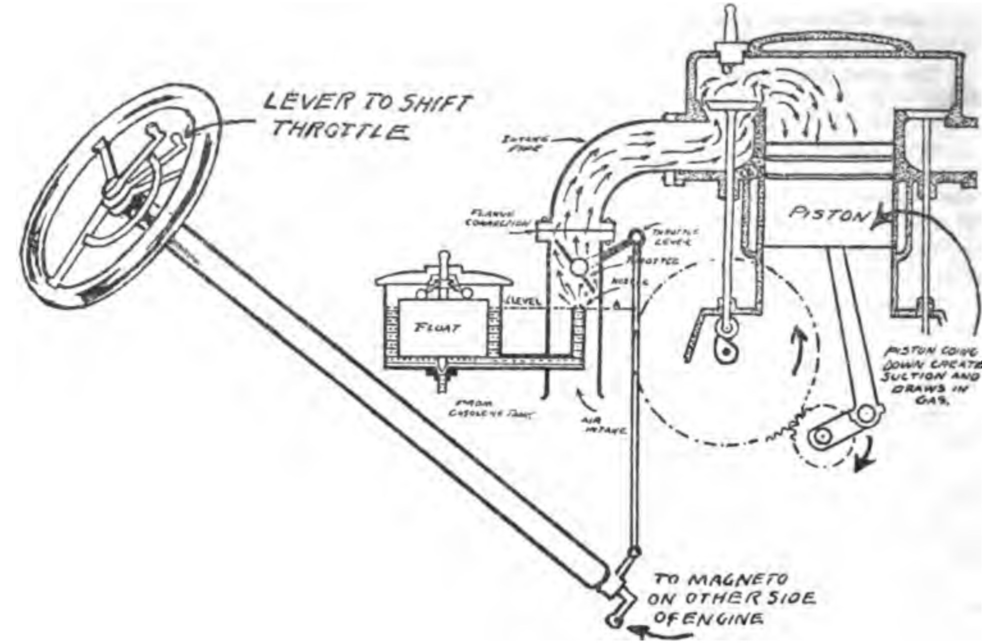


Fig. 1.—Illustrating the principle of opening and closing the throttle valve on the carburetor by the throttle lever on the steering wheel.

See Chart 8 and note Fig. 68 and follow the rod leading through the steering column (63) and note how it connects at (72), with carburetor.

Opening the butterfly throttle valve on the carburetor admits more gas into the cylinder, thereby increasing the speed. Closing this valve reduces the speed.

At the same time the throttle lever is "advanced," the spark lever, which shifts the contact breaker on the magneto, is "advanced" also.

If a timer with a coil system of ignition is used, then the spark lever (see page 60) shifts the timer instead of the contact box on magneto.

The object in advancing the ignition as the throttle is opened, is to cause the gas to ignite earlier—which is explained on page 67.

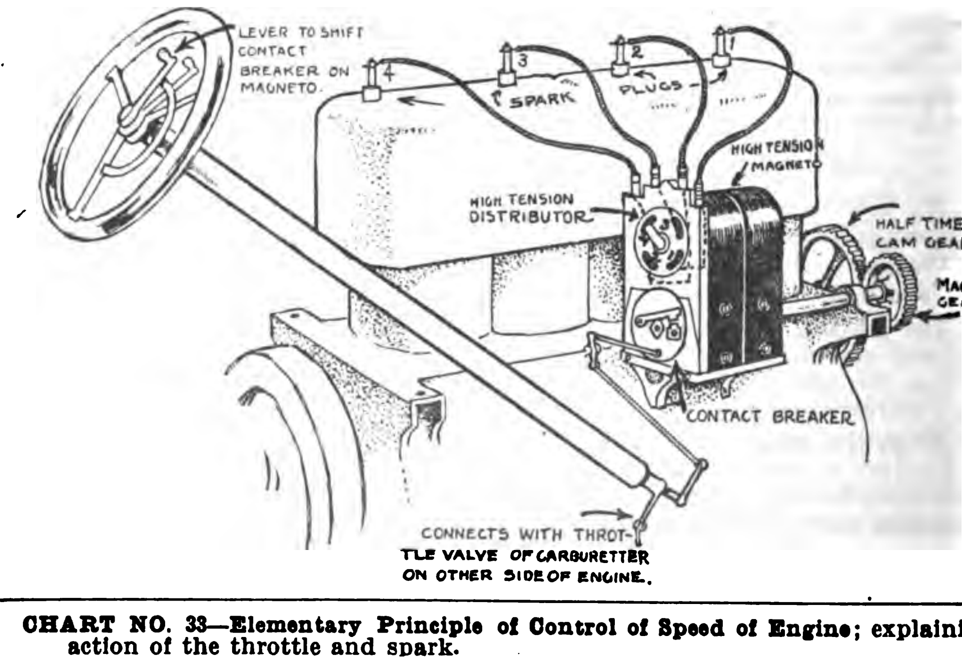

CHART NO. 33—Elementary Principle of Control of Speed of Engine; explaining the action of the throttle and spark.

The suction stroke is now completed; the gas which was drawn into the cylinder must now be compressed. **Just as it is compressed,** the electric **spark occurs** at the point of the spark plug and ignites the gas.

At the moment the gas is ignited, the force of the explosion forces the piston down and this force gives momentum to the fly wheel, which will keep the crank shaft in motion until another piston in one of the four cylinders has drawn in and compressed its gas and fired. **The cycle operation** explained in chart 29, is **repeated over and over** again in each cylinder. (See page 116, how a 4 cylinder engine fires.)

Control of Speed of Engine.

After the engine is started with starting crank (self starters will be explained further on), the **speed of engine is controlled** by opening and closing the throttle of the carburetor which, when opened admits gas to the cylinder. The **more gas admitted** the stronger the explosive force will be, **hence more speed.** The gas of course, is admitted through the inlet valve during the suction stroke.

The opening and closing of throttle is regulated **by hand** by means of the throttle lever (fig. 1, chart 33 and 106) on the steering wheel, or by a foot pedal connected with the same throttle lever called an "**accelerator.**" (See index.)

Carburetion; the carburetor is connected to the inlet manifold by the inlet pipe, and the gasoline flows to it from the supply tank through a small brass or copper pipe, called **fuel pipe.**

Pure gasoline vapor will not burn, but must be mixed with **air** before it can be used to develop pressure. The mixing of gasoline vapor and air in the proper proportions is called carburetion. To give the best results, the mixture of gaseline vapor and air must always be in correct proportion. (See index.)

There is a passage through the carburetor into which the air is drawn as the piston makes the suction stroke. The liquid flows to the carburetor and is brought into contact with the current of air. The gasoline turns to vapor, and is absorbed by the air, the mixture being sucked into the cylinder on the suction stroke.

The quantity of mixture that is drawn into the cylinder during one suction stroke is called the **charge.** Details of carburetion are given in Instruction 12.

Ignition; when the throttle is being opened and the engine begins to speed up, it is then necessary to also "**advance**" the time of ignition in other words, cause the spark to occur sooner than when engine was running slow.

A spark lever is usually placed on the steering wheel along side of the throttle lever, which is connected by a rod and bell crank to the contact breaker box on the magneto or if a coil and timer is used, to the timer. (See chart 33 and 106.)

When the spark lever is moved, it also moves the contact breaker box on magneto or commutator, which causes the spark to occur "late" or "**early**" according to the movement of this lever, (chart 33).

The reason for advancing the spark is as follows: To begin with, the charge is set on fire, or ignited, at the proper time by an electric spark.

The current of electricity that supplies the spark is produced by a battery, or a magneto or dynamo driven by the engine.

The exact instant for the ignition of the charge depends on the kind of work to be done, the speed of the engine, and the quality of the mixture. If the charge is ignited **too soon** or **too late,** the engine will not run properly.

The time of ignition, or instant when the electric spark sets fire to the charge **is controlled** by means of a **commutator, timer or contact breaker** which is advanced or retarded by the driver by means of a spark lever on the steering wheel.

We have up to this time supposed that the spark occurs exactly at the moment when the piston reaches the top of the compression stroke. Now, this would be its correct timing were it not that the gas takes quite an appreciable time to explode after being ignited, an interval let us say of 1/240 of a second, so that before the gas has had time to burst into a full explosion, the piston, on account of its great speed (suppose it is traveling at 1,500 revolutions per minute), will have traveled about a quarter of a stroke down the cylinder before being affected by it. This means a quarter of every power stroke wasted.

***The advance of spark**; the remedy for this is to make the spark occur a quarter of a stroke earlier; that is, make it occur when the piston has completed but three-quarters of the compression stroke so that the full burst of explosion and the piston arrive simultaneously at the top of the stroke, or on top "dead center." This is called advancing the spark.

The retard of spark; suppose the engine is now running at only half the speed, say 700 revolutions per minute. During the exploding or igniting period, which we assumed to be 1/240 of a second, and which remains the same, the piston, with its speed now reduced, has not time to travel so far, and the spark therefore need not be so much advanced.

Again, when the engine runs dead slow, say at 100 revolutions per minute, which is slow for a motor car engine, the spark requires hardly any advance at all. So that we see at once that the **faster** the engine runs the more the spark must be **advanced,** and that the **slower** the engine runs the less it need be advanced, or, to express it in a more usual way, the more the spark must be **retarded.**

Let it be clearly understood that to "advance" or "retard" the spark, means to cause the spark to occur **earlier** or **later** relatively to the position of the piston. It does not mean that the spark is made to occur more frequently or less frequently.

Question.—How can the spark be made to vary as to the time at which it takes place?

Answer.—In chart 33 a device is shown on the magneto which is called a "contact breaker." This is usually placed on the end of the magneto armature shaft which is operated by the cam shaft. It is nothing more or less than what we might call a rotary or revolving electric switch. For instance, suppose the contact is made on dead center, but should it be necessary to advance the spark, the contact breaker can be turned, by means of a spark lever on the steering wheel. This will cause the spark to be turned on earlier or before the piston has reached the top of the stroke.

Question.—Suppose I do not advance the spark when the throttle is opened and engine is running fast, what then?

Answer.—The engine wastes say quarter of every explosion stroke, and fails to run so powerfully as it would were the spark properly timed or advanced.

Question.—What if I advance the spark when the engine runs slowly?

Answer.—Then there will be a fierce struggle inside the engine; the piston fighting to complete the compression stroke, and the explosion, which has occurred too soon, trying to force it back again. And which wins? If the engine is working fairly briskly, the piston overcomes the explosion; otherwise the explosion drives back the piston, and stops the engine

This is why frequently when an engine is cranked it "kicks back"; the spark has been advanced too far, and the piston can't overcome the early explosion.

Question.—How can I tell when the spark is too much advanced?

Answer.—There will be a sound in engine as of a hammer striking the top of the piston. The engine will be said to knock, and the more the spark is advanced the louder will be the knock.

*Note.—Lag in the explosion stroke is also due to the electrical apparatus producing the spark, see pages 308 and 243. *See also pages 305 to 309.

Question.—And what should make it knock? Does the piston strike the top of cylinder?

Answer.—We have already pointed out that this is impossible, as the length of the stroke is invariable; neither does it appear that it is caused by a general looseness throughout the parts of the engine, since new engines knock as much as old ones.

A possible explanation, and one which has received some support, is that the charge in the cylinder detonates in much the same way as certain solid explosives. A piece of gun-cotton, for instance, if laid upon an anvil and lighted with a match, burns silently, because it has all the space to expand in that it requires, but if instead of its being lighted it be struck with a hammer, it goes off with a loud report.

Now, in the case of the gas exploding in the cylinder, if the piston is able to move away from it easily and thus give room for the expansion, there is no noise, but if, as in the case we are discussing, the piston moves against the explosion, like the hammer falling on the gun-cotton, the result is a report.

The knocking is not always detected easily by the novice, who will probably confuse it with other sounds on the car, but when once it has made itself evident, the spark should be instantly retarded until the knocking ceases.

The strains set up in an engine which is allowed to knock may seriously damage connecting rods and cranks.

An engine should not be slowed by retarding the spark. If it has been noticed by the reader during the last few paragraphs that it is possible to slow an engine by retarding the spark, let him at once understand that this is the last method by which it ever ought to be done.

It is not only unscientific, but is also wasteful of fuel, unnecessary work for the engine, and causes rapid pitting of the exhaust valves, the gases passing through them in an incandescent form.

The correct method of slowing down or increasing the engine speed is to shut or open the throttle valve, which is situated between the carburetor and the inlet valve, by which the amount of fuel supplied to the engine may be regulated (see illustration, chart 33, fig. 1). Then as the engine varies its speed slower or faster, the spark should be retarded or advanced accordingly.

The rule therefore is to let the engine speed follow the throttle and make the spark follow the engine speed; or to put it in another way, to drive economically, keep the throttle valve closed as much as possible and the spark advanced as far as possible, short of knocking or tendency to knock.

Retarding the spark too much produces heat, see page 319.

Ignition.

Consists of a spark plug, a source of electric supply, which may be either a magneto, generator or battery and coil. If the latter system, then a timer or commutator is used to make contact from the battery to the coil, causing a spark to occur at the points of the spark plug. See fig. 5, chart 39 for an early form of commutator—more modern methods will be treated further on.

The spark plug can be placed over center of piston or side of cylinder if overhead valves. If side valves; over inlet valve—usually screwed into inlet valve caps—see chart 30-A.

Carburetion.

This subject is treated under instruction numbers twelve and thirteen

Cooling.

The explosion of the charge in the cylinder produces **heat**. This heat is so intense that the lubricating oil will burn and be made useless if the cylinder is not kept fairly cool. If the lubricating oil were burned, the friction of the piston against the cylinder walls would be so great that they would cut each other, and the piston would stick, stopping the engine. The cylinder must therefore be kept from heating to the point at which the lubricating oil would burn, but as the heat develops the pressure, the cylinder must not be too cool.

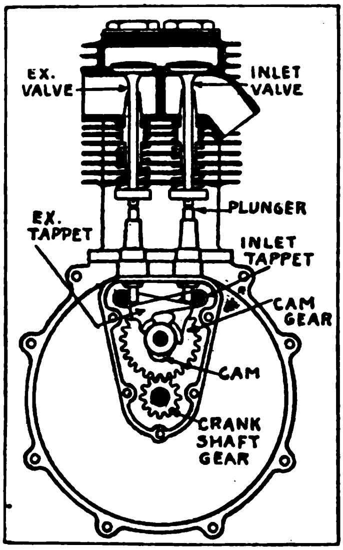
The cylinder may be cooled either by a current of **air**, or by **water** circulating around it. See instruction number fourteen on the subject of cooling.

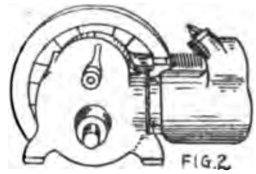
Fuel System.

There are two fuel systems in general use for feeding the gasoline to the carburetor: **the pressure and gravity feed**—the two will be explained further on under instruction number twelve.

Lubrication.

There are several methods for lubricating the moving parts of an engine, which will be fully treated further on under instruction number fifteen.





-A Single Cylinder Horizontal

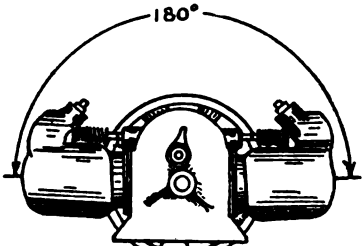


FIG. 3
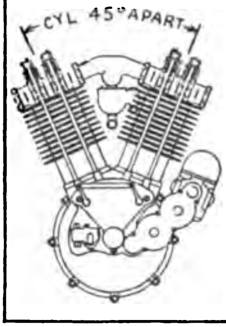
Two Cylinder Opposed Type



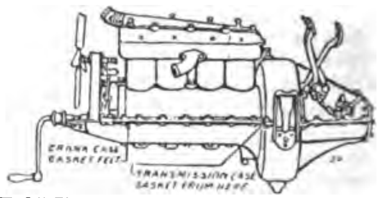


Fig. 1. A single cylinder vertical type of engine, with air cooled cylinder. Valves are both on the side and mechanically operated. There are two fly wheels with a crank pin between them. The fly wheels run inside of the aluminum crank case. This type of engine is used on motorcycles, cycle cars, and railroad light cars.

Fig. 2. A single cylinder horizontal type of engine, with water cooled cylinder. Formerly used on light weight automobiles. Seldom used, valves mechanically operated.

Fig. 3. A double cylinder opposed type of engine, with water cooled cylinders and mechanically operated valves. Note cylinders are 180° apart. Cylinders are "L" type. The crank shaft is also 180° type.

Fig. 4. A twin cylinder "V" type of engine, with cylinders placed 45° apart. Cylinders air cooled. Valves mechanically operated from overhead. Cylinder is the "round" type. This type of engine used on motorcycles and cycle cars.

Fig. 5. A four cylinder vertical type of engine, with transmission and clutch in one housing joined to engine—called a "unit power plant." This engine is suspended in frame at three points, therefore it would be called a "three point suspension" type of power plant. Valves all on one side of the "L" type cylinders.

The cylinders are all cast together or "in block." The cylinder head is in one piece. (The Ford.)

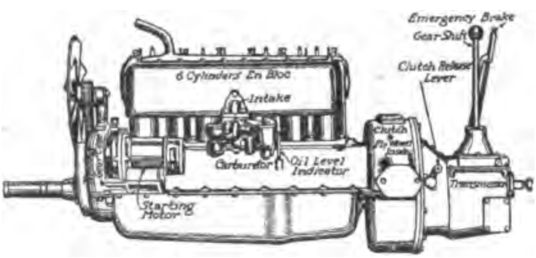

Fig. 6. A six cylinder "unit power plant." Transmission, clutch case join the engine. Cylinders are cast together or "in block."

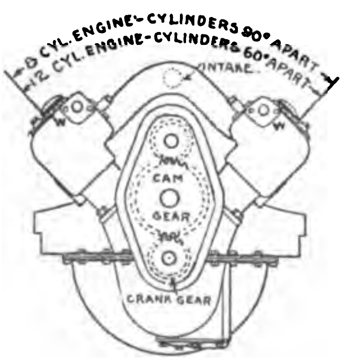

Fig. 8. Eight cylinder "V" type engine, with cylinders placed at an angle of 90° apart. One cam gear operates the valves on both sides of the "L" shaped cylinders. There are four cylinders on each side, usually "in block." Crank shaft is a four cylinder type (180°) crank, with two connecting rods to each crank pin.

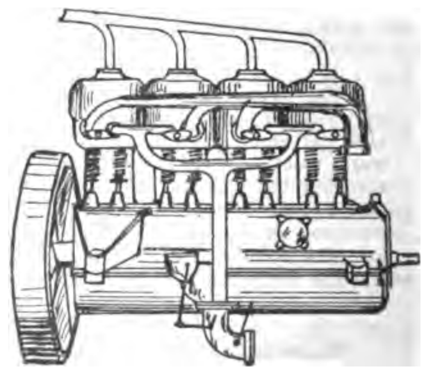

Fig. 7. A four cylinder engine with cylinders cast separate. All valves are on one side; hence "L" type cylinders.

CHART NO. 30—Types of Four Cycle Gasoline Engines.

Chart 34 on page 74.

The Automobile Engine.

The 4, 6 and 12 cylinder engine is used for automobile work. The six is used most.

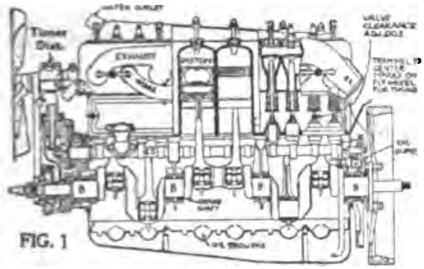

FIG. 1

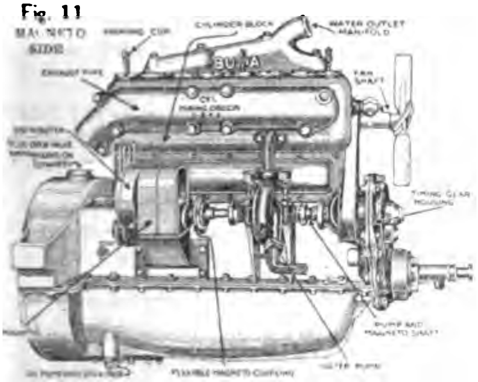
Valves are placed on the side or overhead. **Ignition,** usually coil and battery, using a timer and distributor. A **generator** supplies current for charging battery, also for lights and ignition. **Battery** supplies current for lights, ignition and starting motor. **Speed of automobile engines** vary from 150 to 2000 r. p. m., for instance, the Studebaker **six 3⅞"** bore x 5" stroke engine, and many others. On some few engines the speed is as high as 3000 r. p. m. **Control of speed** is by a hand throttle lever and foot-accelerator. A governor is never used.

The Truck Engine.

Usually a 4 cylinder engine is used on trucks, for reasons stated on page 747. **Valves** usually on the side. **Ignition** usually a high-tension magneto and on the Buda engine, per figs. 11, 12, used in the Master truck, the Eisemann magneto with automatic advance, per page 289 and 285 is used. **Speed of engine** is comparatively slow, 950 to 1000 r. p. m. **Speed is governed** by McCann or Pierce governor on this engine, per pages 840, 841 and for reasons explained on page 839. **Stroke of piston** usually long and in this instance, bore is 4½"x6" stroke or 32.4 H. P. (S. A. E.), or 52 actual H. P. **Truck speed is from 12 to 17 m. p. h. Starting** is usually by hand-crank in connection with an "impulse starter," per page 832. **Control of speed** by hand trottle and accelerator.

Fig. 11



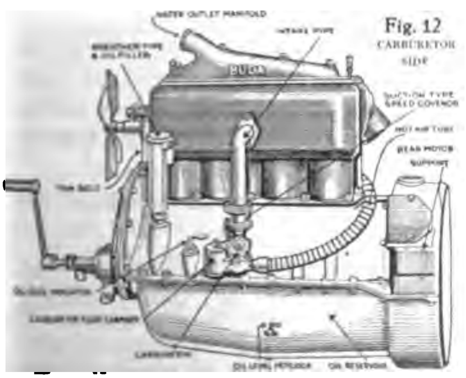


Fig. 12

Airplane Engine.

Many airplane engines use the overhead valves and overhead camshaft as per pages 912, 916, 918, 921, 922, 936. **Ignition** used is high-tension magneto or coil and battery ignition. **Speed of engine** at **flying** speed 1400 to 1700 r. p. m. **Number of cylinders,** usually 8 or 12. See above mentioned pages for further details.

The Tractor Engine.

Usually a 4 cylinder engine is used on tractors, for reasons stated on pages 753, 831. **Valves** overhead or on the side and some use the overhead "dual" valve system. **The stroke** is usually long, average being 4½" bore x 6" stroke.

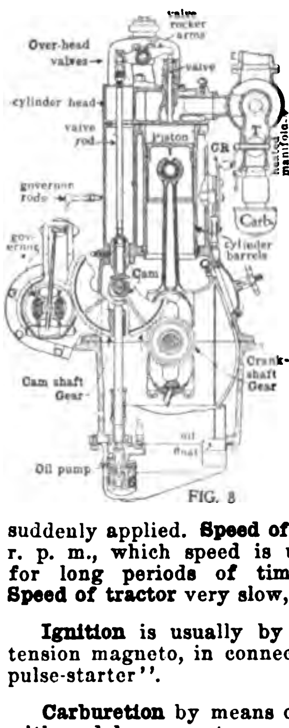

FIG. 8

Speed of engine is controlled by a governor, per fig. 8, which is a centrifugal ball-type, operating through levers to carburetor throttle (T).

The governor is used to maintain a uniform speed and to prevent engine from "racing" if load is suddenly released, of from "stalling" if load is suddenly applied. **Speed of engine** usually 950 r. p. m., which speed is usually maintained for long periods of time while working. **Speed of tractor** very slow, see pages 830, 831.

Ignition is usually by means of a high-tension magneto, in connection with an "impulse-starter".

Carburetion by means of gasoline to start **with and kerosene to run on after engine is** heated up. **The heating of fuel around intake** manifold from exhaust gases is very important when using kerosene—see pages 827, 831.

Cylinder barrels or liners, are used on many tractor engines. They consist of removable liners (fig. 8) placed in cylinder blocks, which in case of wear or accident can easily be replaced with new ones.

The reader can now compare the relative difference between the four engines and thus note, that while the construction may vary, the same underlying principles are used.

CHART NO. 30A. Relative Difference Between the Automobile, Truck, Airplane and Tractor E gine.

INSTRUCTION No. 8.

*ENGINE PARTS: Stationary Parts. Moving Parts. Purpose, Principle and Location of Parts.

The stationary parts are: crank case, upper and lower half, bearings, cylinders, exhaust and inlet ports, valve caps, compression or relief cocks, water cooling pipes, carburetion and part of the ignition systems, exhaust and inlet manifolds.

The moving parts are: crank shaft, connecting rods, pistons, piston rings, piston pin or wrist pin, cams, cam shaft, timing gears, crank shaft gear, valves, valve plunger or tappet or lifter.

Crank Case.

The cylinder is attached at its open end to the crank case, which forms a box around the crank shaft.

The crank case is of irregular shape, so that while there is plenty of room for the cranks and connecting rods to operate, there is little waste space. It contains the crank shaft bearings, and forms the bed-plate or foundation, for the engine.

It is often made in two parts, an upper part bolted to the cylinder and containing the crank shaft bearings, and a lower part enclosing the crank shaft and which is called the "oil pan."**

As the lower crank shaft case is intended to contain lubricating oil, it is tight so that there may be no leakage. Usually the lower part of crank case can be removed for adjustment of bearings.

The crank case is usually made of aluminum alloy, or if in two pieces, the upper may be made of bronze, and the lower of aluminum and sometimes cast iron.

The crank case is used to support various parts of the mechanism, like the pump, magneto, etc. For an illustration of a crank case, see chart 31, fig. A, and chart 32, figs. E and F.

The arms for supporting the crank case on the chassis are sometimes made short to bolt to a sub-frame (22), as shown in chart 5, while other manufacturers make longer arms to extend and bolt to the main frame (21).

A "**three point suspension**" is where the power plant is suspended in frame at three points of contact.

A "**unit power plant**" is where engine clutch and transmission are in one unit as in fig. 6, chart 30 and page 44.

*Engine Bearings.

Engine crank shaft bearings are known as **main bearings.** Most of the manufacturers make four cylinder engines with **three main** bearings for the crank shaft, while others have as many as five.

On six cylinder crank shafts there are as many as seven bearings, the majority using three. See chart 36 and 55.

If the six cylinders are cast "**single**" which is unusual, usually 7 bearings; 2 ends and 5 inside are used. If cylinders are cast in "pairs" usually

*For repairs on engines, see "repairing instruction."

**The S. A. E. designate two types of crank cases; the "split type" where the lower part is separate and contains no bearings. The lower part is then called the "oil pan." The "barrel type" is when the lower part is permanently attached and has a hand hole plate for reaching the bearings, and crank shaft is removed from end of crank case with the removal of crank case head.

3 bearings; 2 ends and 1 inside. If cylinders are cast "in block," usually 3 bearings; 2 ends and 1 inside center (small engines). If ball bearings are used, then there are usually 3 bearings.

The bearings of a crank shaft are usually in two parts and made of bronze or *white metal babbit, or other metal that does not wear rapidly. These bearings are split lengthways into two parts, one part being supported by the engine base (called the bearing journal—fig. 1, chart 35), so that the shaft lies in it, and the other part covers the shaft at the same point, and is held in place by means of cap screws, (see fig. 3, chart 34).

When one of the main bearings becomes worn the lower cap is removed and a shim is taken out so it can be drawn tighter to the shaft. If it is burned or cut then a new lining of brass or babbit called a "bushing" must be put in or it can be dressed by scraping.

These **shims** are plates of thin metal placed in both main and connecting rod bearings (see fig. 2, chart 34), which are fitted in between the cap and upper part of bearing, so that by removing a shim or two they can be drawn closer together when loose.

A bushing is that part of a plain bearing that the shaft comes in contact with. They are usually made of babbit, phosphor bronze or white metal. The phosphor bronze are very hard and last a long time, but are somewhat liable to "sieze" if run without oil.

A white metal bushing consists of a layer of white metal, run, (when in a molten state), into a channel in the bearing. It then hardens and is scraped and polished. White metal has the virtue that if ill treated it does not seize and do much damage, but if run for a long time a knock would result.

Probably the first bearings to require renewal are those of the connecting rod. See page 641.

Connecting Rod Bearings.

The big end of the connecting rod is attached to the crank pin, and a bushing of bronze or white metal or other metal (with a melting point lower than that of cast iron) in the form of a shell surrounding the crank pin is secured in it. (Chart 34, fig. 1.)

The bushing is split lengthways into two halves, like the bearing of the crank shaft, one part being set in the connecting rod and the other being held in place by the **connecting rod cap.**

The small or upper end of the connecting rod contains a solid bushing that forms the **wrist or piston pin bearing.** (Fig. 1, chart 34.)

Because of the small space in the piston, it is not possible to have this bushing split and held in place by a cap. The bushing is therefore set in the connecting rod, and the wrist or piston pin pushed through it. The wear of the wrist pin bearing is slight, and if it should wear loose, a new bronze bushing is driven into the connecting rod.

The wrist or piston pin is passed through the piston, and secured so that it cannot move. (See fig. 4, chart 34.) It is usually case hardened.

On the Ford, fig 5, the wrist or piston pin moves with the motion of the connecting rod. The small end of connecting rod being clamped to it. The wrist pin moves in bronze bushings fitted in the piston.

Through the connecting rod, the piston transmits the pressure of the explosions to the crank shaft and fly wheel In order that it may withstand the heavy shocks of the explosions, the connecting rod must have great strength.

It is made of drop forged carbon steel, heat treated and in rare instances bronze. A straight I-beam type is used almost universally.

*See index for "white metal bushings." Connecting rods for high speed engines must be made light as possible, hence bronze being heavier is seldom used.

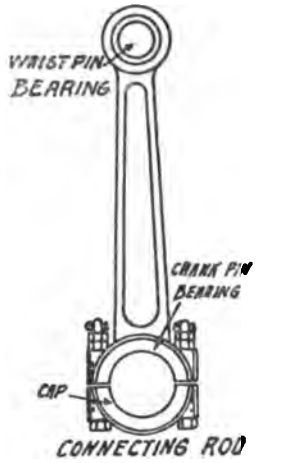

Fig. 1.—A connecting rod showing wrist pin bearing and crank pin bearing and cap.

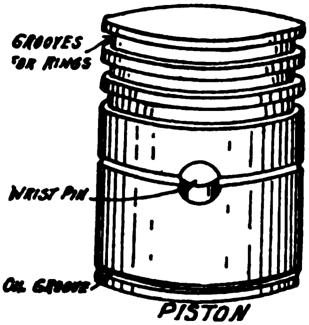

Fig. 6.—A trunk type of piston.

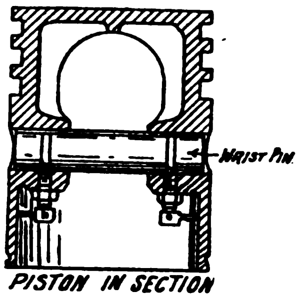

Fig. 4.—Sectional view of piston. Note wrist pin is stationary.

Fig. 9.—In order to prevent compression passing through joints of rings; they are placed as illustrated. Three rings is the usual number to a piston.

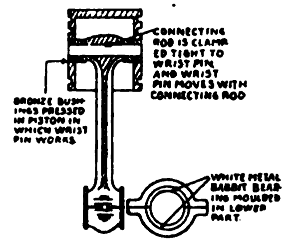

Fig. 5.—Note in this type (Ford) the wrist pin moves with the upper end of connecting rod.

Fig. 8.—Two types of piston ring joints.

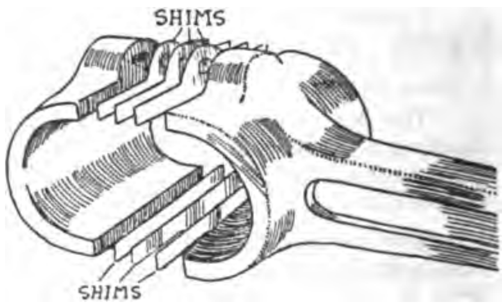

Fig. 2—Connecting-rod bearing end with cap removed to show shims

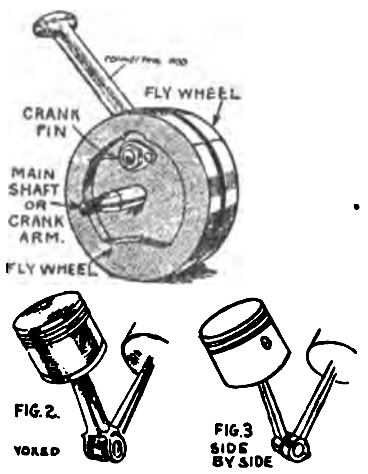

Fig. 7.—Upper illustration shows a connecting rod, crank pin and crank arm on a single cylinder motorcycle or cycle car engine. Note crank pin is between the two fly wheels which are placed in the crank case. Lower illustration explains the method of connecting two connecting rods to one crank pin on a "V" type engine.

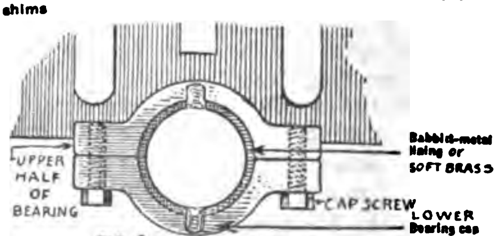

FIG. 3 —Crankshaft bearing

Fig. 2.—Illustrating how shims or liners are placed between lower connecting rod cap and upper part. When worn a liner can be removed. This permits the cap to be drawn closer to crank pin.

Fig. 3.—Showing how one of the main crank shaft bearings is lined with white metal babbit or bronze. Liners or shims are also used.

CHART NO. 34—Engine Parts; bearings, connecting rod, piston, piston rings.

Note—S. A. E. have discontinued the use of word wrist pin for piston pin which of course is more applicable. Chart 31 on page 62.

Connecting rod on a crank shaft of a "V" type engine can be placed either "yoked" or "side by side" as shown in fig. 7, chart 34. When they are yoked, the cylinders would be "in line"; if side by side the cylinders would be "staggered" or slightly out of line. See fig. 5, chart 36 of connecting rods on an eight cylinder engine.

*Piston and Piston Ring.

The piston of a gasoline engine is called a trunk piston, to distinguish it from the **disc piston** of a steam engine. (See chart 34, fig. 6.)

A trunk piston is longer than its diameter, and is hollow, with one closed end. The closed end is toward the combustion space, and it is against the closed end that the force of the explosion acts.

The piston pin passes through the piston, usually about the middle or a little nearer the top (dependant on the stroke.)

The open end of the piston permits the connecting rod to swing from side to side.

*The piston does not fit the cylinder tightly, for a tight fit would cause friction and wear. This space is called **piston clearance.** (see index.) The piston is usually slightly smaller at the top than bottom because the heat is more intense at top and expansion must be allowed for.

The pressure from the explosion is prevented from escaping between the piston and the cylinder wall by **piston rings.**

†**The piston rings fit** in the groove around the upper end of the piston, and there may be from two to five of them, usually three. The rings fit the groove snugly, but not so tight that they may not move freely.

They are cut crossways, so that they may be sprung open. When closed, so that ends touch, the rings are a trifle smaller than diameter of cylinder.

When sprung open, they are larger than the diameter, or bore of the cylinder. They are so made that they always stand a little open.

The rings are slipped into the grooves by springing them open, and sliding them over the piston.

When a piston is to be placed in a cylinder, the rings are drawn together (see repair subject), so that they will slide in easily. The piston with its rings fits the cylinder snugly, and the elasticity of the rings keeps them pressed against the cylinder wall, **making a fit that keeps the pressure from escaping.**

None of the pressure of the explosion being able to escape, it is all exerted against the closed end of the piston, or **piston head.**

The rings must be placed on the piston so that the ends are not one over the other, for if they were in line the pressure might escape through them.

The rings are prevented from moving around the piston by **pins** placed between the ends. (Not on all pistons.) The only motion they have is the spring in and out.

The ends of the rings are beveled, or made with a joint that is shaped so that it is tight whether the rings are closed or open to the size of cylinder.

*For piston ring fitting, etc., see "repair instruction." Aluminum alloy pistons are now being used to a certain extent instead of cast iron for the following reasons: They are about one-third lighter. The inertia of the reciprocating piston is reduced considerably. This cuts down side pressure or thrust on the walls of the cylinders. This reduces friction and the consumption of lubricating oil. The great heat conductivity of aluminum alloy lessens the carbon deposit on the piston head and the deposit is more easily removed. In case of extreme heat if the piston seizes or buckles the cylinder is not damaged with aluminum pistons. First, there was a little trouble from wear on the skirt; it was difficult to get a close enough fit to insure absence of slap without abrasion. The trouble was overcome by one concern, the Franklin, by turning a shallow, square groove of screw thread form from the bottom of the skirt to just beneath the lower ring. This holds oil securely and allows a smaller clearance than is possible with a plain piston. Also see page 645 and 651, 637, 792.

*Pistons and connecting rods must be made lighter for high speed work. Where cast iron is used, which is general, the piston is made lighter by making the skirts thinner and piston pin boss, lighter. On small high speed engines the piston skirt is drilled all over with large holes for lightness.

*The usual clearance between a piston and the cylinder wall is explained in repair subject. See index for "piston clearance." The maximum clearance is at the upper part, for here the expansion is greatest owing to the heat of the explosion. †Piston rings are measured according to bore of cylinder. See pages 543 and 864G for bore of engines on leading cars.

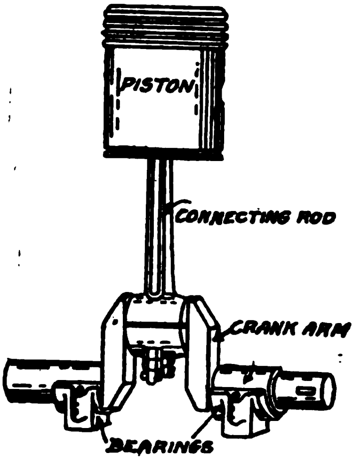

Fig. 1 — A single throw crank shaft. Crank set at 360 degrees.

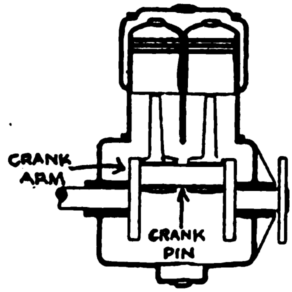

Fig. 2—A two cylinder vertical engine with a 360 degree crank shaft; both connecting rods on one crank pin.

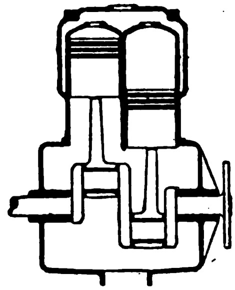

Fig. 3—A two throw crank shaft for a two cylinder vertical engine, crank set 180 degrees.

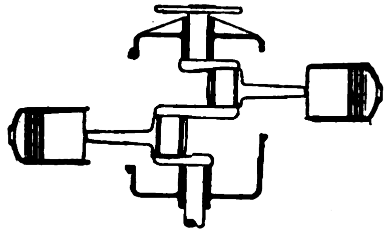

Fig. 4—A two cylinder opposed type of engine with crank shaft set 180 degrees. Cylinders are also 180 degrees apart.

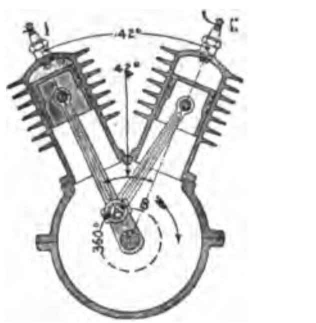

Fig 7—A two cylinder twin type of engine used on motorcycles and light cars. Note the 360 degree crank. Cylinders at 42° angle.

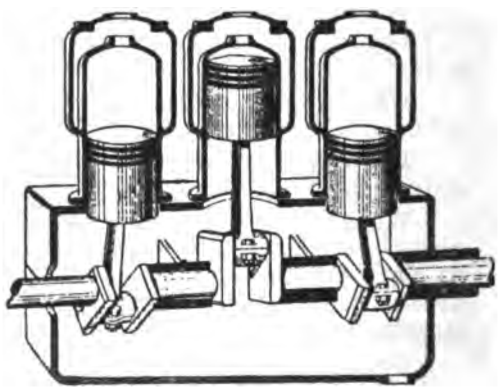

Fig. 5—A three cylinder vertical type of engine with cranks set at 120 degrees. Note No. 2 piston is up. No. 3 (right) would be 120 degrees or one-third of a revolution; No. 1 would be 120 degrees or one-third revolution from No. 3, or two-thirds from No. 2.

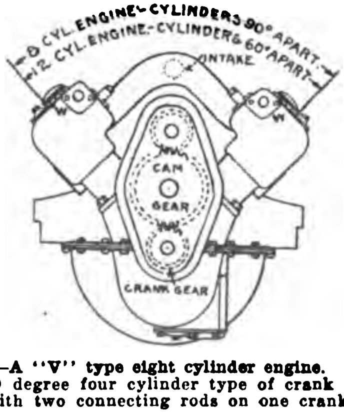

Fig. 8—A "V" type eight cylinder engine. A regular 180 degree four cylinder type of crank shaft is used with two connecting rods on one crank pin.

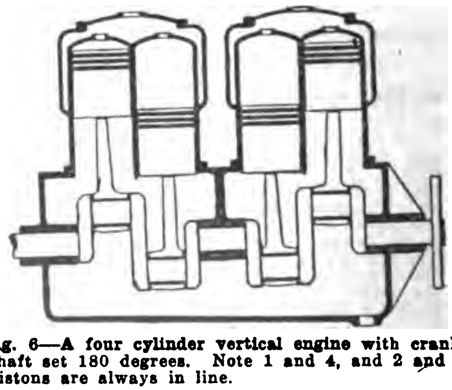

Fig. 6—A four cylinder vertical engine with crank shaft set 180 degrees. Note 1 and 4, and 2 and 3 pistons are always in line.

Two of the usual types of piston rings are shown in chart 34, fig. 8. **piston rings are made of cast iron** of a slightly softer grade than cylinder.

There are many improved types of piston rings which the manufacturers claim will not leak; usually three rings are placed on a piston. The Falls Co. has changed to two rings and claim that for high speed work two is sufficient whereas, for slow speed work three rings are necessary.

†The Crank Shaft.

The crank shaft throw changes the reciprocating motion of the piston to the rotary motion necessary to turn the wheels. It rests in bearings that hold it in a fixed position, but permit it to revolve.

The crank pin must be rigidly attached to the crank shaft, and to secure this rigidity they are usually made in one piece, solid as in fig. 1, chart 35, and is made of chrome nickel steel.

The crank projects from the crank shaft, and when the shaft revolves, the crank makes circles around it. A crank is one of the most common mechanical devices. The crank pin is that part to which the connecting rod fits and is also called the "**throw**" of the crank.

A windlass is turned with a crank; a bucket or chain pump is operated with a crank; the pedals of a bicycle form cranks.

In a bicycle, the crank arms are attached at their inner end to the crank shaft, and to their outer ends the pedals are attached.

When riding a bicycle, the feet press on the pedals at the ends of the crank arms, and make the crank shaft revolve. The feet describe circles around the crank shaft. Each crank arm and pedal form a crank and there is only one arm to a crank.

In a gasoline engine, two arms are necessary for the reason that the cranks are not at the ends of the shaft, there are therefore **two arms** to each crank. (Fig. 1, chart 35.)

The outer ends of the crank arms are connected by the **crank pin.** The crank pin corresponds to the pedal of a bicycle. A gasoline engine **has as** many cranks as it has cylinders* (see foot note).

Meaning of Degrees as Used with Crank Shaft.

The position of a crank on a crank shaft in relation to other cranks on the same shaft is expressed in **degrees** of a circle.

If a crank shaft has **two cranks projecting in opposite directions,** as in fig. 3, 4 and 6, chart 35, it is called a **180 degree** crank shaft.

If the **cranks project from the same side of the shaft,** as in figs. 1 and 2 so that the crank pins are in line it is called **360 degrees** crank shaft.

In such a case, as shown in fig. 2, chart 35, instead of having two pairs of crank arms with a crank pin to each pair, the crank pin may be made long enough to hold both connecting rods, and has only one pair of crank arms. Both connecting rods drive one crank. This type of engine, **however is not** used on account of its uneven firing (see chart 53, page 116, for firing orders). Engines with crank shafts as shown in figs. 3 and 4 would fire more regularly.

The engine in fig. 4 is called the opposed type of engine. It was formerly used to a great extent on small cars and is still used to some extent on trucks and tractors for heavy work. The cylinders are placed **180 degrees** apart (see fig. 1, chart 38); the crank shaft is also 180 degrees.

The four cylinder engine, fig. 6, chart 35, employs a **180 degrees** crank shaft. Note "throws" of crank on cylinder 1 and 2 are 180 degrees apart, and 3 and 4 are 180 degrees apart.

†See chart 55 for six cylinder crank shaft explanation.

*Fig. 2 shows a two cylinder engine with one crank. This type, however is obsolete.

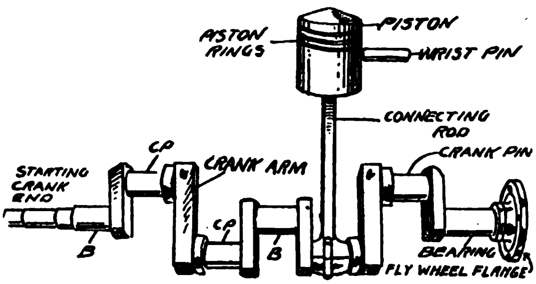

Fig. 1. A solid type of crank shaft—three bearing type, four cylinder.

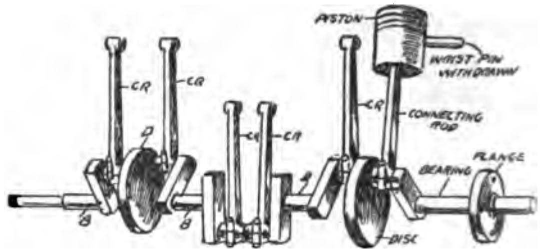

Fig. 2. A built up type of crank shaft (seldom used). The above is a six cylinder crank, with four bearings.

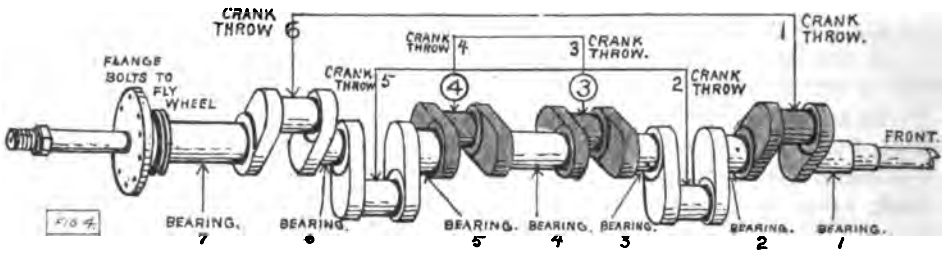

Fig. 4. A solid crank shaft, with seven bearings. Six cylinder.

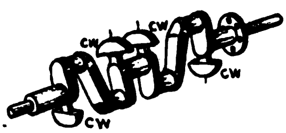

Fig. 12. Typical counterbalanced four-throw crankshaft. This method of balancing is used on the Stearns-Knight, Cole and Oakland engines.

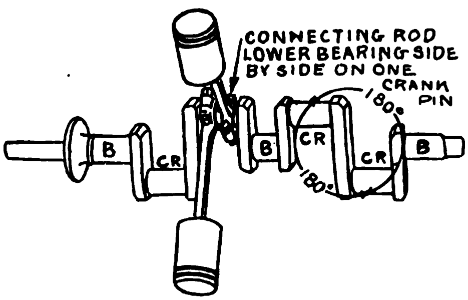

Fig. 5. A regular four cylinder type, 180° crank shaft is used on the 8 cylinder "V" type of engine. Two connecting rods are placed on one crank pin; either side by side, or yoked (see fig. 7, chart 34).

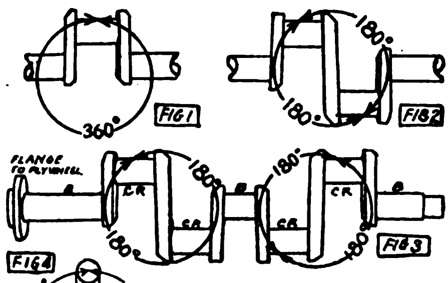
If side by side the two cylinders would not be in line but "staggered." If connecting rods were "yoked" then the cylinders would be in line.



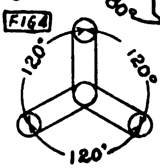


Fig. 6. In this illustration the idea is to explain the term "degree" used in connection with crank shafts.

Any perfect circle is 360°. If the circle is divided into quarters, each quarter would be 90°; half of the circle 180°; a third 120°.

Fig. 1. Note one crank pin—hence 360° crank.
Fig. 2; from center of one crank pin to center of other is half a circle or 180°.
Fig. 3; here we have two pairs of crank pins as shown in fig. 2, but on one crank; also 180°.
Fig. 4; end view of a three or six cylinder crank shaft. Note crank arms are one-third apart or 120°.

CHART NO. 36—Crank Shaft Construction.

Therefore, pistons on cylinders 1 and 4 are always up or down **together**, and 2 and 3 are up or down **together** or in line.

The eight cylinder "V" type engine would in reality be nothing more than two four cylinder engines with cylinders set "V" shape. The angle of cylinders usually being **90 degrees** or one-half of the 180 degrees of the crank shaft. The same four cylinder 180 degrees crank shaft is employed. **There are two connecting rods to each throw of the crank,** which can be placed "**side by side,**" fig. 5, page 78 or "**yoked,**" fig. 7, page 76.

If connecting rods were side by side, then it would be necessary to "**stagger**" cylinders by setting them out of line with each other.

A three cylinder engine must have a crank shaft with the three crank pins placed in three positions, or one-third of a revolution apart; **this would be placing them 120 degrees** apart, see fig. 5, chart 35, and fig. 5, **chart 52.**

A six cylinder engine would have a crank shaft with six crank pins or crank "throws" placed in thirds, or **120 degrees apart.** There would be three pairs in line—see fig. 4, page 78 and figs. 4 and 5, page 122.

***A twelve or twin six cylinder "V" type engine would use the same type of six cylinder crank shaft,** but with two connecting rods to each crank pin. The cylinders would be placed †**60 degrees** apart or one-half of the 120 degree crank shaft. The cylinders would be "staggered" if connecting rods were placed "side by side" per fig. 5, page 78.

The twin cylinder "V" type of engine used on a cycle car and motorcycle would use a **360 degree** crank or one crank pin, with connecting rods yoked.

Cylinders on this type of engine are usually placed at an angle from **42** to **45** degrees apart.

Construction of Crank Shafts.

There are two kinds of crank shafts, one known as the "solid crank **shaft**" and the other as the "built up crank shaft." (See figs. 1 and 2, chart 36.)

The solid is by far the most used. It is made from one piece of steel, **which is** forged to shape and then turned up in a lathe, the workmanship **in many** cases being accurate to a ten-thousandth part of an inch.

The built up crank shaft has each of its parts made separately and then fixed strongly together and quite often fitted with ball bearings.

An advantage of the built up crank is that the crank shaft bearings could be fitted with ball bearings. However, built up shafts of this kind **are not** usual, and in the case of powerful engines, only the strongest solid crank shafts are ever used.

The counter balanced crank shaft with counterweights (CW) electrically welded to the crank shaft and an integral part of the crank shaft, as illustrated in chart 36 is becoming popular. It permits high speeds to be obtained without detrimental vibration, and relieves the tendency to "whipping" of the crank shaft and "slapping" of the pistons. (see fig. 12, chart 36.)

Cylinders—see chart 37.

The cylinder of a gasoline engine is made of cast iron or 20 per cent semi-steel, and the water jackets are generally cast in one piece with it.

In some designs, notably the old Pope-Toledo and 1914 Cadillac, the water jackets were formed by surrounding the upper part of the cylinder with sheet copper. See fig. 2, chart 37.

The cylinders of an engine with more than one cylinder, are either cast **singly,** or **in pairs**; that is, two cylinders with their water jackets are made in one piece.

*The twelve cylinder engine was formerly referred to as used on motor boats, where 12 cylinders were placed in a row. The "twin six" refers to cylinders of 6 to a side, placed "V" type. However, inasmuch as the 8 cylinder is referred to as an "eight," although it is also placed 4 cylinders "V" type, we will not adhere to this rule entirely.

†On some of the twelve cylinder airplane engines (see page 918), the cylinders are 45 degrees apart. The Liberty engine cylinders are 45 degrees, see page 934.

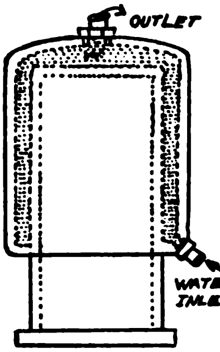

Fig. 1. A single cylinder with water jacket cast around it.

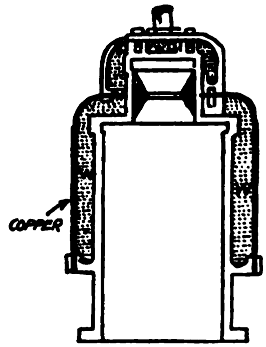

Fig. 2. A single cylinder with a copper water jacket placed around it.

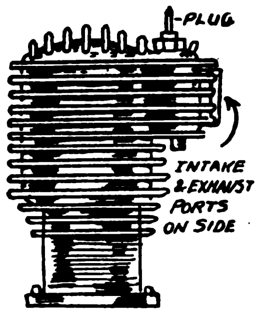

Fig. 3. Air cooled flange type single cylinder.

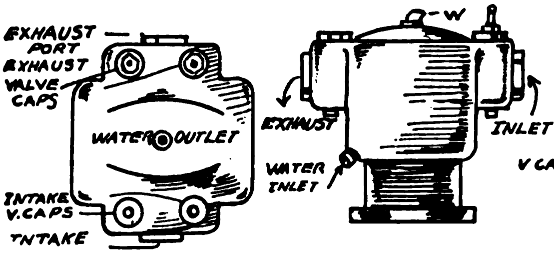

Fig. 4. "T" type of cylinder. Note inlet ports on one side and exhaust ports on other side. Called "T" type because it is T-shaped.

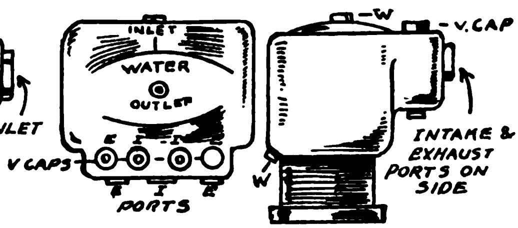

Fig. 5. "L" type of cylinder. All valves are on one side. Called "L" type because it is L-shaped.

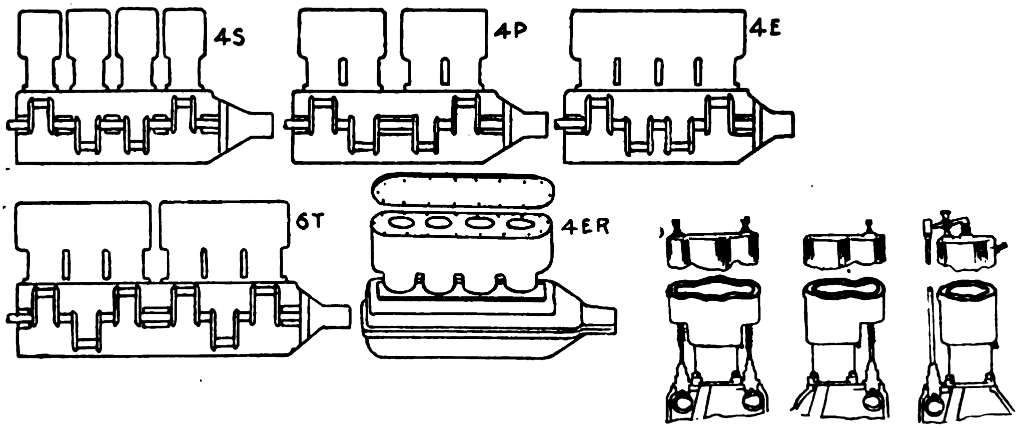

T-head L-head I or valve-in-head

Fig. 6. METHODS OF CYLINDER CASTINGS—Cylinders cast "singly" is illustrated at (4S). The crank shaft is a 180° with five bearings.

Cylinders cast in "pairs" in fig. (4P). Crank shaft 180° with three bearings.

Cylinders cast "in block" fig. (4E), note a two bearing crank shaft. Seldom used, only on very small engines with short crank shaft.

A six cylinder engine, with cylinders in "triplets," (fig. 6T). Note the crank shaft appears to be 180° type, but is divided into thirds (see fig. 4, chart 36).

Cylinders in block with detachable cylinder head is illustrated in fig. 4ER).

Fig. 7. Round type of cylinder. Valves overhead. The upper part with the valve in the head is detachable and is called "valve in the head" type of valve arrangement. This type of cylinder is also called "I" type.

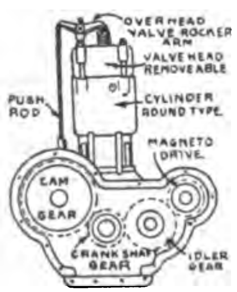

Fig. 7. Round or "I" head, with detachable head.

The portion of the cylinder in which the piston moves should be a true circle, and as smooth as possible. In the better grade of cars the cylinders walls are ground to a smooth finish so that there may be as little friction as possible. Any roughness of the walls will cause wear, which comes in the form of cuts and scratches lengthways, that permit the pressure to escape around the piston.

Cylinder heads may be cast solid or with **detachable** head, see fig. 9, page 90; also Ford engine, page 783 and insert No. 2. The detachable head is gaining in favor. It permits easy access to the valves, and for removing carbon, removing pistons and is good manufacturing practice because it makes grinding of cylinders easier.

Types of Cylinders.

Cylinders of engines are made in several different shapes and are usually made of cast iron. Some of the airplane engines have cylinders made of steel. See pages 916, 934.

†The "T" head type of cylinder is made so that the exhaust valves are on one side and the inlet valves are on the other side. Note the "T" shape in fig. 4, chart 37.

†The "L" head type of cylinder is made so that the exhaust and inlet valves are all on one side of the cylinder. Note the "L" shape in fig. 5, (if turned up side down).

†The "I" head type of cylinder is made so that the valves are placed in the top of head of cylinder—both valves on one side or opposite, fig 7.

The "F" head type of cylinder: inlet valve in the head, exhaust valve on side. See fig. 6, page 88.

When an engine has more than one cylinder, the cylinders can be cast **singly** or in **pairs**—and can be of either the T, L, round or I head type. (See figs. 4, 5 and 7.) Sometimes multiple cylinder engines use all cylinders **cast** singly (4s fig. 6). They can be of the T, L or I head type.

***Cylinders cast** "en-bloc" means that the four cylinders on a four cylinder engine, are all cast in one piece (see fig. 4E). They can also be of the T or L head construction.

Cylinders on the six cylinder engine (6T); can be cast in "triplets," singly, in pairs or in block. The "L" type is used on the most of the six cylinder engines. They are usually cast in pairs of three cylinders to a block.

Cylinders on an eight cylinder "V" type engine are usually cast "in block" and are placed 90 degrees apart, and on a twin six cylinder engine, 60 degrees apart. On a twin "V" cycle car or motorcycle engine, 42 to 45 degrees. (See chart 35.)

The offset cylinder with an offset crank shaft or offset cylinders, as you choose to say, is represented in fig. 5, chart 38. The line A, which passes through the center of the cylinder, is some distance to one side of the line B, which passes through the center of the crank shaft. Some of the advantages claimed for the offset crank shaft are less liability of a back kick, reduced wear on the bearing surface of the cylinder walls, connecting rods and crank shaft, less liability of the engine to be stalled, when the car is running slowly on a high gear, and other construction facilities. The cylinder set central over the crank shaft, as in fig. 4, is the type in general use. Cylinders can be placed horizontally, vertically or at an angle, (see chart 38).

Meaning of Bore and Stroke.

The stroke is the length or distance the piston travels up and down inside of cylinder.

The bore of a cylinder is its inside diameter.

*The word "en-bloc" is taken from the French. The S. A. E. now term this word as "in-block."
†See index for "advantages and disadvantages of the T, L and I head cylinders."

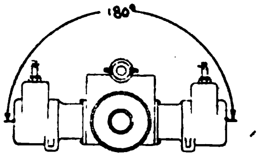

Fig. 1. Note cylinders are placed 180 degrees apart and are in a horizontal position. Termed an "opposed cylinder" engine.

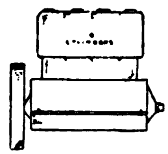

Fig. 2. Cylinders vertical-type; in general use.

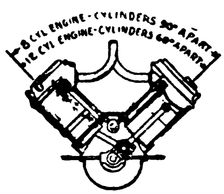
Fig. 3. Cylinders at an angle—called "V" type. Note a 180 degree crank is used on an eight "V" type, and cylinders are placed one-half of this, or 90 degrees apart.



The crank shaft on a 12 cylinder engine is a 120 degree crank, and cylinders are placed at an angle of 60 degrees apart.

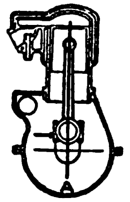


Fig. 4. Diagram of usual method of setting cylinders central, directly over crank. Note line (A)—both connecting rod and crank arm are in line.

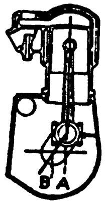

Fig. 5. The offset cylinder or Des Axe crank shaft setting. Cylinders may be L, T or round type. Note line (A)—connecting rod is in a perfect vertical position, but crank arm (B) is at an angle. The cylinder being "offset" causes this.

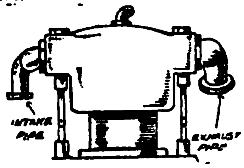

Fig. 6. "T" head type of cylinder with exhaust manifold on one side and intake manifold on the opposite side.

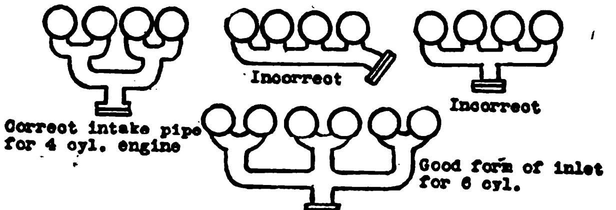
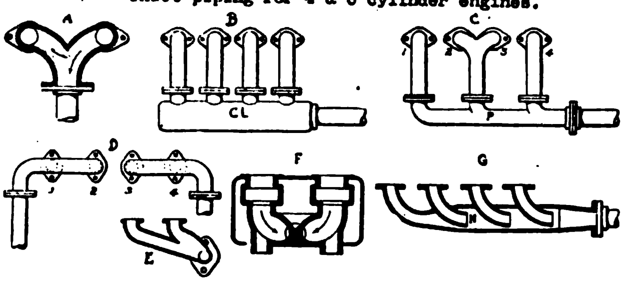
If cylinder was "L" type, the exhaust and inlet manifold would both be on one side or the valve side.



Inlet piping for 4 & 6 cylinder engines.



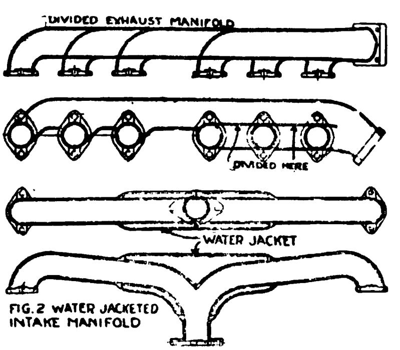
Inlet and Exhaust Manifolds.

Exhaust manifold construction: A is a good method of exhaust outlet for a 2 or 4 cylinder vertical engine.

"B;" a simple manifold in which an individual pipe from each cylinder injects directly into the large collector chamber "CL." In this manifold the collector tube is made sufficiently large so that when the exhaust valve closes, the pressure in it is less than that in the cylinder at the valve, so that there is no danger of back prèssure.

"C" shows an arrangement in which the pipes 2 and 3 for the middle chambers are formed in one, whereas they are separate for cylinders 1 and 4. This works satisfactorily in that cylinders 2 and 3 never explode consecutively, and the one pipe is capable of taking care of the exhaust of the two.

"D" is quite similar to that in "C," excepting in that there are individual pipes for cylinders 1 and 2, and 3 and 4. This is bad construction, in that 4 explodes immediately after 3, and 1 immediately after 2.



As the direction of exhaust leaving the cylinders is the same, it is very easy to make a manifold in which the exhaust pipe, instead of having a tendency to obstruct one another, assists the other cylinders to exhaust.

In engines which have their inlet and exhaust valves opposite, frequently all four of the exhaust valves are connected through one manifold with a single orifice. "F" is one example of an arrangement where it is possible to make the two passages unite. This is suitable for engines with cylinders cast in pairs. The defects of "A" and "D" can readily occur in this one; if makers were considering loss of power they would not use this one, but they only want to save space.

For the best design, illustration "G" offers a reasonable solution. In this illustration there is an individual pipe from each cylinder to the large collector. At the end, each individual pipe projects into the collector tube and curves in the direction of the exit for this collector tube.

The divided exhaust is used on several six cylinder engines with cylinders cast in two blocks of three cylinders to a block. This is claimed to prevent overlapping and refilling of the cylinders with burned gases.

The water jacketed inlet manifold is shown in the lower illustration. The water connection is with the pump circulating system, see also page 157.

CHART NO. 38—Cylinder Angles (also see page 134). Inlet and Exhaust Manifolds. Also see pages 164 and 157.

The modern type inlet manifold is jacketed to take either the hot exhaust gases or hot water, per pages 157 and 158, in order to heat the gas mixture before entering cylinder.

Square stroke; when the piston travel in a cylinder has the same length as the bore in diameter, then it is called a square stroke and bore.

†**Long stroke**: when the piston travel is much more than the bore diameter, then it is called a long stroke. For instance, a piston 4x4 inches is called "square stroke." A cylinder whose bore is, say, 4 inches and the stroke is 5½ inches, this would be called a "long stroke."

The valve chamber is that part surrounding the valve. **The valve port** is the opening for the intake or outlet of gas.

The combustion chamber is the inside upper portion of cylinder, above piston, when the piston is at the top of its stroke.

****Inlet Manifold and Pipe**—see chart 38.

The inlet manifold is the part which connects to the inlet port openings in cylinders, from carburetor. If there is only one connection to cylinder, as on a single cylinder engine, then it is called an **inlet pipe.**

When the valves are all placed on one side of the engine, as in the "L" head type of cylinder, then the inlet and exhaust manifold are both on the same side of the cylinder.

When the inlet valves are on one side and the exhaust valves on the other side, as in a "T" head cylinder, then the inlet manifold is generally on one side and the exhaust manifold on the other side.

In order that there may be as little resistance as possible to the flow of the mixture, this manifold should be as straight as the position of the carburetor will permit. There should be no sharp angle bends, the bends being as flat and easy as possible and the distance from carburetor to inlet ports as short as possible to prevent condensation.

When more than one cylinder is supplied from one carburetor, the distance from the carburetor to each valve should be the same. The inside of the inlet manifold must be smooth and clear inside so that there is no obstruction offered to the flow of gas.

In those marked "incorrect" (chart 38), the distance from the carburetor to the inlet valves are not equal, and consequently the valves nearest the carburetor will get more of the mixture than those farther away.

In the arrangement marked "correct," the distances are equal, and consequently the valves get equal quantities of mixture, and the engine will run more evenly than if the cylinders received different amounts.

Exhaust Manifold Construction.

In chart 38 exaggerated and simplified illustrations are shown in order to give the reader an idea of the different methods.

Sharp bends in the exhaust pipe cause back pressure, and should be avoided. Dirt in the pipe or muffler has the same effect, and this should be guarded against.

Exhaust Pipe and Muffler.

The exhaust pipe leads from the exhaust manifold to the muffler. If engine is an eight or twelve "V" type, there are usually two exhaust pipes and two mufflers.

In order that the exhaust manifold may be cooled as rapidly as possible, the exhaust manifold and pipe, connecting the exhaust valve chamber to the muffler, is exposed to the air.

The connection from exhaust manifold to exhaust pipe is usually made with a flange connection with asbestos packing between.

***The muffler and exhaust** pipe should be made so that there is as little back **pressure** as possible. Back pressure is caused by anything that prevents the free escape of the gas therefore sharp bends should be avoided, otherwise the incoming fresh mixture becomes mixed with that part of the burned gas left from the previous charge, and the power of the engine is cut down accordingly. The muffler is explained in chart 39.

†See page 531 for "advantages and disadvantages of long and short stroke."
**The modern inlet manifold is water jacketed or gas heated as per pages 157 and 164.

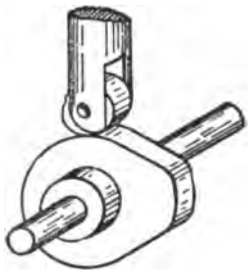

Fig. 1.—Showing the nose of cam.

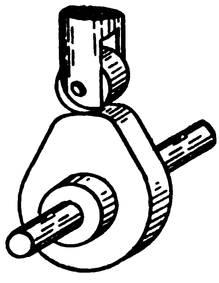

Fig. 2.—Nose of cam raising valve plunger which raises valve.

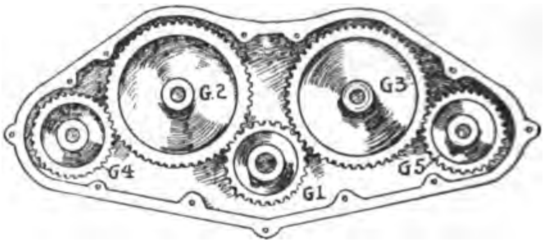

Fig. 3.—End view of the cam gears and drive gear. The two cam gears are called "half time" gears, because they revolve just one half the time or revolutions as the drive gear. G1—drive gear, on crank shaft. G3, cam gear to drive inlet cams. G2, cam gear to drive exhaust cams. G4 and G5 are extra gears to drive magneto and generator. ("T" head engine.)

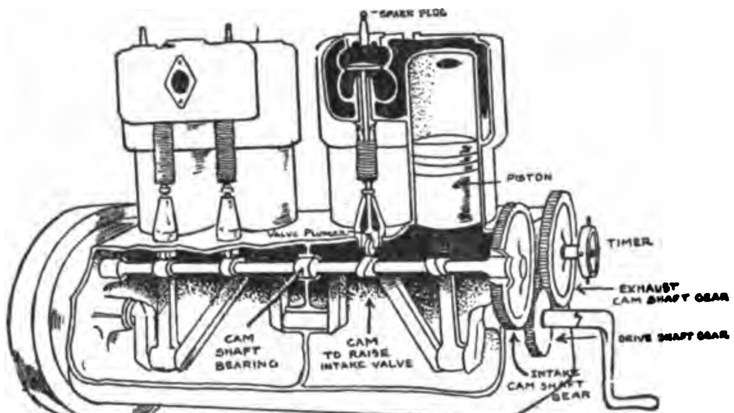

Fig. 7.—Illustrating how the cam shaft on a four cylinder engine is operated by timing gears. Also how the nose of cams raise the valves. There are two cam shafts placed opposite, therefore it would be a "T" head type.

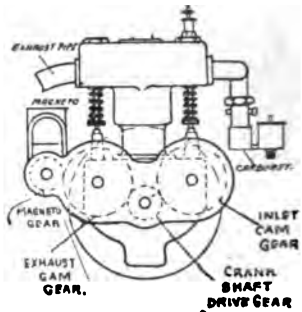

Fig. 4.—Showing method of driving the two cam shafts and magneto on a "T" head engine.

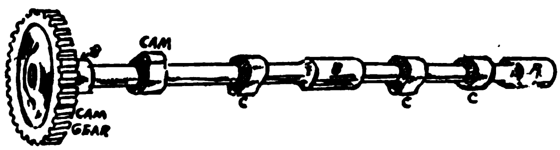

Fig. 8.—The cam shaft as used with a four cylinder T-head type cylinder. There are two shafts, an intake cam shaft and an exhaust cam shaft—one on each side of the cylinder as shown in fig. 4. There are four cams on each shaft.

The nose of the cams are placed at different positions so that the valves will be raised at a certain time. C—are the cams. B—are the bearings for the cam shaft.

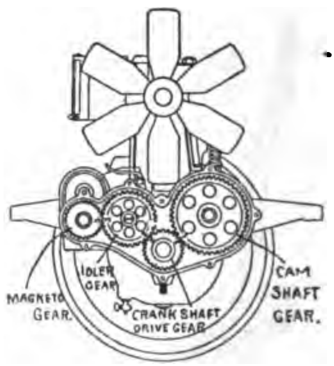

Fig. 5.—Method of driving the one cam shaft, and idler gear to drive magneto drive gear on an "L" head cylinder engine.

Fig. 9.—The cam shaft as used with a four cylinder, L-head type of cylinder. There is but one cam shaft in this type because all of the inlet and all of the exhaust valves are on the L-side of the cylinder—see fig. 5. There are eight cams on the cam shaft.

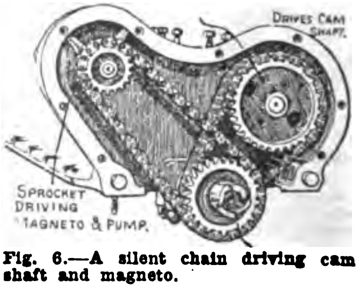

Fig. 6.—A silent chain driving cam shaft and magneto.

CHART NO. 40—Cams. Cam Shaft; method of driving.

Chart 42 on page 90.

Valve Caps.

Where valves are on the side and the head cast integral with cylinders, valve caps are screwed over the valves in the cylinder (see figs. 7, 8, page 90, also chart 32). By removing these caps the valves can be lifted from their seat and ground. There are two valve caps to each cylinder; an **inlet valve cap** and an **exhaust valve cap.**

Compression or Relief Cocks.

Consist of small pet cocks screwed into the exhaust valve caps. By opening when the engine is running, it is possible to see if any of the cylinders are missing fire. A flame will shoot out if firing. If mixture is right the flame will have a blueish color. They are also used for injecting gasoline in winter when engine is cold and hard to start—see chart 32, page 64. The S. A. E. now term this a "priming cup."

*Cams and Cam Shaft—see chart 40.

A cam is a device that produces intermittent motion. When an object is in motion part of the time and at rest between motions, its action is said to be "intermittent." A cam may best be described as a wheel with a hump or nose on one side (figs. 1 and 2), or in other words, it is a piece of metal revolving with a shaft, part of its circumference being farther from the shaft than the rest. The part of the cam that projects is called the **nose.** Anything resting against the cam will be moved only when the nose comes around to it; otherwise it remains stationary.

For a four cylinder engine, four cams on the inlet cam shaft are shown in chart 40, fig. 7. Four more cams on an exhaust cam shaft are provided on the opposite side of this engine, because it has "T" head cylinders. The cams are divided in four positions on the cam shafts, and are made in one piece or integral with the cam shaft. If the cylinder is "L" type then all cams would be on the one cam shaft—see fig. 9, chart 40.

†For each cylinder there is one inlet cam and one exhaust cam. The **exhaust cam** usually has a **broader nose** because it must hold the **valve open longer.**

The cam shaft, also called the "secondary" or "half time shaft," has a cog wheel or gear, called a *timing gear, on one end, which meshes with the drive shaft gear on the crank shaft.

When the crank shaft revolves, the drive gear on the crank shaft drives the timing gears, which drive the cam shaft and thereby rotate the cams.

The nose of the cam raises a valve lifter or tappet, which plunges against the end of the valves and raise them from their seat. When the nose of the cam is under the roller or valve lifter, the valve is held open; the valve is closed after the nose passes, by the action of a strong spring. (see page 92.)

The valve stem being held in a valve guide, cannot move in any direction but up and down. Thus the steady **rotary** motion of the cam is changed to the **intermittent** motion of the valve.

As has been shown on four cycle engines, **each valve opens only once** while the crank shaft makes two revolutions. Therefore the cam shaft should revolve only once while the crank shaft revolves twice.

‡Timing Gears and Silent Chains.

If two gears running together (or in other words, in "mesh"), have the same number of teeth they will make the same number of revolutions.

*For setting cams, see valve timing instruction No. 9. Also Dyke's 4 cylinder engine model.

†Special racing type engines, as the Stutz, page 109, have two inlet and two exhaust valves, and as many cams. The White also. This is termed "dual valves," see page 109 and 927.

‡For "adjustment of timing gears," "silent chains," etc., see index.

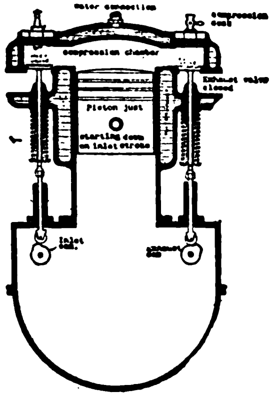

Fig. 1—Poppet Type of Valve; so named because the valve pops up and down. There are two valves to each cylinder; an inlet and an exhaust valve. This type of cylinder is a "T" head, therefore valves are on opposite sides and mechanically operated.

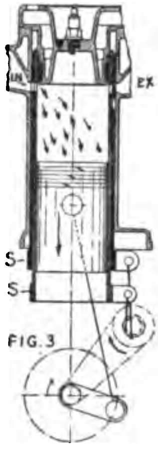

"IN" means inlet, and "EX" exhaust.

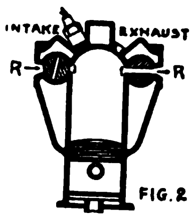

Fig. 2—The Rotary Valve—See chart 70.

Fig. 3—The Sleeve Type of Valve; there are two sleeves with openings at upper end. When these openings are together, the fresh gas is admitted or burnt gas discharged.

See pages 139 and 140.

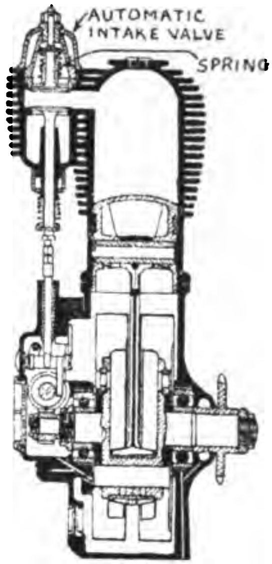

Fig. 4—Automatic Inlet Valve. Suction of piston draws the valve open against the tension of spring. Exhaust valve mechanically operated.

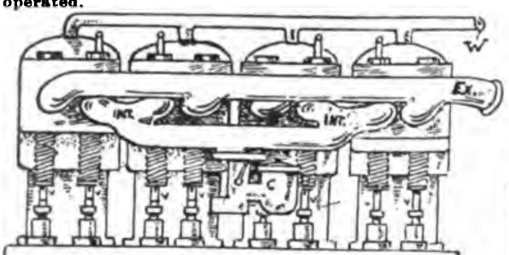

Fig. 5—Cylinders are "L" shaped, all valves on one side. Note the four inlet and four exhaust valves on four cylinders. These valves are the "poppet" type and are mechanically operated.

To remove valves; there are valve caps over each valve.

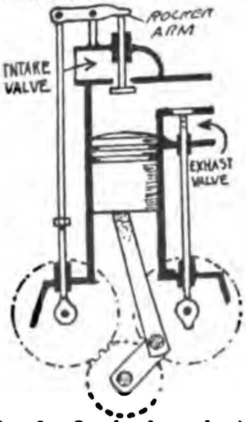

Fig. 6.—Overhead mechanically operated inlet valve and side mechanically operated exhaust valve on "F" head type of cylinder. The inlet valve in this instance would be "Cage" type (fig. 4, page 90). The cage with valve is screwed into cylinder head.

To remove the inlet valve the cage with valve is screwed out.

To remove exhaust valve a valve cap over the valve is removed.

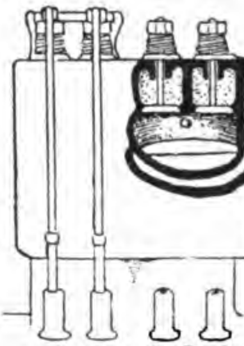

Fig. 7.—Overhead mechanically operated inlet and exhaust valve.

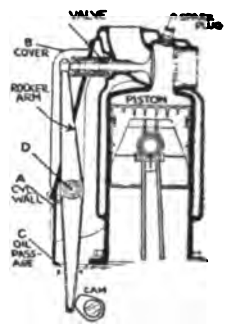

Fig. 10.—The Duesenberg principle of operating valves from the side. There are 2 inlet and 2 exhaust valves per cylinder.

Valve Operation and Location.

Valves are operated either mechanically or automatically. The inlet valves can be of the automatic type (fig. 4), but is seldom used for automobile work. It is used to some extent on the single cylinder motorcycle engine and quite often on light duty stationary engines.

The exhaust valve is always mechanically operated, in fact it could not be operated automatically by suction.

There are different arrangements for operating the valves mechanically as shown in illustrations and on page 90.

The sleeve and rotary valve would be classed as mechanically operated.

The location of the inlet and exhaust valve can both be on the side, per fig. 5, or inlet overhead and exhaust on the side, per fig. 6, or both inlet and exhaust overhead, per fig. 7. See also, page 90.

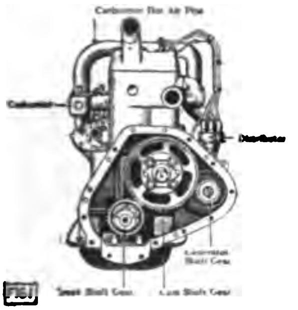
ART NO. 43—Valves; Types, Construction and Operation. See also, page 90.

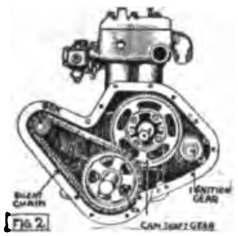
Chart 41 on page 85.

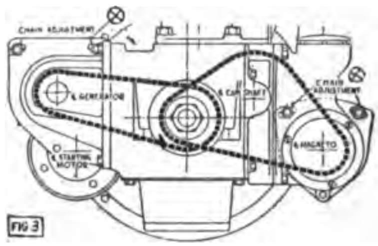
If the **driven** gear has twice as many teeth as the **drive** gear, it will revolve only once while the other revolves twice. This is called a "two-to-one" or "half time" gear.

Because the cam shaft must revolve only once while the crank shaft revolves twice, the cam shaft gear has twice as many teeth as the crank shaft drive gear. See chart 40, fig. 3, for an example—and below.

The cam shaft revolves in **opposite** direction to crank shaft when driven by gears without an idler and **same** direction when driven by a silent chain or an idler.







The wide face helical gear is most popular for the timing gears. Special material as fabroil, micarta and other compressed materials are used by many as material for making gears which are silent. Drop forged gears are also used to a great extent. Also steel for the crank shaft gear and cast iron for the cam gear.

The silent chain for driving the generator is quite popular and it is also being used to a certain extent for driving the cam shaft. The object is to obtain quieter running. This type of chain must not be confused with the ordinary roller type as used on chain driven trucks. The silent chain is more positive in action, otherwise the timing would be thrown out of adjustment.. The teeth on a sprocket used for a silent chain are very close together and accurately made.

Any undue slack in the chain can be taken up by sliding the magneto or generator shaft outwards (see fig. 3). This chain is self-adjusting for pitch.

Engine Valves.

Purpose of valves: There are †two valves to all four cycle gasoline engines; an **inlet** valve and an **exhaust** valve. By referring to charts 29 and 26 the location and purpose of the valves will be understood.

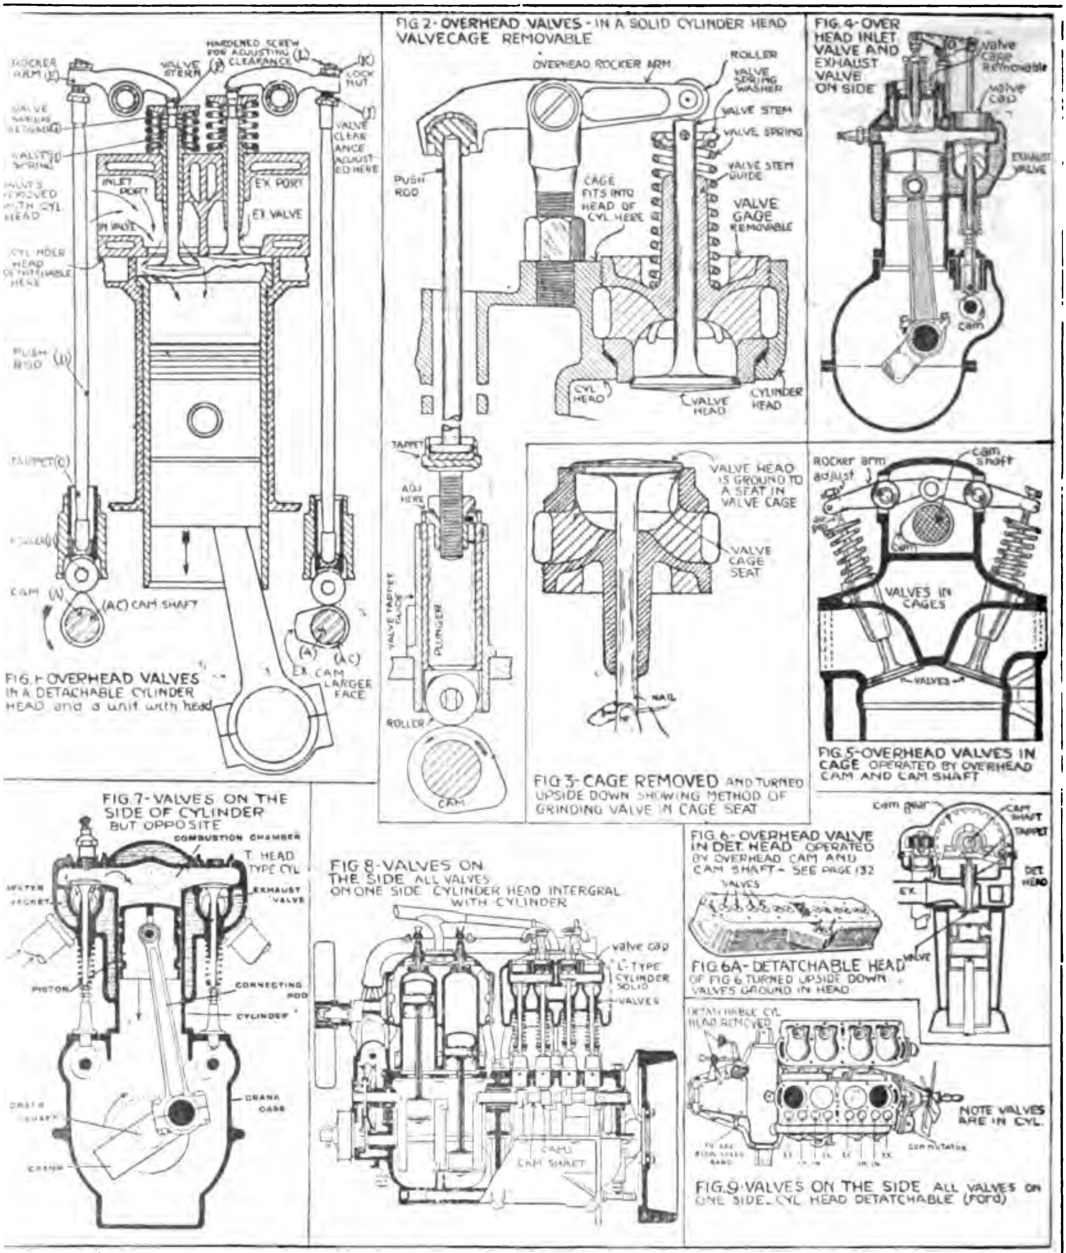
Types of valves: There are three types in general use; the "poppet," "sleeve" and "rotary" (see chart 43). The poppet type being used almost exclusively.

The inlet valve admits fresh gas to the cylinder. As fresh gas is going into the cylinder during only one stroke of every four, the inlet valve is opened during only one stroke of every four, or in other words, during one stroke of every two revolutions of the crank.

The exhaust valve permits the burned and useless gas to escape. It is opened and held open by a cam on the cam shaft. This is termed "mechanically" operated.

Direction of travel of fly wheel and cam gears: When standing behind a fly wheel on an automobile engine it turns to the left, whereas standing in front of engine it turns to the right. Also note the direction of rotation of cam gears, fig. 2, chart 29.

†There are a few engines using four valves for each cylinder, see page 109, fig. 3.



Valve construction: There are two different valve constructions in general use: (1) the **overhead;** (2) the **side.**

The overhead valve may be divided into two types; (1) the overhead valve in **a detachable** cylinder head and a unit of the head; (2) the overhead valve in a cage and a separate unit from the head.

The operation of the overhead valve may be divided into two methods; (1) by **push rods,** per figs. 1 and 2; (2) by an ***overhead cam** shaft, per figs. 5 and 6.

The side valve construction may be divided into two constructions (1) where inlet valve **is** located in cylinder head on one side and exhaust valves on the other or **opposite, as per** fig. 7; (2) where all valves are on **one side. The operation of the side valve is invariably by a** cam and tappet lifting the valve.

Cylinder head on side valve cylinders may be cast **integral** with body of cylinder as per **figs.** 7 and 8 or **detachable** as per **fig.** 9.

A combination overhead and side valve arrangement is shown in fig. 4. **This type is** called the "F" type. The head could be **detachable** with valve in the head, or **cage** type with head integral with cylinder. With this type, the usual method is to operate the inlet overhead, and the exhaust from the side, both being operated from a single cam shaft.

IART NO. 42—Valve Construction and Relation of Valves to Cylinder. Chart No. 44 is on page 94.

*he overhead cam-shaft with overhead valves is the popular method used on airplane engines—see pages 911 to 916.

Mechanically operated valves are opened and held open by means of cams and closed by means of a strong spring. (see chart 44.) The exhaust valve is **always mechanically operated.**

Inlet valves are generally mechanically operated, but some of the old and motorcycle type of engines have valves of the "automatic" type.

Automatic operated valve is held against its seat by a light spring—see **chart** 43, fig. 4. During the suction stroke, the sucking action of the piston **as it travels** downward in the cylinder, draws the valve open. At the end of **the suction** stroke, when the suction ceases, the spring forces the valve disc **back** to its seat, and the gas is prevented from escaping through the valve.

It must be understood that the valves of a gasoline engine always open inward. Thus the pressure from the power and compression strokes tends to keep them firmly on their seats.

Usually inlet and exhaust valves are made the same size. Some manufacturers are making the inlet larger, for instance the Sterling engine has 1¼ inch inlet valves and 1⅛ inch exhaust valves. **The lift of a valve** is the height it is raised from its seat by the cam.

Valve Operation and Location.

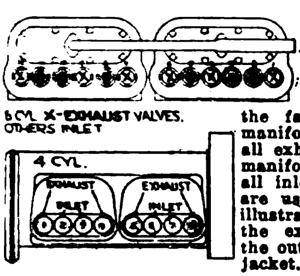
The "mechanically" operated "poppet" type valve is the type in general use, therefore we shall confine our attention to this type.

Valves are operated; or opened by the intermittent motion of a cam and closed by a strong spring, as explained under "cams" on page 87.

****The cam shaft may be overhead or on the side,** as per page 90.

The location of the valves are **overhead** or on the **side** as per page 90, or a **combination** as per fig. 4, page 90, which is termed the "F" type.

Overhead operated valves may be in a detachable head of cylinder or in **cages** as per figures 1, 2, 5 and 6, page 90.



On "L" head type of cylinders, all inlet and exhaust valves are on one side, but they do not run consecutively. Owing to the fact that the exhaust manifold must connect with all exhaust valves and inlet manifold must connect with all inlet valves; the valves are usually arranged as in illustrations above. Note the exhaust is always on the outside next to the water jacket.††

Illustration at top, is that of a 6 cylinder engine. The one at bottom, 4 cylinder.

Side operated valves may be placed all on **one side,** or **opposite sides** of cylinders. When on opposite sides, two cam shafts are necessary; one on each side—see fig. 7, page 90. When all valves are on one side or overhead; one cam shaft is sufficient—see figs. 8, 1, 2, 4, 5 and 9, page 90.

†To grind valves in an overhead valve engine with detachable head, the head is removed, and valves are ground in the head (fig. 6A, page 90)—unless valves are in a cage.

To grind valves in an overhead valve engine with "cage" type valves, the valve is ground in the "cage" as per fig. 3, page 90.

To grind valves on a side valve engine, the **valve caps** are removed if head is integral with cylinder as per figs. 7 and 8. If head is **detachable** as per figure 9, then **head is removed** but valves are **ground in their seats in the cylinders.**

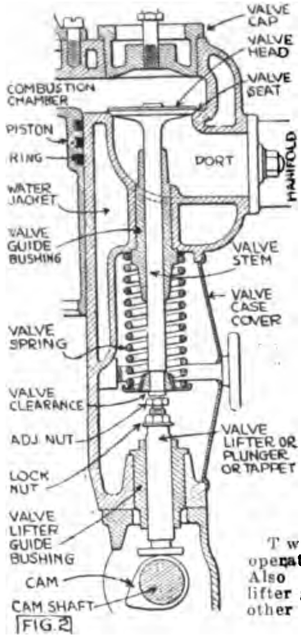
Although the valves vary in location and methods of operation, the principle or purpose remains the same; the inlet to **admit fresh gas,** and the exhaust valve opens at the correct time to **expel** the **burned gas.**

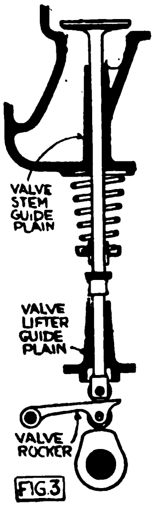
*Valves are made of cast iron electrically welded to a steel stem. They are also made of nickel steel or Tungsten steel. The latter being considered best.

†See index for "valve grinding." **See foot note page 90. ††The spark plugs (S) are usually placed over inlet valves, per page 121.

Valve Parts.

A "poppet" type valve has three parts; a "head;" a "stem," which forms the moving part, and a "valve face" which seats into a "valve seat." This valve face is beveled and is perfectly round. When seated, it must fit the





Two methods of operating valve-lifter. Also note valve and lifter guide; one plain other bushed.

valve seat perfectly tight, otherwise during compression stroke the gas would leak, and on power stroke, a loss of power would result, by the valve leaking at the seat. Therefore it is ground to this seat.

The valve-spring holds the valve tight in its seat and must have sufficient tension at all times (see page 635). If too strong, the valve will close with more noise. If too weak valve will not seat properly. The exhaust valve spring usually weakens first on account of greater heat.

The valve-spring-retainer-and-lock, formerly called valve spring washer, is placed at bottom of spring and held in place by a two part lock. Formerly a "key" passed through a hole in the valve stem (see page 630, fig. 1).

Valve-face is the beveled part of valve head. **The valve-seat is the part of cylinder head in** which valve face is placed. The valve face and seat can be "conical" or "flat." They are usually conical as per fig. 2 above, and fig. 7, page 94. **Valve head** is upper part of valve stem.

Valve-stem is the stem part of valve head.

The stem of a mechanically operated valve on "L" or "T" head cylinder of the "side valve" principle, usually extends about half way down to the cam shaft. A valve-lifter then lifts the valve stem by action of a nose on cam as cam revolves. (See page 87.) To set this cam, to raise valve at the proper time, is called "valve timing."

On engines with overhead-valves, there is a rod, called the "push rod," between valve lifter and rocker arm, see fig. 4, page 94.

Valve-clearance also called "air-gap," is the distance between lower part of valve stem and valve lifter. On the push rod type, it is usually between rocker arm and end of valve stem. This distance is regulated by an adjusting nut.

Valve-lifter, also called "valve plunger," "valve tappet" and other names, is the part placed between valve stem and cam. The top part has an adjustable screw which can be slightly raised or lowered to get correct valve clearance.

The bottom of this valve lifter is sometimes fitted with a "roller," per fig. 3, page 94. The "mushroom" type, fig. 2 above, and figs. 1 and 2, page 94 is the type used most.

A valve-rocker—upper, is used on overhead valves, also called "rocker arm;" **a valve-rocker —lower, is the principle shown in fig. 3. It is** also called a "side tappet lifter." The latter is seldom used.

A valve-stem-guide holds the part through which the valve stem passes. Sometimes it is "bushed" as shown in fig. 2, also see **page 634,** fig. 7. Quite often it is plain as per fig. 3.

A valve-lifter-guide (also called "plunger" and "tappet" guide), is shown in fig. 2, which is fitted with a bushing and can be renewed when worn. It is bolted, sometimes screwed to crank case (see also page 54). In fig. 3, a plain guide is shown.

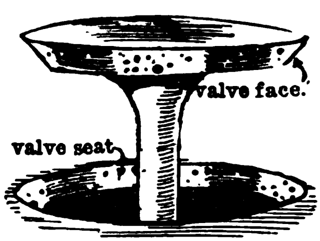
Enclosed valves are where a cover fits over valves (fig. 2). This deadens the noise of lifter striking valve stem and keeps out dust. Also see page 121.

Although valves may be placed overhead, or a combination, as overhead and on the side—the principle of operation is very much the same. (see page 90.)

**Purpose of Valve Grinding.

The exhaust valve is surrounded by flame when open, and will become "pitted" in time, as per (fig. 4).

The exhaust valve requires more grinding than the inlet valve because the hot gases pass out between the valve seat and valve face when valve is raised. When the valve is opened, there must be sufficient space to let the burnt gas pass freely.



The inlet valve, admitting gas instead of ejecting a flame does not pit as badly as the exhaust valve.

In a perfect seated valve, the valve face and seat are smooth and even, with dull gray surface. **A pitted valve** is rough, uneven, and full of tiny holes, and cannot come to a tight seat. Therefore valve must be ground.

The process of grinding a valve is the placing of a grinding paste between the valve face and the seat, and the revolving of the valve until the roughness is worn down. See index for "valve grinding" and "valve re-seating."

*The "tulip" shaped valve is another type of inlet valve seat but now seldom used—see page 128.

**See first paragraph this page and pages 628 to 632. *See foot note page 94 for valve material.

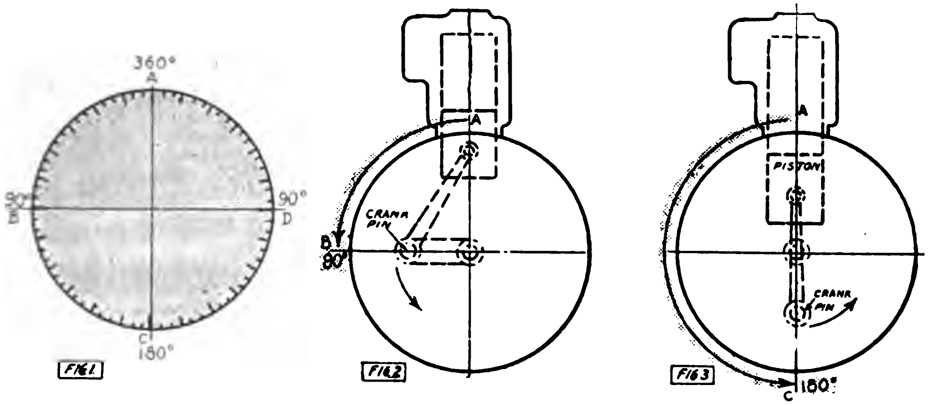


Fig. 1. Example; suppose we take a fly wheel and divide its circumference into 360 equal parts; each part would be a degree—expressed with a small "o" as 360°.

In fact, any perfect circle can be divided in degrees. The crank shaft revolves in a circle, therefore we will designate the travel of the crank shaft in degrees.

One half of the circle would be 180°, which would represent a stroke of the piston, or a half revolution of the crank. One quarter of the circle would be 90°, one third of the circle would be 120°.

Any circle, or say, travel of the crank pin, would represent 360° when it made a complete circle or revolution.

Fig. 2. Example; piston has traveled down from upper dead center, one quarter of the circle or one-half of a stroke; crank pin and fly wheel have turned 90°.

Fig. 3. Example; piston has traveled from top dead center to bottom of stroke, or one half of a revolution; fly wheel and crank pin have traveled 180°.

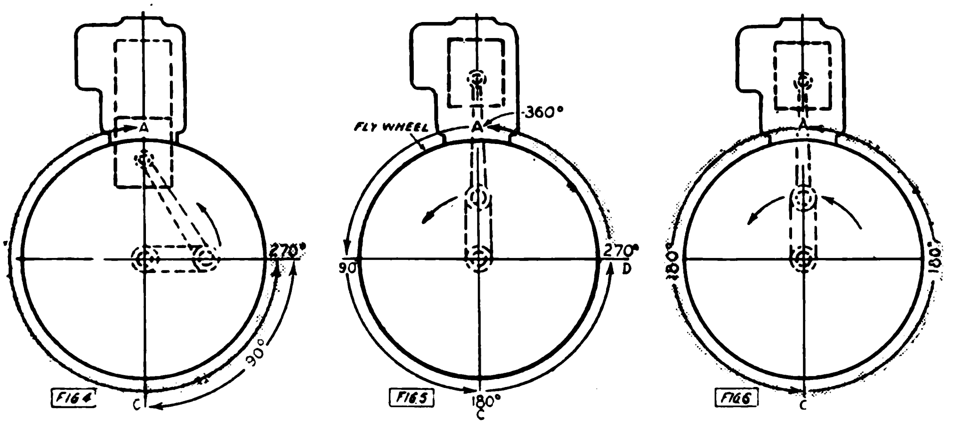

Fig. 4. Example; piston has traveled up from bottom. one-half of a stroke; crank pin and fly wheel have traveled one quarter of a circle from bottom or 90° from C to D. In all, the crank pin and fly wheel have traveled from A to D, three quarters of a revolution or 270°.

Fig. 5. Example; the piston has made two strokes, one down and one up, therefore crank pin and fly wheel have made a complete revolution or traveled 360° in all.

The idea is to learn that the crank pin travels in a circle and the fly wheel travels in a circle, and a revolution is a complete circle, and a complete circle is 360°.

The piston travels in strokes, each stroke representing a half revolution of crank.

If we spaced off 360 marks, equal distance apart, on any circle, then each mark would be called a degree. In fig. 1, we have spaced off the marks as 5 degrees each.

Now we can divide each degree into say, sixty equal distances apart and call each part or mark, a "minute."

We could go still further, and divide each minute into sixty equal distances apart and call each part or mark, a "second."

A minute is usually expressed with a single mark after the figure, as, 25′.

A second with two marks, as, 25″.

Example; express, ten degrees, six minutes and five seconds. It would be as follows; 10° 6′ 5″.

Note—To find the circumference of a fly wheel; multiply the diameter in inches by 3.1416. If the circumference is then divided by 360, the distance or portion of the fly wheel circumference equivalent to one degree may be ascertained.

CHART NO. 45—Explanation of the Meaning of Degrees, Minutes and Seconds. Note; **Crank Shafts** on Engines usually turn to the right—(When in front). On above illustrations **we are supposed** to be standing in the rear of fly wheel, turning it to the left which would **cause crank shaft** to turn to the right (from front).

Chart 43 on page 88.

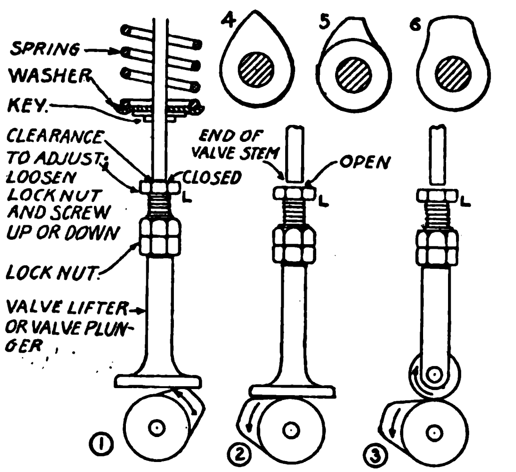

Fig. 1-2.—Mushroom type of valve lifter.

Fig. 3.—Roller type valve lifter.

Note in Fig. 1; valve just starting to lift. Figs. 2 and 3, valve just closed.

Exhaust cams usually have broader nose than inlets, because the exhaust valve remains open longer.

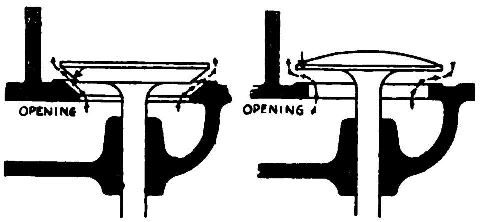

Fig. 7.—Note the "flat" and "conical" type of valve. It is said, the flat valve gives greater opening for the same valve lift and has greater possibilities for high speed work, however, it is seldom used.

*Valve Clearance Adjustment.

This subject is explained on page 110. **An example of adjusting the valve clearance on a "side valve" engine will be given here.**

Valve clearance means the distance between the end of valve and the end of tappet or plunger which lifts it.

When an engine becomes noisy and a clicking noise is heard, the trouble is likely in the valve ends having worn or the adjustment nut become loose.

This adjustment can usually be made by screwing up on the adjustment screw (fig. 5) and then locking the position with lock nut.

The clearance is necessary in order that the valve seats properly and should usually be from .003 to .005 of an inch **when engine is cold.**

The adjustment should always be made—after the valves of an engine are ground or when checking the valve timing—see also, pages 635, 785.

The procedure to adjust is as follows: turn fly wheel of engine over until the other tappet and valve in the same cylinder is up as far as it will go, or the valve wide open. The first valve will then be closed. As previously stated there should be from .003 to .005 of an inch between the head of the tappet screw and the end of the valve stem.

If it is found that the clearance is not right, loosen the lock nut on the tappet screw and turn the screw up or down as may be required to obtain the correct clearance.

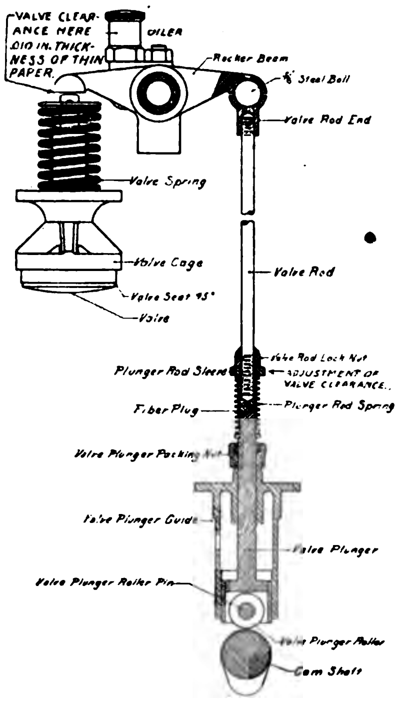

Fig. 4. Valve-clearance on valves-in-the-head is measured between end of rocker-arm and top end of valve, as above. **Adjustment** is made on lower part of valve rod on the Dorris, as above. On the Marmon, adjustment is at the top of rod as per J, fig. 1, page 90. On the Buick, at the top, per page 109.

It is best to use a "thickness gauge" (page 700), but if a gauge is not obtainable a piece of newspaper will serve as a gauge, a sheet of ordinary newspaper is between .002 and .003 of an inch in thickness.

After the tappet screw is adjusted so that the clearance is correct, tighten the lock nut.

"Back lash" or lost motion in the cam shaft driving gears should be taken up in direction of rotation when clearance is adjusted.

A noisy valve tappet, caused from wear, and where no adjustment is provided, can be, in some instances repaired by placing fibre or steel washers under or over valve ends.

To adjust valve clearance on overhead valve engines—see fig. 1 on page 109.

The opening and closing time of the valve is not when the lifter begins to rise or comes to rest but when it makes or leaves contact.

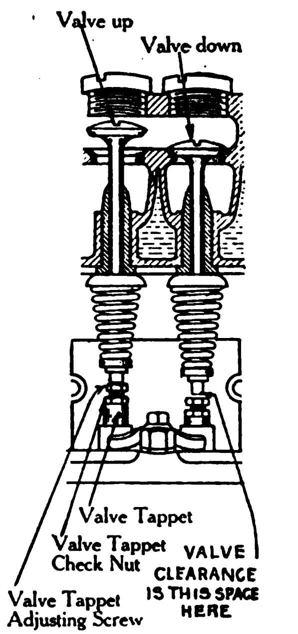

Fig. 5.—Type of valves on side of "L" head engine—clearance is adjusted as shown in illustration. (Hudson six.)

Grinding and Reseating Valves.

If valves become pitted and leak, they need re-grinding. If warped or shoulders form in the seat, then the seat and valve ought to be refaced. See index "Grinding Valves," "Reseating Valves."

CHART NO. 44—Valve Clearance. Valves and Cams. See repair subject and index for valve grinding. See page 542 for valve timing of different engines.

(Chart 46 on page 100). *See pages 631, 634 and 630.

INSTRUCTION No. 9.

*VALVE TIMING: Valve Clearance. Meaning of Degrees. Periods of Travel of Cam during the Four Strokes. Examples of Valve Timing.

Before the reader can thoroughly master the subject of valve timing he must first **learn the four cycle principle** as explained on page 57 to 59, as it is with this principle we will deal. In addition to the above, the **meaning of degrees** as explained in chart 45, and the **relation of the valve cam speed to the engine crank shaft speed** and the importance of **valve clearance adjustment** must be thoroughly understood.

Valve Clearance and Lift of Valve.

If no space was left between the end of valve stem and the cam, even very slight wear of the stem and seat would prevent the valve from closing properly. Furtherfore there must be some cognizance taken of the expansion due to heat. As the stem expands, it gets longer so if no clearance were provided the stem would rest against tappet and be unable to seat properly.

****Valve clearance, also called "air gap" space, is the space between the end of valve stem and the lifter or plunger.** The width of this air gap ranges from the thickness of tissue paper to 1/16 of an inch. The average gap is somewhere about or slightly less than postal card thickness (see index; Standard Adjustments of Leading Cars).

Some manufacturers give about 1/1000 of an inch less space to the inlet than the exhaust, because the exhaust valve stem lengthens more; due to greater heating. For instance, Hudson gives .004 of an inch to the "air space" on the inlet valve and .006 to the exhaust.

The adjustment should always be made with engine **cold** and **after** the valves are ground, as the grinding may slightly lower valve.

The valve lift: the inlet cam has a sharp nose. The exhaust cam has a broader nose, because it must hold the valve open longer. The height of the nose **less the air gap,** regulates the lift.

The average lift of either exhaust or inlet is approximately, 3/8 or 9/32 of an inch. It is thus evident that if the air gap is 3/8 or 9/32 inch too large, the valve will not open at all.

Now if the air gap (3/8 inch) is slightly decreased, the valve will lift very slightly and stay open but a few degrees. If the air gap is again slightly decreased, the valve will open sooner, raise higher and close later. This process can be repeated until there is no air gap left.

Therefore, suppose an engine was designed to have 1/16 inch air gap and there was no air gap at all; the valves would open possibly 50° too soon, raise 1/16 inch higher than intended and close 50° too late.

As to wear of end of valve stem or tappet; it is apparent that as the wear increases, the space or air gap increases and valves will have **less** lift, **open late and close early** and become more noisy. All of which will affect the power of engine.

*For valve grinding and other repairs, see "repairing instruction."

The study of valve timing will be simplified if the reader will refer to Dyke's four and six cylinder engine models. **Valve timing** of leading automobile engines given in "Standard Adjustment of Leading Cars," see index. **A table for converting degrees** into inches, and fractions of hundredths into sixty-fourths of an inch is given in chart 51, page 115.

**On actual tests it has been found that by adjusting the air gap properly almost double compression and more than double power has been secured.

When valves are noisy the cause can usually be traced to the wear of valve stem, although they are case hardened at end as well as the head of tappet, the wear however, will come in time. Too great a lift will also cause noise.

Remember; always adjust valve clearance according to measurement given by the manufacturer.

It is essential that the valve clearance adjustment be made **with the "back lash" or lost motion in the driving gear entirely taken up** in direction of rotation.

Remarks on Inlet Valve Opening and Closing.

We have explained that the valves are raised by means of cams operated by a cam gear placed on the front of the engine in mesh with a gear on the crank shaft.

Inlet valve opening: if, when one of the cams raise an inlet valve just as the piston is starting down on the suction stroke, then a charge of gas will be drawn into the cylinder as long as the piston is on the suction stroke and the valve is open.

Therefore the valve ought to open in time to give the piston a chance to draw in **a cylinder full of gas.**

If the valve were to open much after the time the piston was starting its suction stroke, then it would not get a full cylinder of gas, and thereby give less power.

Therefore it is important that the inlet valve be made to open exactly at the **right time**, and the method employed to cause it to open at the right time is through the inlet valve timing gear and the proper valve clearance (see pages 94 and 95).

The practice is to allow the piston to descend slightly in the cylinder on the suction stroke before the inlet valve opens, so as to reduce the pressure and create, if anything, a vacuum which causes a greater suction.

Inlet valve closing: when we come to the closing of the inlet valve we find the practice almost universal of leaving the valve open until the piston has not merely reached bottom dead center, that is, the bottom of the stroke, but has actually traveled slightly up on the compression stroke again.

It seems as though the gas already sucked in would be forced out again, but we are forgetting the speed of the engine—15 complete cycles of operation in one second, or one stroke of the piston to a one-sixtieth part of a second; such a speed that the piston has reached the bottom of its stroke an appreciable time before the gas has been able to fill the cylinder, so that even after the piston has started to move upward on the compression stroke, there still remains suction in the cylinder which, if the valve remains open, will continue for a short interval to draw in a further charge of gas.

Obviously the exact point at which the inlet valve should close depends upon the speed of the engine, and whatever setting is arranged, it will not be equally suitable for all the speeds attained by one engine.

As, for instance, when the engine runs dead slow, the late closing would be a distinct disadvantage—the gas being partially driven back on the compression stroke, while at maximum speeds the valve will close before the suction has finished its work.

However, there is an average speed for every engine, and the valves are set to it accordingly.

Remarks on Exhaust Valve Opening and Closing.

Exhaust valve opening: when we come to the opening of the exhaust valve, there are no two opinions about it.

The valve must open considerably before the piston reaches the end of the explosion stroke, and if this wastes some of the force of the explosion, it is amply compensated for by the freedom afforded the piston in commencing the exhaust stroke.

It would obviously be wrong to keep the exhaust valve closed up to the very moment before the piston is about to move upward, because on commencing the exhaust stroke it would find itself confronted for an instant with the force which had just driven it down, and until the valve was wide open, it would be considerably impeded on its journey.

So the exhaust valve is usually opened as soon as the piston has moved through about seven-eighths of the power stroke; that is, before bottom dead center.

Exhaust valves opening too early causes a waste of power. Stationary gasoline engines, which run at much lower speeds than automobile engines, do not hold their valves open so long, the chief difference being in the times of exhaust opening and inlet closing.

Other effects of valve timing are dependent upon the short or long stroke, the side valve, as in the "L" head, the opposite valves as in "T" head, and the overhead valves, high and low compression. All this must be considered in valve timing.

The term "valve timing" refers solely to the points at which the valves open and close and does not in the present section include the **height** to which they lift. (see page 95.)

The most sensitive point in the cycle of a four cycle engine is the **top center position**, between the exhaust and induction strokes, for the reason this is the critical scavenging point.

At a certain point **before the bottom** of the firing stroke, the **exhaust valve is opened**, and kept open during the succeeding exhaust stroke, to enable the ascending piston to expel as much of the exhaust gas as is within its sphere of action, but, having come to rest at the top of its stroke, there is still the contents of the **combustion head** yet to be dislodged.

Exhaust Valve Closing.

As to when the exhaust valve should close, there is but little to be said about it. Suffice it to say that it may not close before the end of the stroke.

As a rule on account of what we have explained about the gas which remains in the head of the cylinder being slightly under pressure at the end of the stroke, the valve is quite often allowed to remain open until the piston has moved slightly down on the induction stroke, so as to give full opportunity for as much exhaust gas to escape as possible.

In order to understand just how important it really is to expel all of the burned or exhaust gas, it must be explained that one of its chief constituents is **carbon dioxide**—which is the most powerful anti-combustion agent known to science. Its presence, therefore, even in small quantities, retards considerably the speed of the explosion development.

The piston now having come to **rest at the top**, we are still faced with the problem of dealing with the volume of burned gas which remains, and for the expulsion of this we must take advantage of exhaust momentum.

The manner in which this principle operates will be apparent if the contents of the exhaust pipe is pictured as a mass of gas moving outwards with explosive velocity. When the influences which started this movement have ceased—namely, at top centre—the gaseous mass will function almost like the piston of an extractor pump, and if the valve timing permits of it will tend to withdraw a large proportion of the residual gases from the cylinder head.

It will now be obvious from the foregoing that, if the extractor action of the exhaust gases is to be taken advantage of, **the valve must be made to close a little later than "top center,"** or—as it is technically described—must have a certain degree of "lag;" for it is evident that if we close it at the exact top of the stroke the contents of the combustion head (which we wish to get rid of) will be imprisoned and will **contaminate the incoming charge.**

The amount of this "lag" will depend on several things—the shape of the combustion head, the weight of the valve, the strength of the springs, and design of the exhaust system.

Valve Effect of "Lag" or Bounce.

As regards valve spring, strength and weight, this has to be reckoned with on account of its influence on inertia lag as distinct from that which is intentional, for it is well known that as the speed of the engine increases the valve tends to "jump" the closing face of its cam and closes later and later as the speed increases. This is what we describe as "inertia lag." There is a point however, past top center that the exhaust extraction lasts, and pending this extracting effect the valve should remain open, but if carried beyond this point, a reverse of the exhaust gases may occur, for it must not be forgotten that the piston has now started down on its suction stroke. It becomes a question therefore, of closing the valve when the scavenging is as complete as possible.

*The best design of cylinder head for an "overlap" is the round or "I" head with overhead valves; the ordinary "L" head is not so good, and in certain kinds of heads in which the inlet and exhaust valves are small and close together in a small pocket an overlap is quite useless.

On the other hand, it has been found in racing practice, where the exhaust pipe is very long, straight and open, and the combustion head suitable for scavenging, that a very considerable overlap can be allowed with advantage.

In some instances however, the exhaust valve is made to close on top, for instance, the Locomobile engine which is a "T" head type (see page 108).

What Governs the Valve Timing.

The different size of cylinder, especially in the stroke and in the type of ignition, shape of manifold and the speed of engine, govern the valve timing.

Early setting of valves on an engine will cause irregular running at lower speeds, unless a very heavy fly wheel is used. It will also increase the gasoline consumption in short stroke engines.

For high speed work, the inlet may be opened and closed late. **For slow speed work,** closing the exhaust and inlet on center, gives the best control, and no blowing back.

The time of opening and closing of valves with reference to the engine speed, of course has an important bearing on its performance. **If the valves open too early it will cause back-firing,** while if they open too late a sluggish engine and overheating will result.

High speed (short stroke) engines, have a longer time of valve opening than medium or slow speed engines. The slower speed engines have the exhaust opening and the inlet closing, nearer to bottom center, while some high speed engines open the exhaust 65° before bottom center and close the intake 70° after bottom center.

Valve timing of different engines will vary according to its intended average speed and the length of stroke. Long strokes are for slower speed engines than short strokes. Obviously high-speed engines are not efficient at slow speeds, because the inlet closes too late and the exhaust opens too soon, thus losing part of the charge and part of the power stroke. And slow speed timing on a high speed engine does not permit of receiving a full charge nor of getting rid of the back pressure during the exhaust stroke.

The value of the design of the cam, can and nearly always is, lost through improper valve clearance or air gap adjustment (see pages 95-107).

*See index for "Compression"—for relation of compression to cylinder head.

Many people who think, because an engine is new or has just been overhauled the timing must be right,—will have a sad awakening if they will only spend a few minutes in verifying the timing.

Most cam shaft gears or fly wheels are marked to insure proper meshing of gears or checking on fly wheel and proper location of the cams. Some times carelessness at the factory in marking this gear may mean that after the first removal of the gear, it will be replaced wrong, because the marking is wrong (see pages 102, 112, 113).

Periods of Time Valves are Usually Open.

Before taking up this subject in detail we shall again review the relation of the speed of crank shaft to cam shaft and get the name of the parts clearly in mind.

A stroke, is the movement of the piston from the top to the bottom, or from the bottom to the top. This motion is called reciprocating motion of piston. When the piston goes from either top to bottom or bottom to top, the crank shaft turns **one-half of a revolution.**

Therefore, **four strokes** of the piston would represent **two revolutions of** the crank shaft.

The cam shaft turns one-half as fast as the crank shaft, because the cam gear is twice the size of the crank shaft gear which drives it.

***The nose of the inlet cam is usually shorter on its length of face than the exhaust cam.** Because the exhaust cam holds the valve open much longer period of time than the inlet cam holds the inlet valve open.

The cams which operate the valves are steel forgings, turned and ground to correct shape. They are then case-hardened to decrease wear, and **are usually** an integral part of the cam shaft.

The shape of the cam determines the actual lift of the valve and the time during which it shall stay open. Chart 44, page 94, shows how cam contours are plotted and several generally used shapes.

Cams which are pointed give a slow opening and slow closing, the greatest opening being at the middle of the valve lift period.

Cams which are more nearly square, open the valve rapidly, keep it nearly wide open until ready to close and then allow it to close quickly.

It is usual to so design the positioning of the cam shaft and valve tappets that the tappets are not directly over the center of the shaft, but are offset slightly on the lift side. This gives a more direct lift instead of a side thrust as would be the case if they were centered.

In actual practice, the inlet valve seldom opens on top, as shown in chart 26 (page 54) but usually **after** the top of stroke, varying from 5 to 15 degrees as explained in fig. 1, chart 46.

The inlet seldom closes when piston reaches bottom, but from 5 to 38 **degrees after** the bottom. (See fig. 2, chart 46.)

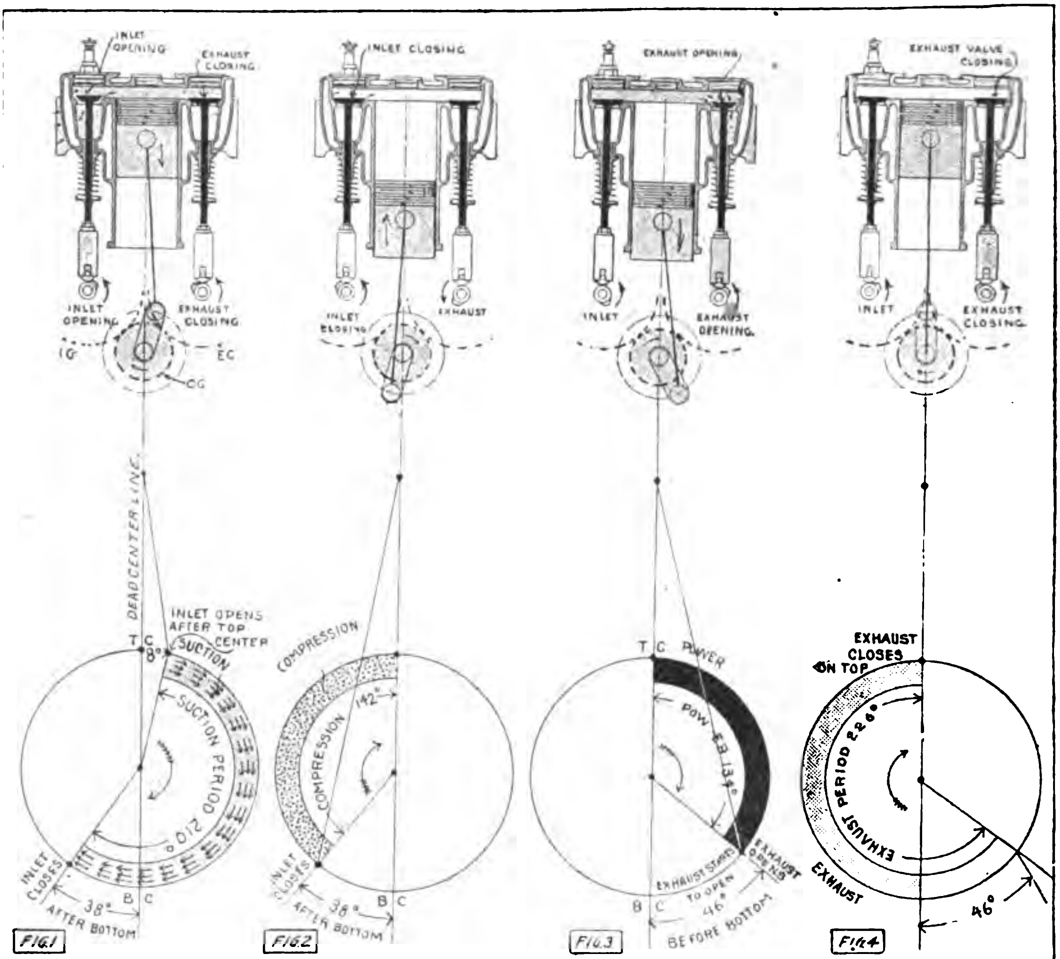
The exhaust valve seldom opens on bottom, but usually 40 to 50 degreees **before** bottom (fig. 3).

The exhaust valve seldom closes on top of stroke, but usually 5 to 10 **degrees after** top. (In fig. 4, chart 46, illustration shows exhaust valve closing on top, in order that reader will more clearly understand the illustration.)

The cam turns the same speed as the cam shaft. The nose on the cam **raises** the valve. Therefore the **inlet** valve will be raised **once** during the **four** strokes, and the **exhaust** valve will be raised **once** during the four strokes.

***A point which suggests itself on the timing of the inlet opening, and which also holds true for other operations on the timing circle, is in the securing of a quiet cam. Quietness in the cams is generally secured at the sacrifice of power. A steep cam is as a rule more noisy and more powerful than one giving a slower opening.**

To secure the full opening of the inlet valve at a point which will not be too late to permit a full charge to be taken into the cylinder, and yet at the same time to have a cam which will not be noisy, means that the inlet opening will have to be started fairly early. This is one of the points which often induces a maker to sacrifice the vacuum to some extent for the sake of quietness.



Example: Inlet opens 8° after top, closes 38° after bottom. Exhaust opens 46° before bottom and closes on top.

Fig. 1: Inlet Valve Starting to Open 8° after top center ("TC") (viewing engine from front); note the inlet will remain open during suction period until crank is 38° after bottom center ("BC"). The period of travel of the crank during suction period is 210°. The inlet valve is open during this period.

Fig. 2: Inlet Valve has Closed and piston will now travel up on compression to top center ("TC"). The period of travel of crank during compression period is 142°.

Fig. 3. The Spark Occurs at Top (in actual practice, just before the top), therefore, the next stroke down will be **power stroke.** Note the period of travel of crank pin during power stroke is only 134°, as the exhaust valve starts to open at 46° before bottom. Note exhaust cam just starting to open exhaust valve.

Fig. 4: **Exhaust Opens 46° before Piston reaches bottom. The Exhaust Valve Remains Open** during a period of 226°; crank traveling from 46° before bottom, to bottom, thence to top ("TC"). In this instance the exhaust valve closes on top or dead center. In actual practice it usually closes a little after top dead center, about 7 or 8°.

Observe Position of cams during the various periods. The cam turns ½ the speed of crank shaft, therefore, if crank shaft revolves **twice** to complete the four strokes, then the cams will revolve **one** revolution.

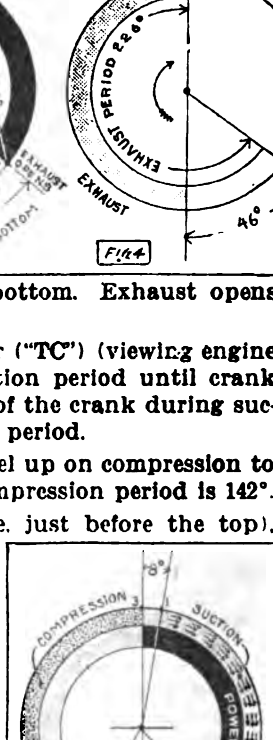


Fig 5, illustrates all the above in one illustration.

CHART NO. 46—Explanation of Period of Suction, Compression, Explosion, Power and Exhaust. (View from front of Engine.)

Chart 45 on page 98.

By referring to fig. 5, chart 29 (page 58), note inlet cam on first stroke will be in position of (1), and will turn from 1 to 2, or 90 degrees during the first stroke.

Exhaust cam will be in position (2) and will turn from 2 to 3, or 90 degrees during the first stroke.

During each stroke the cam moves 90 degrees, whereas the crank moves 180 degrees.

Inasmuch as a stroke of the piston is from top to bottom, or 180 degrees travel of crank, it will then be necessary to distinguish the difference between the time of opening and closing of valves and the period of travel of the crank shaft during the four actions of suction, compression, explosion and exhaust periods. (See chart 46).

Meaning of Valve Lap.

The word "lap" is used often in connection with valve timing, also firing order of cylinders.

In speaking of firing order of cylinders we speak of one cylinder "lapping" another, for instance, on a certain eight cylinder engine there are eight periods of 44 degrees travel of crank when two cylinders are on power, or "lapping" at the same time.

In using the word "lap" in connection with valve timing, it means the period of time that both valves are open at the same time, or -|- (plus lap).

We will divide the laps into "zero lap,"—(minus) lap, and -|- (plus) lap.

Zero lap: If the exhaust valve closed just as the inlet valve started to open, we will term this, "zero lap" (no lap at all).

The "zero lap" means exhaust closes at the same time the inlet valve opens. With zero lap there is no vacuum in the cylinder at time of inlet valve opening.

Minus lap: If the exhaust valve closed before the inlet valve opens; this we will call "minus lap," designated with a (—) mark.

The "— minus lap," which is the general condition used on most engines, the exhaust closes an appreciable period before the inlet opens. This permits the piston to descend slightly on the suction stroke before the inlet valve opens, thus creating a vacuum in the combustion space. Therefore, the rush of gases into cylinder is greater, due to this partial vacuum.

By referring to fig. 1, chart 29, note exhaust valve closed before the inlet starts to open; this would be termed "— minus lap."

Plus lap: If the inlet valve opened before the exhaust valve closed; this we will call "plus lap," designated with a -|- mark.

The "-|- lap," means that both exhaust and inlet valve are open together for a period of the lap. In other words the inlet opens before the exhaust closes. The theory is that the inertia or rush of exhaust gases passing out the exhaust port is sufficiently great to create a partial vacuum, and causes a stronger in-rush of fresh gas.

Owing to the fact that the exhaust and inlet gases should not conflict in their direction, the -|- plus lap is generally used on "T" head engines.

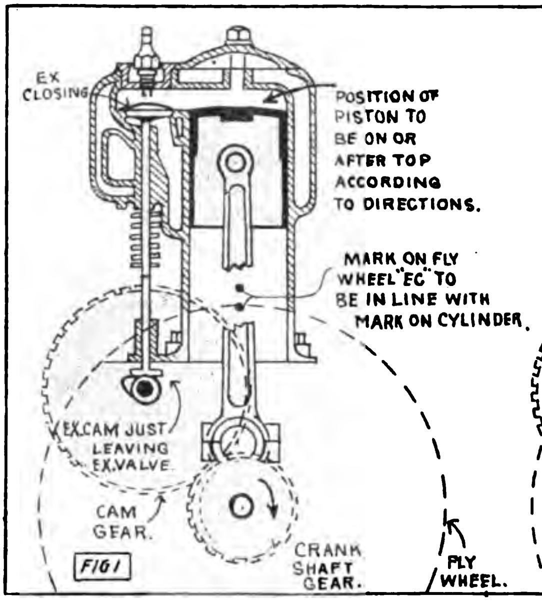
See page 114 and note the average valve timing of various engines. Compare the inlet valve opening and exhaust closing.

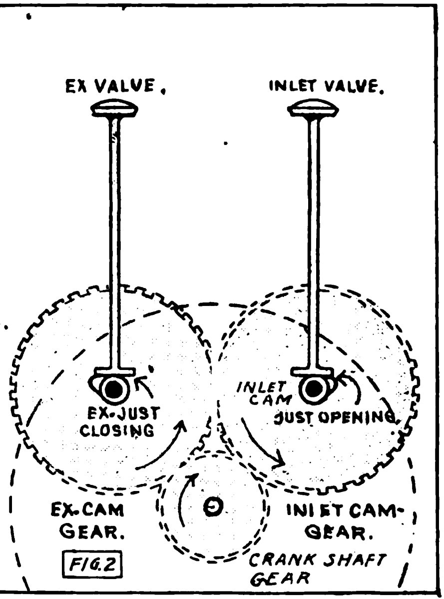
Valve "Lag" and Valve "Lead."

If a valve opens late, or remains open after it is supposed to close, it is said to "lag." For instance, the exhaust valve is usually allowed to "lag" about 10 degrees after leaving top of its exhaust stroke before it closes.

Valve "lead" usually applies to the valve opening before piston reaches top or bottom center, this distance is called "lead;" if it closes after center, this distance is termed "lag."

For instance, the setting of spark is sometimes given a "lead" or the exhaust valve is usually given a lead of 46 degrees, meaning opening before





View from front of engine. Below the view is from the rear.

Fig. 1.—To set the cam for valve opening on an "L" head cylinder it is only necessary to set the one cam, which is the exhaust cam—at the closing point. If engine has a multiple of cylinders all other cams will then operate as they should; as all exhaust and all inlet cams are on the one cam shaft and are set permanently when cam shaft is made.

Fig. 2.—When setting valves on a "T" head cylinder engine, there are two cams to set; the inlet and the exhaust. If cylinder is a four or six, or any multiple of cylinders; by setting the cam on the first, or say, No. 1 cylinder—is all that is necessary.

The usual plan is to set the exhaust as it is just closing, and the inlet as it is just opening.

On a "T" head, all exhaust cams are on the exhaust cam shaft and all inlet cams are on the inlet cam shaft.

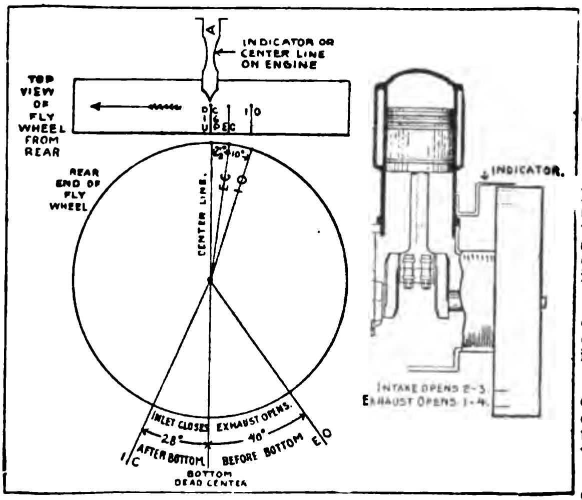


Fig. 3. Example of setting by "indicator."

Example of Valve Timing.

Example, set valves as follows; exhaust closes 2½° after top, inlet opens 10° after top.

There are usually marks on the face of fly wheel, which indicate the position for placing the crank shaft when setting the cams.

For instance; when piston of No. 1 and No. 4 or 1 and 6, cylinders are on top of stroke, a line will often be made on fly wheel which is supposed to line up with a mark on the cylinder, or with "indicator" placed on lower part of rear cylinder.

This line will read "DC 1-4 UP" (if 4 cylinder engine), meaning "1 and 4 are on dead center-up" (or "DC 1-6 UP," if a six cylinder).

If exhaust closed 2½° after upper dead center, then a mark would appear on fly wheel 2½° further away from the center mark (standing in rear of fly wheel).

If inlet opened 10° after upper dead center, then another mark would appear as shown.

To then set the valve on "L" head engine, first place No. 1 piston on dead center (D C), then move fly wheel to left 2½° to "E C" (exhaust closing), and set exhaust cam at the closing point.

To set "T" head, first place No. 1 piston on dead center with "D C" line, in line with "indicator," then move fly wheel to left to "E C"—set exhaust valve closing. **Next,** move fly wheel still further to "I O" (inlet opening), and set inlet cam at opening point. Mesh the gears and valves are timed.

Timing valves on a round or "I" head cylinder with valves overhead, the procedure is the same as in the "L" unless valves are on opposite side, as on a "T" head.

CHART NO. 47—Timing Valves on a "T & L" Head Cylinder Engine. Example of Fly Wheel Marking.

Note: An indicator is also termed a "trammel."

bottom. The faster engines are designed to run, the greater the amount of "lead" or "advance" given the opening of the exhaust, also the spark when running.

Valve Timing Position.

The position of the crank shaft determines the position of the piston.

The position of the piston determines the point where valve is set to open or close.

Therefore the cam shaft must be so placed, that the cam will raise the valve when piston is at a certain position.

*This is accomplished by meshing the cam gear with crank shaft gear when piston is in correct position.

Marks are usually placed by the manufacturer on the cam gears which will indicate just where to mesh gears (see page 106). The fly wheel is seldom used for timing unless there are no marks on gears or if it is desirable to check the valve timing.

It is also important to secure the proper valve clearance as per pages 94 and 95, before timing the valve.

Setting Valves on a Single Cylinder Engine.

For instance; suppose the valves are to be set on a single cylinder "T" head engine with exhaust to close on dead center, and inlet to open one-eighth inch after top on suction stroke.

Setting exhaust valve: first; place piston (by turning crank shaft) on dead center, then mesh exhaust cam gear with crank shaft gear, so that exhaust valve is just seating. (See fig. 1, chart 46.) **Setting inlet valve**: move piston down one-eighth of an inch from top, mesh inlet cam gear with crank shaft gear.

It will be noted that the inlet opens and suction stroke begins right after exhaust closes. Therefore the closing of the exhaust and opening of the intake is the point to work from.

A matter of importance to remember, is **the spark**. When setting valves, be sure the contact on timer or magneto is set to occur when piston is on top of compression stroke, a full revolution from where inlet valve starts to open. (This will be treated under ignition timing.)

Also remember to first get the "valve clearance" or "air gap" correct as per pages 94 and 95.

Setting the Valves on a Multiple Cylinder Engine.

Setting the valves on a multiple cylinder engine is identically the same operation as timing a single cylinder engine

†If there are a multiple of cylinders, say four, then there must be at least one inlet and one exhaust valve for each cylinder. Therefore, there must be four cams for the four inlet valves and four cams for the four exhaust valves.

If engine cylinders are "T" **head**, then there are **two cam shafts**; one for the inlet valves and one for the exhaust valves, placed on opposite sides of the cylinders.

If cylinders are "L" or "round" head with valves in the head, then there is but **one cam shaft**. (See chart 40, page 86). (On some 8 and twin six engines however, there are two cam shafts.)

†In some of the late makes, each cylinder has two inlet and two exhaust valves, called "dual valves." See pages 109, 927.

*Sometimes reversing the crank shaft gear will give better results, due to key-way being slightly offset.

It is well to note that even though there are four cylinders, six, eight or twelve cylinders, each of the pistons must pass through the four strokes during two revolutions of the crank shaft, even though two of the cylinders are firing at once during part of the time (which they are in a six, eight and twelve cylinder engine).

Just how these four strokes are made by each piston during two revolutions of the crank, is explained under "firing order," instruction No. 10.

We will next take up the method of setting the cams, so they will open and close the valves at the correct time.

If a **four cylinder** engine, remember that owing to the shape of crank shaft, pistons 1 and 4 are always up or in line, when 2 and 3 are down, or vice-versa (see page 116). If a **six cylinder** engine, pistons, 1 and 6 are in line, 3 and 4, and 2 and 5 (see chart 55).

If cylinders are "L" type or "round" type, with all valves on one side, then it is only necessary to **set the one cam shaft,** and do the timing from one cylinder, usually the front one, see fig. 1, chart 47, page 102.

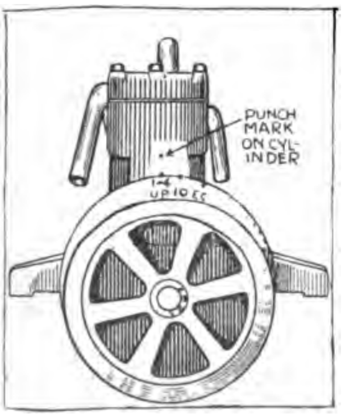
If cylinders are "T" type, then it will be necessary to **set the inlet cam shaft and the exhaust cam shaft separately,** but it is necessary only to set valves in one cylinder, as the other cams are fastened permanently on the cam shaft, and must open and close all other valves at the correct time. See fig. 2, chart 47.

Therefore the **cams do not need to be set on the shaft,** but by meshing the cam gear in front of the engine with the drive gear, the position of the nose of the cams can be adjusted. **The usual plan** is to place piston of No. 1 cylinder at the top of its stroke, and work from that point.

An eight cylinder engine, usually employs one cam shaft with 8 or 16 cams. The Cole has 16 cams, one for each valve whereas the Cadillac has eight cams.

To set the valves of the Cole engine, place piston of No. 1 cylinder on top dead center, then turn fly wheel in direction of rotation say 10°, to where the **exhaust is supposed to close,** at this point mesh the exhaust cam gear so exhaust valve is just closing, or cam is just leaving the end of valve. Either side can be timed, which will suffice for both sides or sets of cylinders. Usually the right side is timed.

†Timing Marks on Fly Wheel.



The usual plan to time valves or set in correct time with cam shaft, is to mesh the cam gears with point marked thereon to correspond with the mark on crank shaft gear at the time No. 1 cylinder is on top of its stroke.

Usually marks also appear on the circumference surface of the fly wheel, which indicate position crank shaft is to be placed for correct setting of valves.

The mark on fly wheel is placed in line with a center mark on cylinder or elsewhere.

If there are no marks on gears or fly wheel, then it will be necessary to first determine where you wish to set the valves.

*Note—Always adjust valve clearance before proceeding to set valve, see chart 44.

See Dyke's 4 and 6 cylinder engine models.

†By referring to inserts and page 120 an "inspection hole" will be noticed in housing over fly wheel for observing marks on fly wheel.

Timing "T" Head Cylinder Engine Valves.

Although fly wheels and cam gears are usually marked and the setting done with gears, the explanation will show how to check the valve timing and mark fly wheel if necessary.

For instance, suppose engine was a "T" head **four cylinder** type of engine, and you wished to time the valves as follows: Exhaust to close 15° past upper dead center. Inlet to open 8° past upper dead center. (This is an unusual timing.)

In actual timing this is really all that is necessary to know, as the other points of closing and opening will be taken care of by the other cams on cam shaft.

***Procedure of marking fly wheel:** (Refer to illustration.) Place No. 1 piston on top or upper dead center. Mark a center mark on cylinder, (usually on **indicator** or what is called a "**trammel**" is placed at this point, **see fig. 3, page 102**). Now mark a line on face of fly wheel and mark on this line "**1-4 UP,**" meaning pistons **1 and 4 are on upper (or top) dead center.**

†Now measure 8 degrees from this line to the **right** and make another mark on fly wheel—mark it "IO." meaning **inlet opens.**

Now mark another line 15 degrees from the DC line, to the right on fly wheel—mark this "**EC,**" meaning **exhaust closes.**

Next, turn fly wheel slightly until line marked "**EC**" is in line with indicator or punch mark on cylinder. At this point piston is 15° down (measured on fly wheel) in direction of rotation from top. Note that **you are supposed to be in rear of fly wheel.**

Setting exhaust cam; take exhaust cam gear out of mesh with crank shaft gear (if a gear, or if a chain loosen chain); turn exhaust cam in direction of rotation (note direction it turns, fig. 2, page 102, opposite that of crank shaft); place exhaust cam at closing point (see chart 47, fig. 2). Now mesh exhaust cam gear and exhaust valves are timed.

Setting inlet cam, next, turn fly wheel to left until line "IO" is in line with center mark or indicator on cylinder;at this point piston is 8° down (measured on fly wheel in direction of rotation from top). Take inlet cam gear out of mesh and turn inlet cam in direction of rotation until it is just at the point of opening (see fig 2, page 102). Mesh gears and inlet valves are timed.

Next adjust the "air gap" or "valve clearance" as per pages 94 and 95.

Timing the Valves on "L" Head Type of Engine.

Only one cam shaft need be set when all valves are on one side, and all cams on one cam shaft, see fig. 1, chart 47.

The usual plan is to place position of No. 1 piston at point where **exhaust valve is to be closed,** and mesh the exhaust cam shaft gear at this point.

Timing Valves on an "I" or Round Head Type of Engine.

The overhead valves are usually operated by push rods. All from one side of engine and from one cam shaft, therefore the timing would be the same as an "L" head.

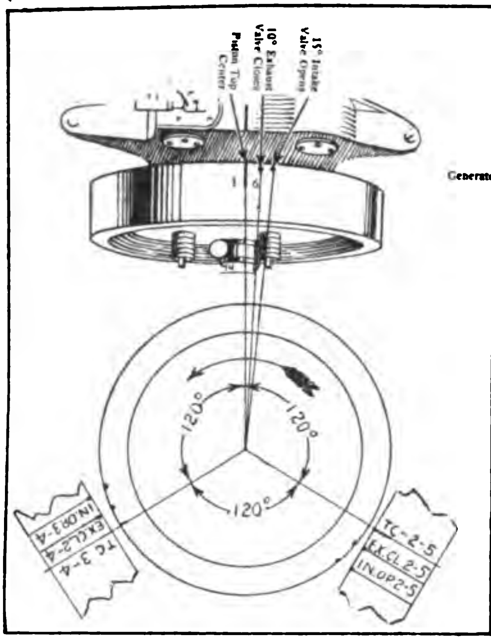
If overhead cam shaft; the valves are usually operated by one cam shaft, therefore the principle is the same, see chart 66, page 137.

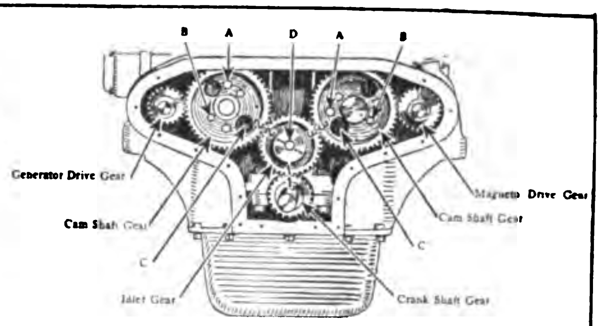
It is important to adjust the "air gap" or "valve clearance."

*A study of fig. 3, page 102, of the six cylinder timing will assist you in understanding this

†See page 115, how to convert degrees into inches or fraction thereof, or just how far in inches to make the mark on different diameter fly wheels.

‡To find position of piston, see index "finding position of the piston."





This Particular type is a "T" Head Cylinder type of Engine. By observing the illustration the reader will note the principle of valve timing on a "six" differs but little from the "four."

A Study of Six Cylinder Crank Shafts in Chart 55 will explain the meaning of the 120° marks.

When the long mark 1-6 is in line with line on Crank Case, pistons number one and six are at their highest points or upper dead center.

When mark 2-5 is in line, pistons number two and five are on upper dead center.

When mark 3-4 is in line, pistons three and four are on upper dead center.

From Upper Dead Center, pistons are ready to start downward on their intake or power stroke as the case may be.

If the Piston of any Particular Cylinder is Ready to Start on its intake stroke, then when the first punch mark from center mark, or 10° of the complete circle is in line with mark on crank case, the exhaust valve of this particular cylinder has just closed.

When the Second Punch mark or 15° is in line, intake valve of this particular cylinder begins to open.

No Reference is made here as to closing of Intake and opening of Exhaust, because it is of no particular advantage when timing valves, as the opening of inlet and closing of exhaust is all that is necessary to know.

The only Points to Determine is when the inlet opens and exhaust closes and set as shown above.

To Remove Timing Gears on the Mitchell. Note there are two cam shafts ("T" head cylinders.) To remove idler gear screw out hexagon headed bolt "D," which has a left-hand thread, from idler gear shaft.

To remove Cam Shaft Gears. Remove hexagon bolts "A" and hexagon nuts "B." The gear now comes off its hub.

To Adjust Mesh of Timing Gears. Through holes "C" of cam shaft gears loosen the bolts that hold bearings to crank case. Bearings being eccentric they can be turned until desired mesh of gears is obtained. No further adjustments of the other cam shaft bearings are necessary to make this adjustment. Be sure bolts are again drawn up tight after adjustments are made.

To Adjust Mesh of Magneto Shaft Gear. Loosen the three bolts tnat hold bearing to crank case; bearing being an eccentric can be turned until the desired mesh is obtained.

To Adjust Generator Drive Shaft Gear. Loosen the three bolts that hold bearing to crank case and proceed same as to adjust magneto drive shaft gear.

HOW TO MESH TIMING GEARS; by removing forward end of crank case cover, gears can be inspected. The gears should be so set that the figure 1 stamped on crank shaft gear should match with figure 1 stamped on idler gear; mark 2 on idler should match with mark 2 on cam shaft gear and mark 3 on idler gear should match with mark 3 on other cam shaft gear.

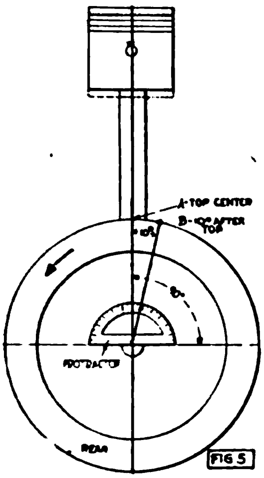
This Principle of removing and meshing gears is common practice.

HART NO. 47A—Valve Timing Marks of a Six Cylinder Engine. Meshing of Timing Gears on a "T" head Engine (Mitchell early model 6-16).

ıte—The later Mitchell timing is given in "Standard Adjustments of Leading Cars" and is an "L" head type engine.

Method of Marking a Fly Wheel in Degrees.

Although a scale is worked out on page 115 to find in inches or a fraction thereof just where to mark fly wheel in degrees, another method is given below. Suppose there are no timing marks on fly wheel and you desire to mark same.



Set the engine so that the piston in No. 1 cylinder, namely the cylinder nearest the radiator, is at the top of its stroke. With the use of the protractor or with a square, make a mark at A on the rim of the flywheel, on the inner edge, which mark will be directly above the center of the crank shaft or piston is at top of its stroke.

Then, with the protractor placed against the fly wheel so that the 90 degrees mark points directly toward mark A, go 10 degrees to the right on the protractor (standing in rear of engine), then make a mark at B on the fly wheel. This mark will be 10 degrees to the right of mark A. Now turn the fly wheel until mark B is at top center.

With the engine in this position mesh the timing gears so that the exhaust valve of No. 1 cylinder is just closing.

It is understood that when standing behind fly wheel it would turn to the left or as per arrow point. Therefore, piston must first reach top center (A) with exhaust valve still open, and travel 10 degrees further to (B) before it closes.

Variation of Valve Timing Marks—on fly wheel.

Sometimes the marks may vary, for instance, instead of "1-4 UP" or "1-4 DC," it may appear as, "T C 1-4" (top center 1-4) or "U C 1-4" (meaning upper dead center), or some similar mark meaning the same thing.

Some manufacturers vary their marking on the rim of the fly wheel as follows: Inlet opens "IN-O" or "I. O." Inlet closes "IN-C" or "I. C."

Exhaust opens "EX-O" or "E. O." or "X. O." Exhaust closes "EX-C" or "E. C." or "X. C."

If the figures 1-4 or 2-3 appear after or before the above marks, as "1-4-IO.," this means the number of the cylinders, as "1 and 4, inlet opens."

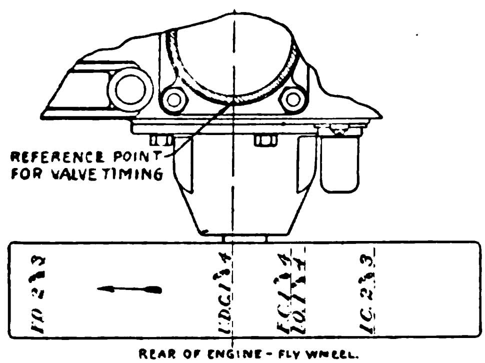


Fig. 1.—Valve timing marks on fly wheel of a Reo four cylinder engine.

For an example of valve timing marks on a four cylinder engine fly wheel, see fig. 1—the engine fly wheel has upon its face, the following marks:

I. O., meaning, inlet valve opens.
I. C., meaning, inlet valve closes.
E. O., meaning, exhaust valve opens.
E. C., meaning exhaust valve closes.

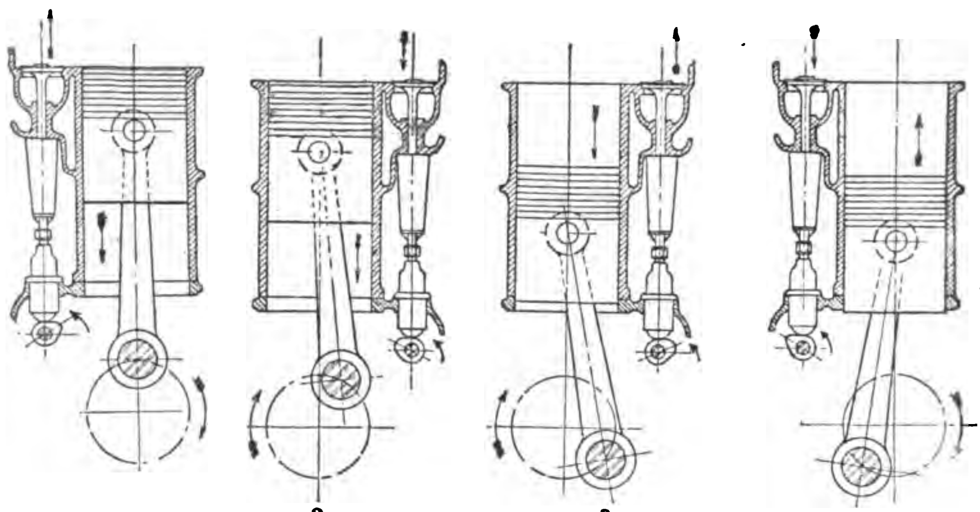
U.D.C., 1 and 4, upper dead center; cylinder 1 and 4.

U.D.C., 2 and 3, upper dead center; cylinder 2 and 3.

These points, marked upon the face of the wheel, show where the exhaust and inlet valves of each cylinder should open and close.

Taking as a reference point the small boss marked with a cross upon cylinder No. 4, next to dash, this being plainly shown in the illustration, together with the marking on one side of the fly wheel.

The engine cylinders are numbered 1, 2, 3 and 4. No. 1 being next to radiator, and No. 4 next to dash. By referring to pages 76 and 78 of crank shafts, previously given, it will be seen that cranks 2 and 3, and 1 and 4 are exactly 180 degrees apart. Therefore, the same marking on the fly wheel that serves for No. 2, also serves for No. 3, and the marking for No. 1 serves for No. 4, these points being exactly one-half revolution, or 180 degrees apart, as before mentioned



2 3 4

1. **Inlet Opens.** Top Center / Top Center

2. **Exhaust Closes.** ⅛" Past Top Center / ⅛" Past Top Center

Fig. 3. Exhaust Opens. "38" ¾" Before Bottom Center / "48" 1" Before Bottom Center

Fig. 4. Inlet Closes. ⅝" Past Bottom Center / ¾" Past Bottom Center

Figures 1, 2, 3 and 4 illustrate the valve timing of the Locomobile "38" and "48" six cylinder engine. The timing being given in inches. The top line is the timing of the model "38" and the lower line "48." **First,** adjust the valve clearance by adjusting check nut on valve lifter or plunger until it just touches the bottom of the valve stem. The cam is then off the bottom of the plunger and piston No. 1 is on the top of stroke. This will give about .005 of an inch clearance. **Next;** the intake valve is set to open at the top of the stroke, therefore set the inlet cam just starting to open the inlet valve at this point. **Next;** set the exhaust valve at point just closing, when piston is down ⅛ of an inch from top.

Cadillac valve timing: Open cylinder relief cocks, turn engine until valve you are timing (say exhaust of No. 1 right) has just seated. Turn still farther, until line marked "Ex. | S." on fly wheel, is under trammel on crank case. The cam is then in correct position for that valve.

To check inlet valve—the same procedure, but mark on fly wheel is "In | S." (inlet seated.)

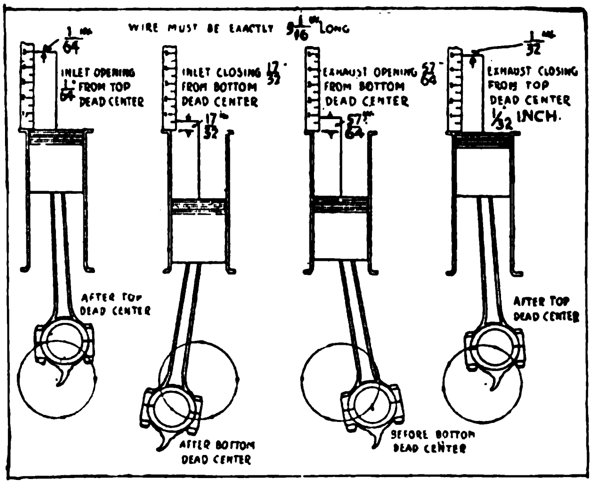


Fig. 3.—The timing of the Hudson Super Six measured according to piston travel: Intake opens 1/64 after top dead center; closes 17/32 after bottom dead center; exhaust opens 57/64 before bottom dead center; closes 1/32 after top dead center.

These measurements are best for timing, but for comparison with other engines it is better to state the valve movement in degrees: Intake opens 7 deg. after top dead center; closes approximately 42 deg. after lower dead center; exhaust opens about 55 deg. before dead center; closes 8 deg. after top dead center.

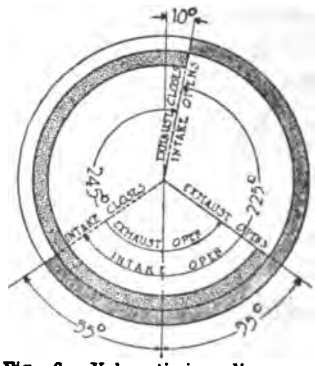

Fig. 6.—Valve timing diagram of the Stutz racing engine explained on page 109.

The Stutz (see diagram above) the **exhaust opens** 55° before bottom and closes 10° after top. **Inlet opens** 10° after top, **closes** 55° after bottom.

Dusenberg racer engine: Ex. opens, 46° before bottom, closes 8° after top. **Inlet opens** 4° after top, **closes** 42° after bottom.

The Maxwell racer engine: Ex. opens 69° before bottom, closes 13° 45′ after top. **Inlet opens** top of dead center, **closes** 32° after bottom.

A prominent French racing engine uses a valve timing of—Inlet opens 10-12° after top, closes 45° after bottom. Exhaust opens 45° and closes 18° after top.

HART NO. 48—Example of Valve Timing in Inches. Valve Timing of Racing Engines.

e page 500 for Locomobile gear shift and page 362 for electric system. **The 1920 Series Five Locomobile:** ılet opens 3/32" past top; exhaust closes top center; exhaust opens ¾" before bottom; inlet closes ¾" past ıttom.

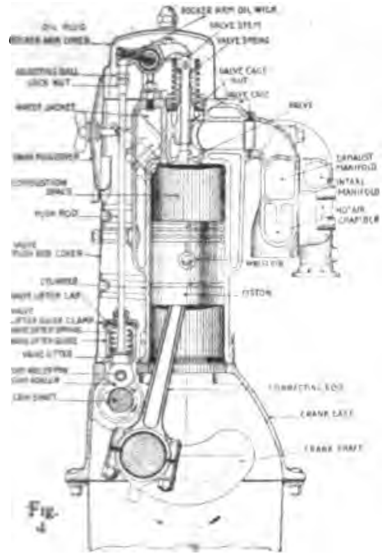

Fig. 4

The Buick six valves, both inlet and exhaust are placed in-the-head of cylinder. The valves are in cages and can be ground by compressing valve spring and lifting push-rod out of socket. Loosen valve cage nuts and nnscrew valve cage. Remove valve spring and after cleaning with gasoline or kerosene, smear the valve and its seat with fine emery flour and grind by turning back and forth on its seat until both valve and seat show a bright ring $\frac{1}{16}$" wide all the way round. After grinding clean thoroughly and adjust push-rods for clearance.

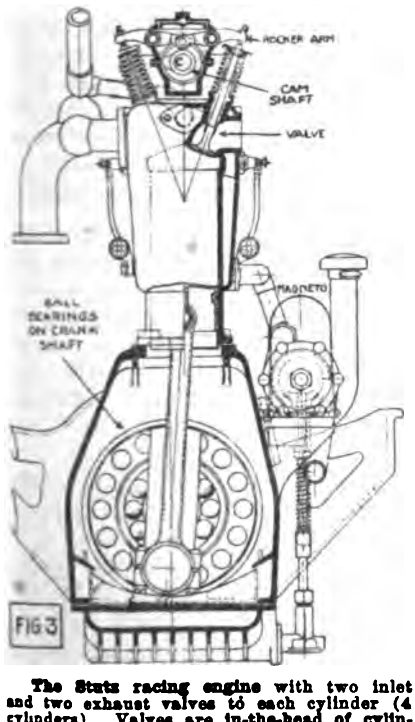

FIG 3

The Stutz racing engine with two inlet and two exhaust valves to each cylinder (4 cylinders). **Valves are in-the-head of cylinders** and operated by **an overhead cam-shaft.** See page 108 for valve timing.

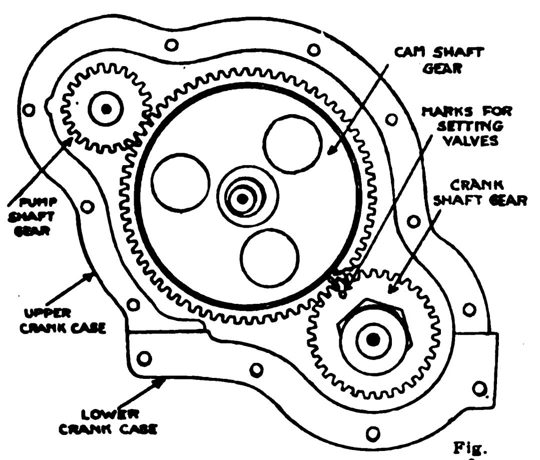

Fig. 2

Timing Buick Six, Valves-in-the-head, Operated by Push-Rods on the Side.

The valve-in-the-head can be timed in just the same manner as timing the valves when placed on the side as described on page 102, but in order to simplify the work, quite often, manufacturers mark the timing gears as described in the illustration fig. 2.

Timing the valves: For instance, to time the valves of the six cylinder Buick; the cam shaft gear which is marked "O" corresponds with the tooth on the crank shaft gear as shown in fig. 2.

Adjusting push-rod clearance: Turn the engine by hand (in a clockwise direction, looking at it from in front), until the line marked "1 and 6" on the fly wheel comes opposite the line on the rim of the inspection hole. This is the firing position for cylinders Nos. 1 and 6, numbering from the radiator back, and one or the other of these cylinders will be found to have both valves closed, so that both rocker arms will have a slight amount of play. The push-rods should then be adjusted from the back of the cams and while engine is warm, so as to have .010 inch clearance between the end of the valve stem and the rocker arm. This is approximately the thickness of a sheet of heavy paper or very light card. Push rods for the other cylinders may be adjusted in the same manner. One-half teaspoon full of kerosene inserted around valve stem once a week while engine is runing will keep valve from sticking in valve cage.

Setting the ignition on Buick: Turn engine clockwise, as before, until "1 and 6" line on fly wheel comes in view; continue turning slowly until line marked "7°" registers with indicator mark (which is approximately 1 inch after dead center mark). This is the point to set ignition timer. Retard spark. Set breaker cam on timer, so lobe of cam is just commencing to separate contact points. Firing order is 1, 4, 2, 6, 3, 5. Spark plug gap is adjusted .030" clearance and timer contacts points .018". Timer is Delco closed-circuit type, page 377, 378, 388.

Timing the Stutz Racing Engine, with Valves-in-the-head, Operated by an Overhead Camshaft.

An end view is shown. A brief detail of the specifications are as follows:

General: Bore, $3\frac{3}{16}$ inches; stroke, $6\frac{1}{2}$ inches. Four cylinders with sixteen valves.

The maximum power is obtained at a piston speed of 3250 feet per minute which corresponds to 3000 r. p. m. and is about 130 h. p.

Valves: There are two inlet and two exhaust valves for each cylinder, which is termed "dual" valves. The valves are operated by an **overhead cam-shaft,** which is operated by a chain of gears from the crank shaft gear.

Where four valves are used to each cylinder, they are known as "dual valves," see page 927.

The crank-shaft is ball bearing with one inch balls.

Valve Timing, see fig. 6 page 108.

CHART NO. 49. Timing the Valves of an Engine When Placed in the Head of Cylinders; Buick Six and Stutz Racing Engine as Examples.

Chart 50 omitted, error in numbering.

Checking the Valve Timing.

The purpose of checking the valves is to see if they are opening and closing as marked on fly wheel.

Although it is only necessary to set the exhaust cam so exhaust valve will just close, on an "L" type of cylinder engine, there are other marks which are used for checking the timing.

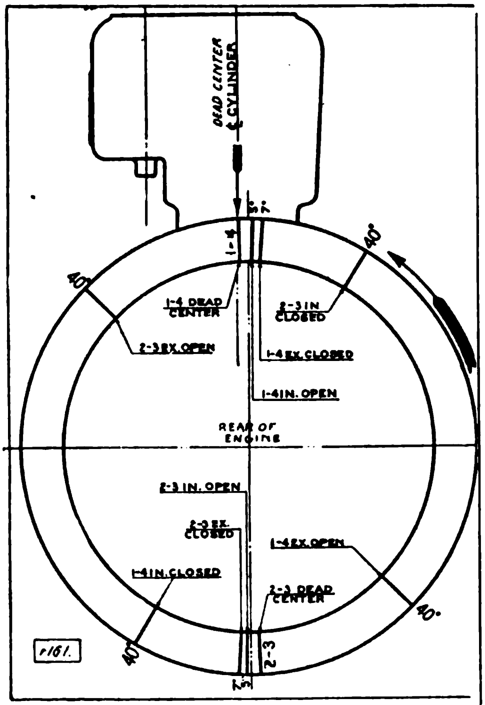

Fig. 2.—An example of valve timing marks on the fly wheel of a four cylinder engine. See text for checking valve timing from these marks. View from rear of engine. Note it turns to the left.

As an example a four cylinder engine is used, with timing scale as follows:

Dead center of cylinders 1 and 4 are marked on fly wheel "1-4."

Dead center of cylinders 2 and 3 are marked on fly wheel "2-3."

Inlet valve opens 5° past top center marked on fly wheel "1-4 IN. O."

Inlet valve closes 40° past bottom center marked on fly wheel "1-4 IN. C."

Exhaust valve opens 40° before bottom center marked on fly wheel "1-4 EX. O."

Exhaust valve closes 7° past top center marked on fly wheel "1-4 EX. C."

Note—the marking on illustration is merely 5° and 7°, the reading at end of arrow lines indicate the meaning.

The same marks appear for cylinders 2 and 3.

The lines on fly wheel indicate the points at which the valves open and close.

When fly wheel is turned so that the line marked "1-4" is up in line with mark on cylinder—No. 1 and 4 pistons are just at the uppermost points of their strokes or at "upper dead center." When line "2-3" is up in line with center mark on cylinder the No. 2 and 3 pistons are at upper dead center.

To determine whether or not the valves are properly timed, first open the relief cocks on top of the cylinders, then have some one crank the engine over slowly until the line marked "1-4" is opposite the center line of the cylinders. At this point **the exhaust valve in either** No. 1 or No. 4 cylinder should be just closed.

If you find that the exhaust valve in No. 4 cylinder is beginning to close and you wish to check up the valve timing in No. 1 cylinder, turn the fly wheel around to the **left** (standing in rear of engine), one complete revolution, until line "1-4" is again brought opposite the center line of the cylinder; then continue slowly turning the fly wheel about three-quarters of an inch farther to the left until the line marked "7° EX. C." coincides with the center line of the cylinders. This is the point at which the **exhaust valve in the No. 1 cylinder should just seat itself or close.**

†**To determine whether or not the valve is seated,** see if tappet or push rod underneath the valve can be turned with the fingers. If the tappet turns freely, the valve is seated, but if the tappet is hard to turn, that will show that the valve is still being held slightly open. If this is the case, loosen the lock nut on the tappet screw, and turn the screw down until the valve has the proper clearance, then turn the lock nut down tight against the tappet.

When the valves are closed there should be clearance between the end of the valve stems and the tappet screws, of from .003 to .005 of an inch. This amount of clearance is necessary to allow the valve to seat tightly (see page 95).

†The opening and closing time of a valve is not when the lifter begins to rise or comes to rest but when it makes or leaves contact—see page 94, figs. 2 and 3.

To check up the timing of the inlet valve in No. 1 cylinder, turn the fly wheel slightly to the **right** until the line "1-4" is in line with the center of the cylinders, and then turn the fly wheel about one-half an inch to the **left** until the line marked "**5° IN. O.**" coincides with the center line of the cylinder. At this point the **inlet valve should just begin to open.**

Continue turning the fly wheel half a turn to the **left**, stopping when the line marked "**40° IN. C,**" just to the *right of the line "2-3" comes in line with center of the cylinders. At this point the **inlet valve should just close.**

To see if the exhaust valve in No. 1 cylinder opens at the proper time, revolve the fly wheel still farther to the **left,** and stop when the line "**40° EX. O,**" which is the first line to the *left of the "2-3" center line, comes up in line with center of the cylinders. This is the point where the **exhaust valve in No. 1 cylinder should just begin to open.** The above operation completes the **checking** of cylinder No. 1.

‡**To check the timing of cylinder No. 2,** turn the fly wheel until the line **marked** "2-3" is in line with the center line of the cylinders. If the **exhaust** valve in the No. 2 cylinder is closed, turn the fly wheel through one complete revolution, until the line "2-3" is up again; the exhaust valve in No. 2 cylinder should then be just starting to close. Proceed now the same as in timing the No. 1 cylinder. The valves in cylinders No. 3 and No. 4 are timed in the same manner.

Cylinders No. 1 and 4 are timed from the center line "1-4"; 5° to left for inlet opening and 7° for exhaust closing, and cylinders No. 2 and 3 from the line "2-3;" 5° to left for inlet opening and 7° for exhaust closing.

It is advisable, when checking the opening and closing points of the valves with the marks on the fly wheel, to make a note of the variation of each of the valves from the marks in the fly wheel.

Then, after all the valves have been checked you can compare the variations for the different valves and in this way determine whether the variations are due to the **large time gear on the end of the cam shaft not being properly set** with relation to the timing gear on the end of the crankshaft, **or to wear** in any particular cam or valve tappet. A variation, not to exceed one-half of an inch either way from the lines on the fly wheel, is permissible, and will not make any material difference in the timing of the valves. If the variations exceed this and are uniform for the different valves the correction should be made by re-setting the cam shaft gear. (See "setting of timing gears," this page.)

When the valves are closed there should be clearance between the end of the valve stems and tappet screws, of from .003 to .005 of an inch. This amount of clearance is required to allow the valves to seat tightly. (See "valve clearance," pages 94 and 95.)

The Timing Gears.

Since the position of the cam shaft is always the same with reference to the pistons (because the cam shaft is always in mesh with the crank shaft gear), and since the cams are all integral parts of the shaft, the valve timing cannot change. If the gears are ever removed, they may be put back in the proper position by seeing that the marks on the edges of the teeth "dovetail" together.

If the timing of the valves of an engine is not correct, it is then necessary to re-mesh or re-set the timing gears. It will be necessary to place piston of No. 1 cylinder at top of its stroke. Then remove the gear cover and turn crank until the "EX. C" (exhaust closing mark of cylinder No. 1) is in line with center mark on ‡cylinder (in rear). Now remove the cam gear from its shaft and turn cam shaft in its direction of rotation (it is opposite from direction of rotation of crank shaft), until the **exhaust** valve on cylinder No. 1 is †**just closing,** keep the cam shaft in this position, replace the cam gear (large one) on the end of the cam shaft properly meshing it with the gear on the crank shaft.

‡**On engines with unit power plants** the center line instead of being on cylinder, a small hole at top of fly wheel case is provided so line and figures on fly wheel can be seen through hole, see page 120.

†**The opening and closing time of a valve** is not when the lifter begins to rise or comes to rest, but when it makes or leaves contact—see page 94.

***When "2-3" fly wheel mark is at** top this marking would be at the right of 2-3. Below, as shown in illustration, it is to the left.

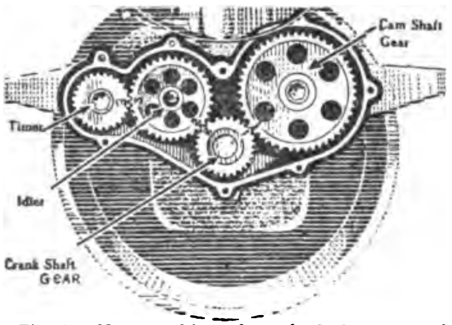

Fig. 1.—Note meshing of crank shaft gear mark (1) between the two teeth on cam shaft gear mark (1). This is the Overland model 85. Note the cam shaft turns in opposite direction to crank shaft when the crank shaft gear drives the cam shaft gear without using an idler gear.

When the gears are originally installed at the factory, there are usually marks stamped on the small crank shaft gear, for instance, a letter "O" or "C," or figures 1 or 2,**and a similar mark is stamped between the two teeth of the larger cam gear** with which it meshes. At this point the valves are supposed to be correctly timed.

If you find that the marked teeth do not come together; do not jump at the conclusion that the gears are improperly set, but first verify the setting by checking the timing of the valves with marks on the fly wheel.

Remarks on the Relation of Timing Gears to Valve Timing.

After your engine has been overhauled a few times the cam shaft gear will have developed a dozen or more meshing marks; each workman having added a few marks that may or may not be right and changed a few that were right until finally it is hopeless to match any of them.

This need not seriously inconvenience you, for if you understand valve timing, you can forget the gear marks and work entirely from the fly wheel marks.

A "**trammel**" is a stationary starting point to base all your work from (see fig. 3, page 102). The trammel generally is directly over or in front of the fly wheel, but may be located elsewhere if some careless workman has removed your fly wheel and replaced it in a different position (flange connection or a new fly wheel with key in wrong place); the trammel should be shifted until it registers properly when the cylinder indicated is at top center.

Check up the top center mark by making sure that the piston in the cylinder indicated is **exactly** at top center and that the trammel registers exactly in line.

Now that you are certain of the trammel, move the fly wheel in the direction it should travel(**generally** counter clock if fly wheel is between you and the cyinders) until the mark I. O. (intake opening) No. 1 and No. 4 registers with the trammel. Leave the fly wheel alone now and turn the cam shaft until the nose of the inlet cam on No. 1 cylinder is down. Adjust the air gap for post card distance Turn the cam shaft in the direction of its travel until the air gap is gone and any further movement would start to lift the valves. Put on the cam shaft gear, being careful to not move either the cam shaft or the crank shaft. Have the gear key in place but don't permanently fasten the gear yet.

Turn the fly wheel in its proper direction and check up the intake closing. If both opening and closing of this valve are right, it means that the cam shaft and air gap are correct and the gear can be permanently fastened.

If the valve opens on time but closes at the wrong time it means that both the cam shaft and air gap are wrong. If the valve closes too soon the air gap is too large and doesn't hold the valve open long enough. If the valve closes late, the air gap is too small and holds the valve open too long. (See page 95.)

Make a mark with a lead pencil or chalk on the fly wheel, midway between the actual closing and the proper closing. Turn the fly wheel to this new mark and adjust the tappet to correspond. The tappet must be just barely in contact with the valve stem. The air gap is now O. K., but the cam shaft is still out of time.

Turn the fly wheel back to the opening mark and remove the gear. Turn the cam shaft until the air gap is gone, replace the gear and check up the closing. The cam shaft and air gap are now correct and the remaining tappets are adjusted after registering each mark with the trammel. Don't use a sheet of paper or post card to measure with. Turn the fly wheel and adjust each tappet by the fly wheel marks.

If the valve opens a certain number of degrees **early** and closes the same number of degrees **late**, the cam shaft is right but the air gap is wrong.

If a valve opens a certain number of degrees **early** and closes the same number of degrees **early**, the air gap is right but the cam shaft is wrong.

Make a habit of checking up this air gap at least once a month, especially if you have fibre inserts or any other noise silencers. Use the fly wheel marks.

After the valves have been ground or new valves put in—check up. Don't let your engine overheat or lose power through the fault of the air gap.

***To assemble timing gears on the Dodge;** turn crankshaft clockwise until top of No. 4 piston is 5/8" (or 5°) below top of cylinder, on compression stroke. Then rotate cam shaft counter-clockwise until No. 3 exhaust valve is ready to open. The crankshaft and cam shaft gear should then be meshed so that the single punch mark in the latter is between the two on the former.

Where silent chains and sprockets are used instead of gears—the procedure is similar, except the cam shaft revolves in opposite direction.

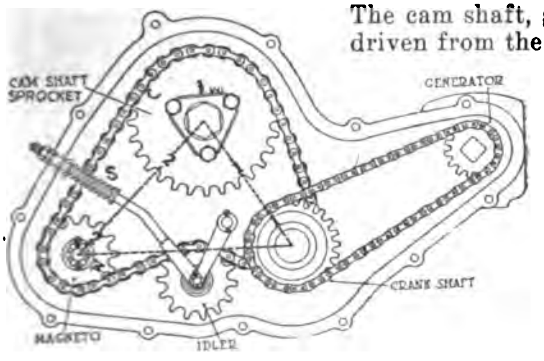

Fig. 2.—Note on the Overland model 75, sprockets and silent chains are used instead of gears.

Note the cam shaft turns the same direction as crank shaft when cam shaft is driven by silent chain.

The cam shaft, generator and magneto shafts are driven from the main shaft by chains at the front of the engine. The timing of these shafts, or the relation of their operation to the crank shaft, determines the time of opening and closing of the valves and the firing of the gas.

Should the chains be removed proceed carefully when reassembling as follows:

Turn the crank shaft until the mark "1-4 UP" on the fly wheel, lines up with the mark on the cross member, and with No. 1 cylinder ready to fire.

Turn the cam shaft until mark 1 on the sprocket is opposite mark 1 on the crank shaft sprocket.

Now turn the magneto shaft until the distributor makes contact with No. 1 brush, the lower right-hand one. Mark 2 on the magneto sprocket should now be opposite mark 2 on the cam shaft sprocket.

†**Wrap the chain around the sprockets** and fasten the master link. The parts should now operate in their correct relation. (see also page 648.)

Notes relative to gears: To reach the gears it is usually necessary to remove radiator, then the starting crank stud, then fan, fan pully and gear housing cover. When replacing be sure the gasket of housing is in good condition. The gears are usually keyed and locked in place by a nut on end of shaft. On most gears there are two holes for a "gear, puller" (see index), which is used to draw off the gear. Should it be necessary to remove the cam shaft sprocket from the hub, see that it is replaced with the tooth marked "C" directly opposite the keyway.

Valve Timing of a 6 Cylinder Engine.

The process is identical with that of a 4 cylinder engine. If all valves are on one side, it is only necessary to time the exhaust valve closing of cylinder No. 1. See page 106 for an example

The timing of a six cylinder engine in *inches instead of degrees is shown below. Also see page 109.

Example of Valve Checking on a 6 Cylinder Engine.

As an additional check, use may be made of the fly wheel markings, as follows:

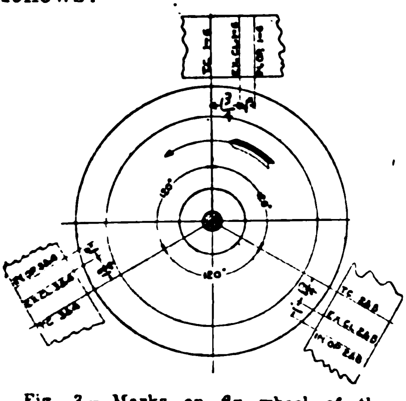

Fig. 3.—Marks on fly wheel of the Marmon 34.

Remove the top cover and twirl between the fingers the long aluminum push rod (for the No. 1 intake valve— the second rod from the front) while someone slowly turns the starting crank. Stop the engine at the exact point when the push rod is no longer free to turn and note the markings on the fly wheel. If the engine is properly timed, the line marked "IN-OP" near "TC 1-|-6" will be directly under the pointer. The exhaust valve is tested in the same way, except that the mark "EX-CL" is used to show the point at which the exhaust valve closes. The point at which the intake closes and that at which the exhaust opens are not shown, as, if the other markings for the same valve are correct, these are sure to be. The marks "TC 1-|-6," "TC 2-|-5" and "TC 3-|-4" designate the top centers of the several cylinders and the timing of each starting from the proper top center is similar to that for No. 1 described above. The marks "IN-OP" and "EX-CL" each refer to the cylinders whose "TC" is nearest. Valve clearance on the Marmon is .003.

*See page 115 for conversion of degrees into inches. *See index for valve timing of a 12 cylinder "V" engine. †See index for "repairing silent chains."

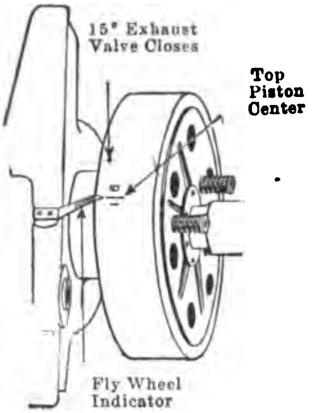

Fig. 4.—Showing the purpose of an "indicator" or "trammel" as applied to a 6 cylinder engine.

Valve Timing "Indicator" or "Trammel."

A trammel or indicator is a stationary starting point to base all work from. It is sometimes attached to the base of a cylinder or other point, instead of a center line on cylinder. It is usually directly over, or in front, of the fly wheel, as per fig. 4 (fly wheel indicator.)

Example of 6 cyl. engine timing: inlet opens and exhaust closing at the same time, or on "**top.**"

When the long mark 1-6 is in line with "**indicator**" on crank case, pistons number one and six are at their highest points or upper dead center. After turning fly wheel to this mark, then turn the fly wheel to the left (when behind it) until the small dot mark is under indicator. This is the point (15°) to set **exhaust** valve just closed. Therefore it is plain to see that setting the exhaust valve just closing on a 6 cylinder engine with valves on the side, is all that is necessary.

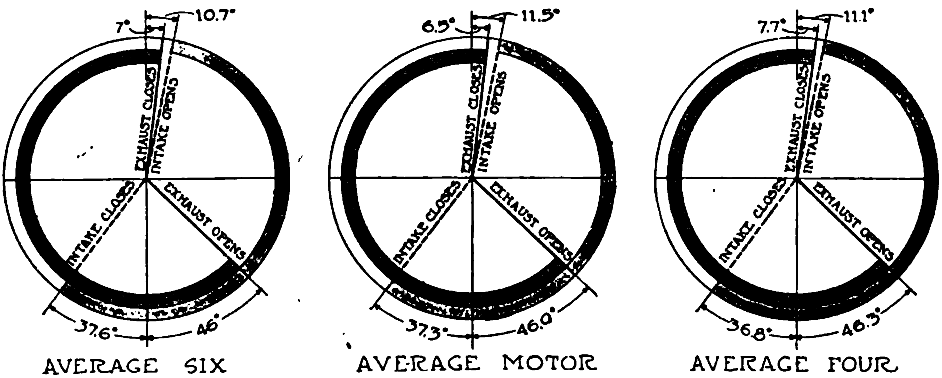

Fig. 3.—Average valve timing diagrams.

Average Valve Timing.

There is very little difference between the average timing of the four and the six cylinder engine. **On the six, the average inlet opening** is 10.7 degrees past top center and closing point 37.6 degrees past bottom center. **On the four the average for inlet opening** is 11.1 after top center and closing point 36.8 degrees after bottom center. The small difference would hardly be noticeable.

The exhaust on the average six opens 46 degrees before bottom center and the **four** 46.3. The **closing point of sixes** average 7 degrees after top, and the **four** 7.7. Therefore, there is very little difference.

On an average of engines, the intake remains open for a period of 205.8 degrees, and the **exhaust remains open** for a period of 233.4 degrees. For an example, see chart 46, page 100, showing how long the valves remain open, or the period of travel. See page 542 for, "setting valves of an engine where timing is not known."

To Find Position of Piston.

To find the top or bottom position of piston, see pages 320, 312.

The best procedure is to calculate the degrees from the center marks on the fly wheel, which are nearly always present either as punch marks, letters, or a simple line filed across the rim. If one person feels the tappet head of the valve which is being checked, while another slowly pulls the fly wheel round in its proper direction of motion, the precise moment at which the valve commences to lift can readily be determined by the binding of the tappet head against the stem of the valve.

Converting inches into degrees:—If the circumference of the fly wheel be then measured in inches by a tape line or its diameter be ascertained and multiplied by three and one-seventh (which amounts to the same thing), the proportion of this measurement to the distance on the rim of the center mark from the perpendicular position will give the degrees of advance or retard.

Suppose for instance, we find that the exhaust valve just closes when the top center mark is 2 inches past the central line in the direction of rotation and that the circumference of the fly wheel is 60 inches. Now there are 360 degrees in a circle, and therefore by the simple process of multiplying this figure by 2 and dividing the result by 60 we get the answer 12 degrees, which is of course the number of degrees represented by 2 inches. Also see page 115 for converting degrees into inches.

Valve timing on Dodge; first see that valve lifter or tappets are properly adjusted, which is .003 clearance for inlet and .004 for exhaust. Then turn crank shaft clockwise until top of piston No. 1 is 1-16 inch above top of cylinder on exhaust stroke. Turn cam shaft clockwise until No. 1 exhaust valve is just fully closed. Gears are then meshed. Dodge **inlet opens** 10° after top and closes 35° after bottom; **exhaust opens** 45° before bottom and closes 8° after top. **Flywheel** is 16¼" dia. for cars using cone clutch and 15½" dia. for cars using the disk clutch. **A degree on** larger wheel spans a distance of 0.1418" and **smaller wheel** 0.1353". See page 542 for dia. of valves.

This table is provided for converting degrees into inches. For instance; if a certain engine is timed when inlet opens, say 10° after top of stroke, and there are no marks on fly wheel to indicat position, by referring to this table the distance in inches to measure on fly wheel from upper dead mark can be found.

It will be necessary however, to know the diameter of the fly wheel. Suppose fly wheel was 17 i refer to first column and find 17, then go out to column under 10° and you have 1.48 (one and fort) hundreths of an inch). This would represent the distance to measure for the inlet opening mark wheel. *

* Forty-eight hundreths (.48) is not so easy to measure on the rule, therefore refer to table below and note it is equal to 31/64 of an inch. Therefore we would have 1 31/64 of an inch.

Another Example: What would 2½° represent in inches on a 17 inch fly wheel? Procedure 17, go out to column under 2° and we find .30. Put this down. Now refer back under column head and we find .15. One-half of this one degree would be .075 This added to .30 equals .375 Refer to below and note .375 equals ⅜ of an inch.

CHART NO. 51—Table to Convert Degrees into Inches. Fractions of Hundredths into fourths of an inch. (From Horseless Age)

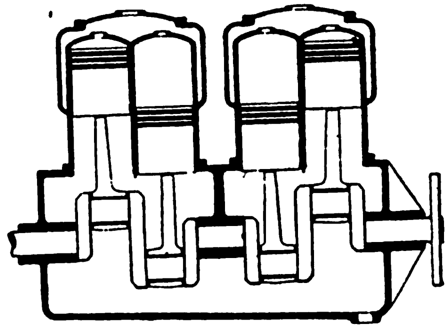

Fig. 1. Four Cylinder Engine: crank shaft set at 180 degrees. Power stroke every half revolution.

Note the shape of crank shaft has an important bearing on the firing order. The actual firing order is governed by the relative position of the cams.

If piston No. 1 is going down say on power, No. 2 must be coming up on either compression or exhaust. If coming up on compression it would fire next. No. 3 would then be coming up on exhaust and No. 4 suction. Therefore the firing order would be 1, 2, 4, 3 (see lower table, bottom of page).

If No. 1 was going down on power and No. 2 coming up on exhaust, then No. 3 would be coming up on compression and would fire next. Therefore the firing order would be, 1, 3, 4, 2.

Remember that the two down strokes are, suction and power. The two up strokes are, compression and exhaust. Each piston must be doing one of the four, during each of the four strokes or two revolutions.

The change of firing is accomplished by the movement of cams on the cam shaft. The cams on cylinder No. 2 and 3 being the only two affected. See below.

If piston No. 1 goes down on power stroke.	Piston No. 2 would be coming up on exhaust stroke if firing order is 1, 3, 4, 2. or **Compression stroke** if firing order is 1, 2, 4, 3.	Piston No. 3 would be coming up on **compression** if firing order is 1, 3, 4, 2. or **Exhaust** if firing order is 1, 2, 4, 3.	Cylinder No. 4 would be going down on **suction** on either firing order.

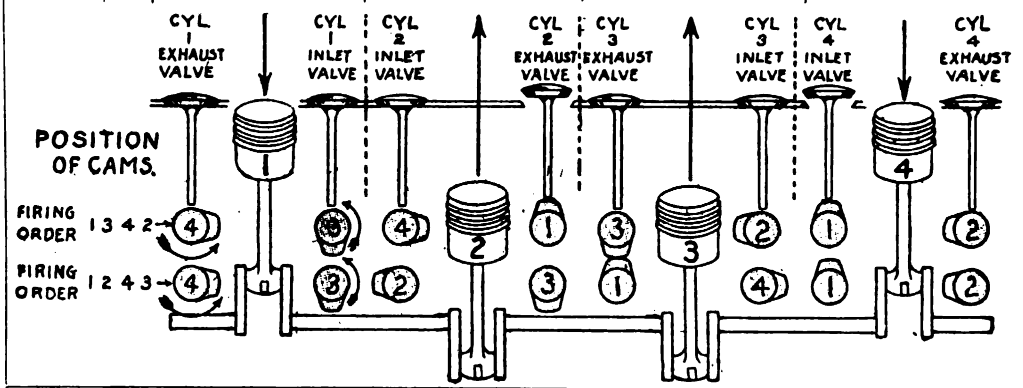

Fig. 2.—Relative position of cams and pistons when No. 1 piston is ready to start down on power stroke. The upper row of cams show position of cams when the firing order is 1, 3, 4, 2.

Note: Cam shaft operated by gears (and not having an idler), turn in opposite direction to crank shaft and just once to the crank shaft twice.

When No. 1 Piston is	No. 2 Piston is	No. 4 Piston is	No. 3 Piston is
STARTING DOWN ON FIRING OR POWER STROKE	Just starting up on COMPRESSION	Just starting down on SUCTION	Just starting up on EXHAUST
Just starting up on EXHAUST	TOP ON FIRING STROKE	Just starting up on COMPRESSION	Just starting down on SUCTION
Just starting down on SUCTION	Just starting up on EXHAUST	TOP ON FIRING STROKE	Just starting up on COMPRESSION
Just starting up on COMPRES.	Just starting down on SUCTION	Just starting up on EXHAUST	TOP ON FIRING STROKE

The lower row of cams show position when the firing order is 1, 2, 4, 3.

Referring to fig. 5, page 58, note numbers on cam denote position. Each stroke of the piston, or half revolution of crank, the cams travel 90 degrees or ¼ of a revolution.

HOW THIS FOUR CYLINDER ENGINE FIRES 4 times during two revolutions of the crank shaft or four strokes of the piston. Fires 1, 2, 4, 3; diagram to the left, and 1, 3, 4, 2; diagram to the right.

It will be noticed that to change from one firing order to another, merely the cams on valves of cylinders 2 and 3 are changed. (Also the ignition wires.)

When No. 1 Piston is	No. 3 Piston is	No. 4 Piston is	No. 2 Piston is
STARTING DOWN ON FIRING OR POWER STROKE	Just starting up on COMPRESSION	Just starting down on SUCTION	Just starting up on EXHAUST
Just starting up on EXHAUST	TOP ON FIRING STROKE	Just starting up on COMPRESSION	Just starting down on SUCTION
Just starting down on SUCTION	Just starting up on EXHAUST	TOP ON FIRING STROKE	Just starting up on COMPRESSION
Just starting up on COMPRES.	Just starting down on SUCTION	Just starting up on EXHAUST	TOP ON FIRING STROKE

CHART NO. 53—Firing Order of a Four Cylinder Four Cycle Engine. Relative Cam Movement to Crank Movement. (See charts 55, 62 and 65, for explanation of firing order of a Six, Eight and Twelve (twin six) cylinder engine.)

How to tell firing order of engine by position of cams; see page 120.

Chart 52 on page 118.

INSTRUCTION No. 10.

FIRING ORDER: One, Two, Three and Four Cylinder Engines.

†Firing Order of One and Two Cylinder Engines.

There are four strokes to two revolutions of the crank to complete a cycle operation, as explained in chart 29.

A stroke of the piston means a travel from top to bottom or bottom to top, or 180 degrees movement, or one-half of a revolution of the crank shaft.

There is but **one power stroke during the four strokes**, or two revolutions of the crank shaft. Also note that the power stroke is a very short one; owing to the fact that the exhaust valve starts to open considerably before piston reaches bottom of its stroke. If the exhaust valve should open 46 degrees before bottom, then the travel on power stroke would be but 134 degrees instead of 180 degrees.

Therefore, if there is but one power stroke to two revolutions of the crank shaft, we would have only 134 degrees out of the two revolutions, (or 720 degrees travel of crank) on which there is power. (See chart 46.)

In an engine with one cylinder (fig. 1, chart 52), there is an **explosion once during** every two revolutions of the crank shaft, or in other words, there is one stroke of the piston when power is being developed, and three when there is no power, the piston then being moved by the momentum of the fly wheel.

As the piston must be carried through the three dead strokes, it is necessary to use a heavy fly wheel, so that when it is started it will continue to revolve for a sufficient time to move the piston until the next power stroke.

There is vibration from a one cylinder engine on this account for the weight of the piston sliding first one way and then the other has nothing to balance it.

It can be balanced to some extent by attaching a weight called a "counter balance," (fig. 12, chart 36), to the crank shaft opposite to the crank pin, in the same manner that the wheels of a locomotive are balanced, but even so there is vibration owing to power stroke at intervals.

An engine with two cylinders: one piston can be arranged to slide inward as the other slides outward, so that one balances the other, as in fig. 4, page 118. This type of engine is called an **opposed** type of engine. Cylinders are set 180 degrees apart, also crank shaft. When one piston starts down on power stroke, the other would start down on suction, therefore referring to the scale under fig. 4, note there would be a firing impluse at each revolution of the crank shaft or every 360°. There is still vibration, however, as the power stroke is not continuous.

The two types of **twin vertical** cylinder engines, figs. 2 and 3, page 118, are explained in text matter in the chart. Fig. 2 would cause considerable vibration, as would also fig. 3.

The fly wheel of a two cylinder engine need not be as heavy as that of an engine with one cylinder, because it is required to carry the piston through only one dead stroke before another power stroke occurs. On 6, 8 and 12 cylinder engines, the fly wheel is very small in diameter.

The more cylinders an engine has, the more steadily it may run, for the explosions may be arranged to follow one another so closely that there is no moment when one of the pistons is not on the power stroke.

**Firing Order of a Three Cylinder Engine.

Three cylinder engine fires 1, 3, 2 from front of engine or 1, 2, 3 if from rear.

The action of the firing of a three cylinder engine is this: Taking three points of the circle (see page 119.) A at the top, B and C on each side below, the piston of No. 1 cylinder is connected with a crank at A, to No. 2 cylinder at B and to No. 3 cylinder at C.

†See pages 122, 131, 135, for firing order of 6, 8 and 12 cylinder engines.

**Based on exhaust interval being equal to 180 degrees travel. In actual practice it is more—See page 100.

Firing Order of One, Two and Three Cylinder Engines.

Fig. 1—Single cylinder engine, with crankshaft set at 360°: There are four strokes of 180° on all four cycle engines, therefore, there would be two revolutions of 360° each, or 720° travel of crank.

If the firing stroke started on top and traveled to within 46° of bottom when exhaust opened, there would be but 134° of the 720° on which the piston traveled on power.

There is one power stroke (firing impulse), **every two revolutions** of the crankshaft on one cylinder, four cycle engines—see diagram fig. 1, below.

Single cylinder engines usually have counter-weights on the crank arms or fly wheel to counter-balance same.

Fig. 2—Two cylinder vertical engine with a 360° crankshaft: If piston of No. 1 cylinder is on power (P), No. 2 would be on suction (S)—see diagram below—therefore we would get an even firing impulse, or one **during each revolution.** But as both pistons are moving together, there would be considerable vibration, as both are on top or bottom at the same time. Counter weights are also used on the crankshaft of this type of engine in order to counter-balance.

Fig. 3—Two cylinder vertical engine with a 180° crankshaft: There are two firing orders of this engine, both of which would cause vibration. Refer to diagram and note first one. If No. 1 is on power (P), No. 2, would be coming up on compression (C), and would fire next. Therefore, there would be **two firing or power impulses during one revolution,** and on the second revolution there would be no firing impulse at all.

With the other order of firing; if No. 1 was on power (P), No. 2 would be coming up on exhaust (E), **the crank would therefore travel 540°, or 1½ revolutions with but one firing impulse.**

Fig. 4—Two cylinder engine with cylinders opposite and crankshaft set 180°: This type of engine **gives a firing impulse every revolution**—see diagram below—it is mechanically balanced.

Fig. 1—One cylinder engine with a 360° crankshaft.

Firing impulse every two revolutions — see diagram below.

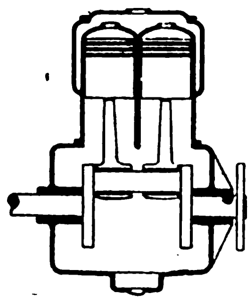

Fig. 2—Two cylinder vertical engine with a 360° crankshaft.

Firing impulse every revolution.

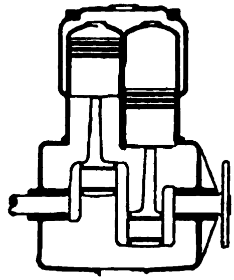

Fig. 3—Two cylinder vertical engine with a 180° crankshaft.

Two different firing orders —see diagram below.

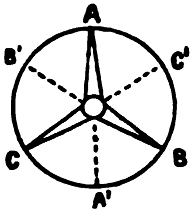
CHART NO. 52—Firing Order of One, Two and Three Cylinder Engines.

Chart 54 on page 121.

—Continued from page 117.



No. 1 cylinder will be at full compression, No. 2 cylinder at two-thirds inspiration, and No. 3 cylinder one-third, exhaust 240°.

No. 1 cylinder: The crank of this performs its half revolution, bringing it to position A', midway between points B and C.

Whilst it is doing this, No. 2 cylinder is completing its inspiration stroke, and two-thirds of its compression stroke, and the crank is passed on to position B', leaving only one-third of a stroke to complete compression, and bring the crank to A, when the firing of B commences.

Meanwhile C is completing its exhaust and inspiration strokes, and has passed through two-thirds of its compression stroke, so that when No. 2 cylinder has completed its impulse, No. 3 has but to be carried over the small gap by the fly wheel, which gap represents the minus lap.

Each of the three cylinders fire once every 720° (two revolutions), or 240° apart.

No. 1 (A) fires and moves 240 degrees, which brings No. 2 (B) in firing position. No. 2 (B) fires and moves 240 degrees, which brings No. 3 (C) in firing position. No. 3 (C) fires and moves 240 degrees, which again brings No. 1 (A) in firing position.

No. 1 (A) has now made two revolutions or 720 degrees, which completes the four cycle evolution.

The working stroke is 134 degrees, therefore 240 degrees less 134 degrees equals 106 degrees, during which time no work is being done (—106° lap), that is, the fly wheel carries the crank 106°.

Firing Order of a Four Cylinder Engine.

Four cylinder engines are so arranged there is a **power or firing impulse every stroke**, or two firing impulses every revolution, one beginning as the previous one ends.

In order to complete the four cycle evolutions of suction, compression, explosion and exhaust for each piston, it is necessary that each piston have four strokes. As 1 and 4 work together and 2 and 3 work together, then four strokes; two up and two down, or two revolutions of the crank shaft will give the complete cycle evolution for each piston, with a firing order of either 1, 2, 4, 3, or 1, 3, 4, 2. (See diagrams bottom of page 116.)

The crank shaft of a four cylinder four cycle engine is always set at 180 degrees. (See pages 78 and 116.)

Note the "throws" of a four cylinder crank shaft (see fig. 1, page 116); 1 and 4 (end cranks) are in line, and 2 and 3 (inside "throws" or cranks), are in line—therefore 2 and 3 are one-half revolution, or 180° from 1 and 4.

The construction of the crank shaft would not permit the firing to be 1, 2, 3, 4, because, when 2 was ready to go down on power stroke, 3 would have to be coming up on compression, but as 3 is always the same position as 2, then it could not be coming up, as it would already be up with 2. (See fig. 1, page 116.)

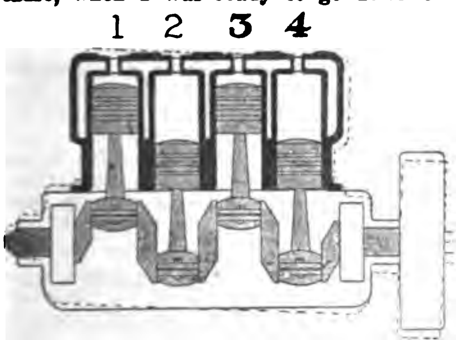


Fig. 2.—Type of crank shaft which would permit a four cylinder engine to fire 1, 2, 3, 4, but is never used.

Type in general use, see fig. 1, page 116.

For the reason that 1 and 4 are together (up or down), and 2 and 3 are together (up or down), the firing order must be 1, 2, 4, 3, or 1, 3, 4, 2. (See page 116.)

A four cylinder engine could be made to fire 1, 2, 3, 4, by having crank shaft made as per fig. 2, but it would vibrate excessively on account of the rocking motion of firing from one end to the other. Therefore the firing order on all engines is arranged to **decrease vibration** as much as possible. The alternate distribution of impulse (firing) tends to steady the engine, as 1, 2, 4, 3, or 1, 3, 4, 2.

Cylinders are originally made to fire in proper order by the manufacturer, by setting the cams on the cam shaft (see fig. 2, page 116), and commutator or distributor wired to connect with the proper spark plugs (see charts 144 and 145).

The order of firing depends on the ideas of the maker, and may be either, 1, 2, 4, 3, or 1, 3, 4, 2, on a four cylinder engine.

The eight "V" type of cylinder engine, uses a four cylinder 180 degree crank shaft with two connecting rods to one crank pin. See chart 36, page 78.

The twin six or twelve "V" type engine uses a regular six cylinder crank shaft. This will be treated farther on, together with firing order. Also see charts 62 to 65.

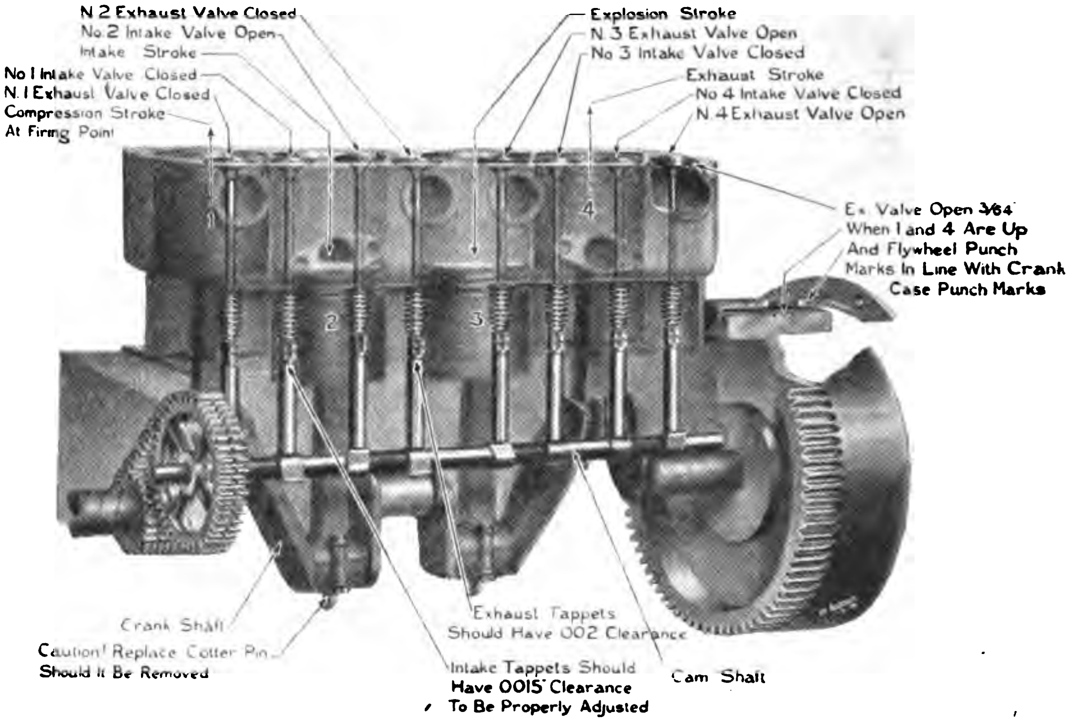

Fig. 3: Illustration showing how the cam shaft with its cams are driven by a silent chain sprocket. Also note the **mark on fly wheel** in line with punch mark on **crank case** when pistons 1 and 4 are on upper dead center which they are now, pistons 2 and 3 are on **lower** dead center. (No. 1 is next to timing gears) at this point, the setting of valves and gears are determined.

For instance, if the exhaust must close say at 10° past upper dead center, then the fly wheel is revolved in the direction of rotation 10° from upper dead center. Then at this point the exhaust valve of No. 1 cylinder should just close. This is sufficient as all other valves will be timed to open and close at the correct time.

If the exhaust did not close at 10° past dead center, then it is either because the **clearance** of the **exhaust valve tappet** is set too close and holds the valve open too long, or the **cam shaft gear is not meshed** properly. (See pages 102 and 112.)

The firing order of above engine can be determined by observing the position of the pistons and valves: Exhaust and inlet of No. 1 are closed; piston of No. 1 cylinder is at top of compression and will go down on **power** stroke. Piston of No. 2 cylinder is at bottom of its intake stroke and will come up on compression; inlet valve still open and exhaust closed. Piston of No. 3 cylinder is at bottom of its stroke and will come up on exhaust stroke; exhaust valve is open and intake valve is closed. Piston of No. 4 cylinder is at top of its stroke and will go down on suction; exhaust valve will close within a 10° movement of crank shaft (note exhaust cam just leaving the No. 4 exhaust valve tappet), and the inlet will open immediately as piston starts down.

Now to determine the firing order: If No. 2 will come up on compression as No. 1 piston goes down, and if the power stroke follows immediately after the compression stroke, then No. 2 will fire next. Therefore firing order must be 1, 2, 4, 3. The only other firing order it could possibly have, would be 1, 3, 4, 2—but this is impossible because No. 3's exhaust valve is open and it will come up on exhaust, then after exhaust comes suction. No. 3 has just fired, therefore No. 1 will fire next.

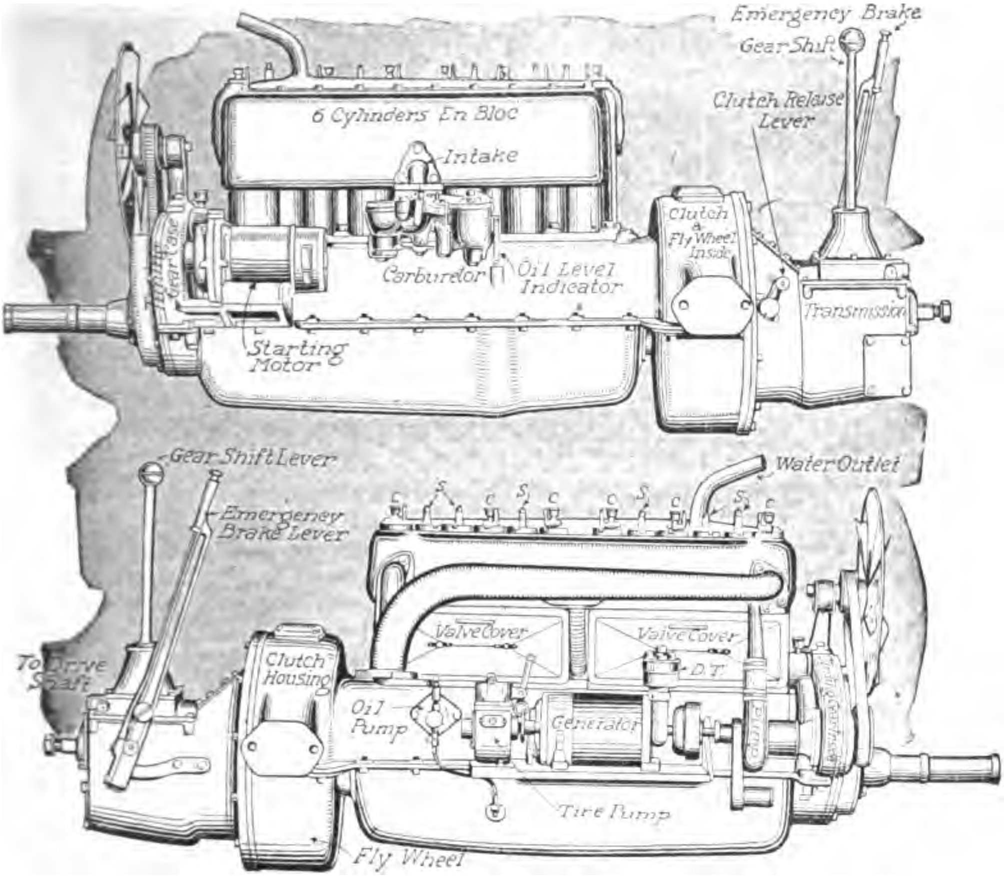
A quick way to determine firing order of a four cylinder engine: when nose of **first** and **third** cam (inlet or exhaust) are on opposite sides of a shaft; engine fires 1, 2, 4, 3. When first and third cams are on the same side of shaft; firing order is 1, 3, 4, 2.

Note—Cam shafts operated by silent chains and sprockets turn in the **same** direction **as the** crank shaft and just once to the crank **twice.**

Cams in fig. 2, page 116 are made to open and close exactly on a stroke of the piston or 180° movement of crank, which is unusual in actual practice.

On above engine, fig. 3, the cams are set as in actual practice, for instance, the above **valves** open and close as follows: **Exhaust closes** 10 degrees after top. **Inlet opens** 6 degrees **after top. Exhaust opens** 50 degrees before piston is at bottom dead center. **Inlet** closes 40 degrees **after** bottom dead center. The **bore** of cylinders is 3¾ inches diameter and the **stroke of piston is 4¼ inches.**

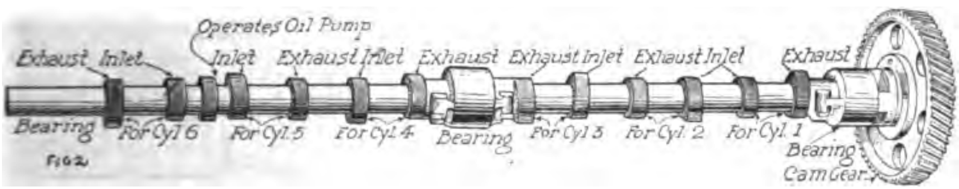
The make of above engine is the Golden Belknap and Swartz Co.'s. model E-M 31, four cylinder side valve detachable head engine. Horse power is 22½ at 935 feet of piston speed per **minute.** Produces 36.9 h. p. at 2,800 r. p. m. on actual brake test and 31.9 h. p. at 2,000 r. p. m.

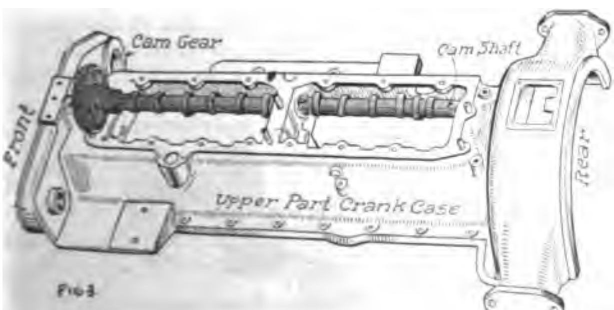


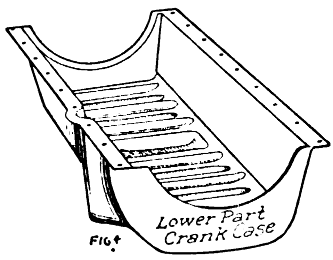
Left and right hand view of a modern type of six cylinder engine power plant.

"Unit Power Plant," meaning engine, clutch, and transmission are all in one unit.

Cylinders are cast "in block." Clutch encased with fly wheel and disc type. **Valves** "L" type enclosed. Gear control by "ball and socket" type of gear shift lever. **Generator** driven from pump shaft. Starting motor drives crank shaft. Note the **spark plugs** (S) are usually over the **inlet valves.**







Note the cams on this the "L" type engine are all on one cam shaft. Cam gear meshes with a gear on crank shaft. Note: "upper part crank case," now known as "crank case." "Lower part crank case," now known as "oil pan.".

CHART NO. 54—Right and Left Side View of a Modern Six Cylinder Automobile Engine. (The Haynes).

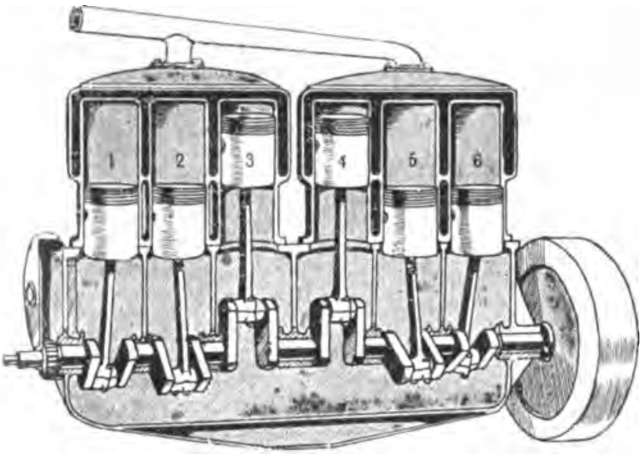


Fig. 1. A six-cylinder engine with seven bearings to the crankshaft and cylinders cast in two blocks of three.

Fig. 1. Note piston and crank 1 and 6 are in line with each other. Also 3 and 4 and 2 and 5. An end view is shown in fig. 2. Firing order of above is 1, 5, 3, 6, 2, 4. **No. 5 has just fired.** No. 3 will fire next, then 6, 2, 4—see illustration, fig. 2, for explanation.

Fig. 2. This is an end view of crank shaft in fig. 1 illustration. Cylinders are in line with each other, when in cylinders. In this illustration they are supposed to be out of cylinders, hence not in line.

The throws of a 6 cylinder crank are divided into three positions, or 120° apart.

1 and 6 are always in line
3 and 4 are always in line
2 and 5 are always in line

but they may be placed to the left or to the right as shown in figs. 4 and 5.

On the above; firing order could be 1, 5, 3, 6, 2, 4 or 1, 2, 4, 6, 5, 3. Assume that we are standing in front of engine; No. 5 has just fired, No. 3 will fire next, then 6, 2, 4.

Fig. 3. Counter balance weights applied to a six cylinder crank shaft with the result that the engine attains a speed of 2,500 revolutions per minute without detrimental vibration.

Bearings on the six cylinder crank shaft are usually three, as per fig. 5, below.

Sometimes seven bearings are used as illustrated in figs. 1 and 4.

The right and left hand crank shaft, referred to on page 123 are illustrated below.

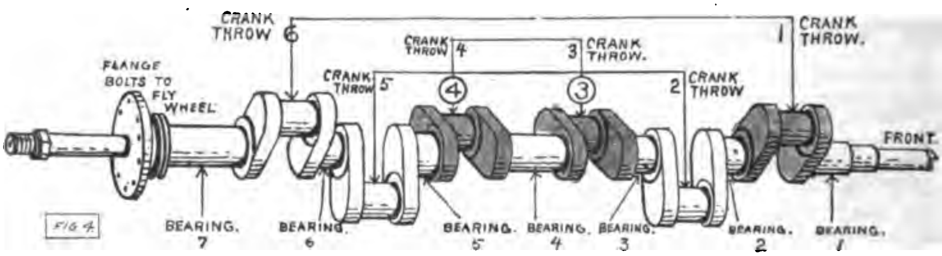

Fig. 4. A right hand 6 cylinder crank shaft, is determined by noting position the center throws, 3 and 4 are to 1 and 6. If they are to the right of 1 and 6, as shown above and as illustrated in fig. 1, page 124, then it would be a right hand crank (view from front).

A right hand crank will fire 1, 5, 3, 6, 2, 4 or 1, 2, 4, 6, 5, 3.

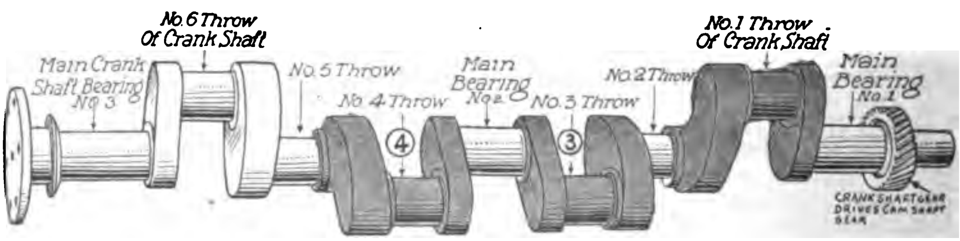

Fig. 5. A left hand 6 cylinder crank shaft; note 3 and 4 throws are to the left of 1 and 6 as illustrated, also in fig. 2, page 124.

Therefore it would fire, 1, 4, 2, 6, 3, 5 or 1, 3, 5, 6, 4, 2.

CHART NO. 55—Crank Shafts of a Six Cylinder Engine.

INSTRUCTION No. 11.

SIX, EIGHT and TWELVE "V" TYPE CYLINDER ENGINES. Rotary Valve and Rotary Cylinder Engines. Sleeve Valve Engine. Overhead Cam Shaft Engine.

The Six Cylinder Engine.

The variance in construction is principally in the addition of more cylinders and the shape of the crank shaft.

The cylinders may be in "pairs" or in "triplets" or "in block." The usual order is in two blocks, of three to a block. Cylinders on a six cylinder engine are usually "L" type. The **cam shaft** is shown in fig. 2, page 121.

The six cylinder engine operates on the four cycle principle, the same as the four cylinder; in fact the general principle is used; the **crank shaft must turn** two revolutions during the cycle or four strokes. The **cam shaft turns** one revolution. The shape of the crank shaft of a six makes it possible for each piston to complete the four strokes—see figs. 1 and 2, chart 55; note the crank shaft is divided into three pairs of "throws." Pistons 1 and 6 are in line; 3 and 4 are in line and 2 and 5 are in line. A "throw" on a crank shaft is the part to which the big end of connecting rod connects and is really the "crank pin." Each pair of these crank shaft "throws" (1 & 6 & 3 & 4 & 2 & 5) are placed 120 degrees or 1/3 the distance of a circle apart.

There are six power impulses or explosions during two revolutions of the crank shaft, therefore the magneto armature* turns 1½ revolutions to one of the crank shaft. When piston, say No. 1 goes down on firing stroke, it must make a full stroke or 180 degrees or ½ of a revolution of the circle, it could not stop at 120—see chart 57 for explanation, also fig. 2, page 122.

A degree is 1/360th part of a circle. There are 360 degrees to a circle. This mark, ° which is nothing more than a small "0" to the side of a figure, represents degrees. For the crank shaft to make one revolution, it must make a complete circle or 360 degrees. Although each pair of "throws" of the crank shafts are placed 120 degrees apart, this would place one pair, say pistons 4 and 3 at A, another pair pistons say 5 and 2 at B, 6 and 1 at C. Each pair would be 1/3 the circle apart.

There are two kinds of six cylinder crank shafts; left hand and right hand—see figs. 4 and 5, page 122. The cylinders usually ‡fire on a right hand crank 1, 5, 3, 6, 2, 4, while on a left hand the order is usually 1, 4, 2, 6, 3, 5—see pages 124 and 122.

The number of bearings for the six crank shaft may be 3, or 7. Three bearings is the usual number. **The carburetion.** A six cylinder engine usually requires special intake pipes and double or multiple jet type of carburetor to meet the demand of the multiple of cylinders and distance the carburetted gas must travel. **The timing** of six cylinder valves is identical with that of the four. The process is gone through with just in the same manner. It is only necessary to time with the **exhaust valve closing** on the first cylinder and the "L" type, and on "T" head type, with exhaust valve closing on exhaust side and inlet opening on inlet side.

If the reader will turn to charts 55, 56 and 57 the explanation of the six cylinder engine will be made more clear.

†See Dyke's working model of the six cylinder engine. *If a timer and distributor, they turn one revolution to the cranks two, or same as the cam shaft. See index "ignition timing." ‡See foot note bottom of page 79.

*See "Specifications of Leading Cars," page 544 for cars using 6 cylinder engines.

‡There are four standard firing orders of a six cylinder engine. Read matter under figs. 4 and 5, page 122.

Firing Order of a 6-Cylinder "Right Hand" Crank.

Fig. 1.

Firing order 1, 5, 3, 6, 2, 4, (could also fire 1, 2, 4, 6, 5, 3.)

Illustration shows pistons 1 and 6 up. If No. 1 starts down on "firing," No. 5 would be coming up on compression, as it would fire next. No. 3 would be 120° behind No. 5 and would fire next. No. 6 being 120° behind No. 3, it would fire next, then No. 2, then No. 4.

To get the second firing order (1, 2, 4, 6, 5, 3,) start with No. 1, then 2, 4, 6, 5 and 3. Note. View from front of engine. Although pistons are shown out of line, this is necessary in order for the reader to understand the relative positions, one to the other. When in cylinders they are all in line and the connecting rods are out of line.

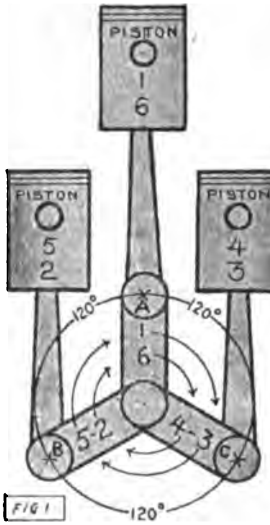

FIG 1

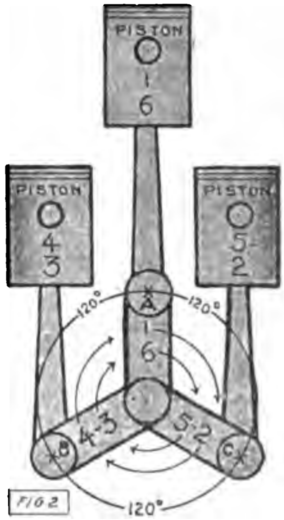

FIG 2

Firing Order of a 6-Cylinder "Left" Hand Crank.

Fig. 2.

Firing order, 1, 4, 2, 6, 3, 5, (could fire 1, 3, 5, 6, 4, 2). If No. 1 starts down on firing, No. 4 would fire next, then No. 2, then 6, 3 and 5 in their respective order.

To get second firing order (1, 3, 5, 6, 4, 2,) start with No. 1, then No. 3, 5, 6, 4 and 2. Note view is supposed to be from the front of engine.

An end view of the Chalmers six cylinder engine ("6-30") is shown to the right. The firing order of this engine is 1, 4, 2, 6, 3, 5—see the top row in table to the left.

This illustration is shown, in order that the reader may see just how the pistons are all in line when in the cylinders, instead of being out of line as shown in the exaggerated drawings, figs. 1 and 2.

Timing Chalmers valves: Turn the fly wheel, bringing the mark "Ex. Cl." (exhaust closes) on the fly wheel, exactly in line with the centered reference mark pointer on the rear of the crank case. With the fly wheel mark in this position, the exhaust valve on the No. 1 cylinder should just close. If not, adjust the exhaust cam so it is at the closing point.

It is essential that these adjustments shall always be made with the "back lash" or lost motion in the driving gear entirely taken up in the same direction, that is, in the direction of the rotation of the engine when running.

CHART NO. 56—Two Firing Orders of a Six Cylinder Engine Explained.

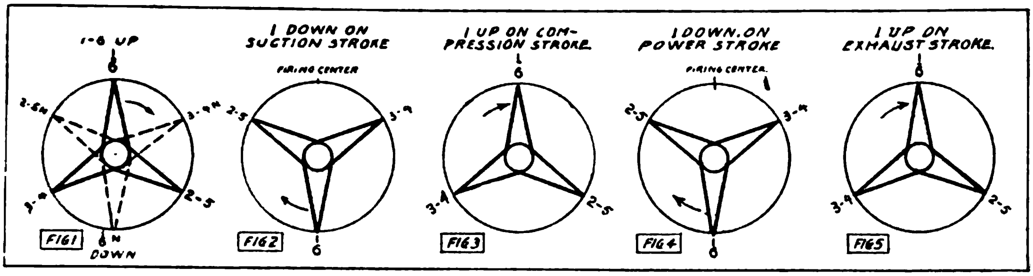

Fig. 1.—Relative position of Pistons on a Six Cylinder Engine. View of illustrations are in front of engine—hence cranks are rotating to the right.

Note pistons must make a full stroke, up or down and crank throws must travel 180° at each stroke, or ½ revolution just the same as a four cylinder.

In order however, to show how and when the cylinders can fire 6 times during two revolutions of the crank shaft—the above illustration and the firing table in Chart 56 is provided.

The pistons must go from the extreme top to the bottom at each explosion or stroke.

***Fig. 1—If 1 and 6 pistons go down** on say, firing stroke, then they would go to bottom "1-6 N down," which is a half revolution of the crank or one stroke or 180°.

Then pistons 2 and 5 would be at dotted line position "2-5 N;" 3 and 4 pistons would be at dotted line position "3 and 4 N."

Therefore we have an "over lapping" of strokes—see Chart 58.

Only two of the six cranks are on dead center at the same time. The firing point is at top.

Fig. 2.—Note position of 2-5 and 3-4 after 1 and 6 have just made a half revolution or suction stroke down. They have both moved 180°. Also note that as 3 and 4 passed the top, or firing center, either 3 or 4 must have fired.

Fig. 3.—1 and 6 have now made another stroke up, on compression, (stroke No. 2), or 180° more or 360° in all, or a revolution. Note 2 and 5 passed the firing point during this stroke; therefore either 2 or 5 must have fired.

Fig. 4.—1 and 6 have now made another stroke down on power and fired, (stroke No. 3) or 180° or 1½ revolutions in all. During this stroke, 3 and 4 passed the firing point again and one or the other must have fired.

Fig. 5.—1 and 6 have now made its fourth stroke, up on exhaust, or another 180° or 2 revolutions in all. During this stroke 2 and 5 passed the top center firing point again, and either 2 or 5 fired.

Note we have followed out the four strokes, during two revolutions, and during the four strokes, there were 6 explosions, or power impulses, as the pistons passed the top.

A six differs from a four cylinder engine, only in the shape of crank shaft, which is divided into thirds instead of halves.

*Note when 1 and 6, or either pair go down or up; only one of the pair is on firing or compression. Both could not be on firing at the same time. (See Chart 56). However, in order to explain how the cranks travel in pairs we will not state which one of the pair is on the above mentioned stroke.

CHART NO. 57—How the Six Cylinder Engine makes Six Impulses during Two Revolutions of the Crank Shaft.

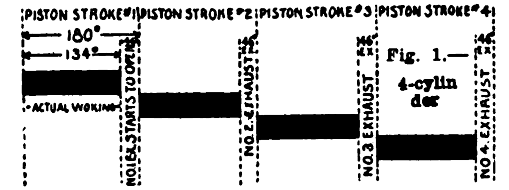

Fig. 2.—6-cylinder.

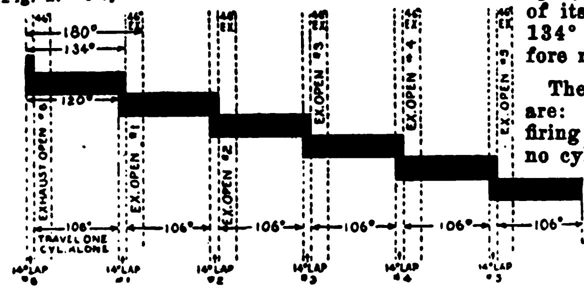

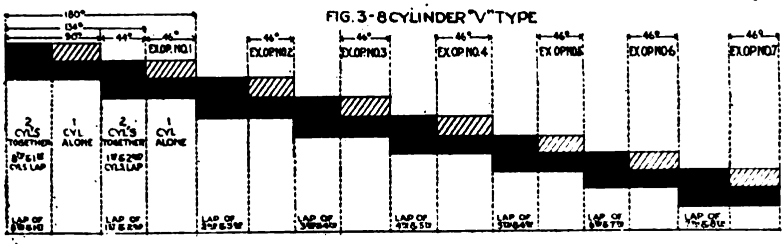

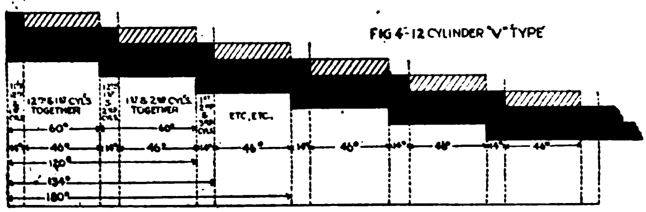

4 Cylinder Lap.

On a 4 cylinder engine there are four periods of 46° travel or 184° in all, during the four strokes that there is no power.

Referring to illustration, fig. 1, note, if piston No. 1 is firing, it does not travel its full stroke with a crank movement of 180° on power, because the exhaust valve starts to open, say 46° before it reaches the bottom of its stroke, therefore it really travels but 134° on its power stroke. Consequently, before next piston fires there is a gap of 46°.

Therefore, in a four cylinder engine there are: 4 periods of 134° when 1 cylinder is firing or working and 4 periods of 46° when no cylinder is firing or working.

The fly wheel must take the pistons over center during the "no" working strokes.

6 Cylinder Lap.

On the six cylinder engine; each piston is working on all of its stroke of 180° except 46°, leaving 134° actually working.

The second cylinder to fire, starts to work 120° after the first starts to work, and works 14° before the exhaust opens or the impulse ends on the first cylinder. Consequently there is no idle space between the firing of cylinders, but quite the reverse, for there is a lapping of power strokes.

There are 6 periods of 106° travel when one cylinder is working alone and 6 periods of 14° travel when two cylinders are working together.

Therefore 7-60ths of the time 2 cylinders are working together and 53-60ths of the time 1 cylinder is working alone.

Eight Cylinder Lap.

The eight cylinder V type with cylinders 90° apart; when one cylinder is firing it travels the same as the four; 134° on power when the exhaust starts to open, say at 46° before bottom of its 180° stroke.

The second cylinder starts to fire 90° after the first, and moves for 134° before its exhaust valve starts to open.

Therefore there are, during the four strokes, 8 periods of 44° travel that two pistons are working together. 8 periods of 46° travel when one piston is working alone. Therefore 22/45 of the time two cylinders are working together and 23/45 of the time one cylinder is working alone.

12 Cylinder Lap.

The 12 cylinder V type or twin six; when one cylinder is firing it travels the same as those previously described; namely; 134° before the exhaust valve opens, it then continues on for 46° more, till it reaches the end of its exhaust stroke.

When the first cylinder fires, and piston has traveled only 60°, the second cylinder fires and joins No. 1; they then work together for a period of another 60° when the third cylinder fires and joins No. 1 and 2. Now No. 1 has still 14° to travel yet before its exhaust valve opens, so consequently the 3 work together until that occurs.

At the 134° point No. 1 cuts out and Nos. 2 and 3 work together for a period of 46° when No. 4 fires and joins them and so it continues throughout the cycle. See page 134.

CHART NO. 58—Illustrating the "Lap" of Power Strokes of a 4, 6, 8 and 12 Cylinder Engine, the 8 and 12 being of the "V" type. Note, the above diagrams are based on the theory that the exhaust opens 46° before bottom. Also note that diagrams are not drawn to scale.

*The Eight Cylinder "V" Type Engine.

Advantage of multiple cylinder engines: "flexibility" of control, meaning quick acceleration or quick pick up of the engine from slow to fast speed, the absence of gear shifting, and a more perfect control are the features of the six, eight "V" and twin six engines. The more cylinders firing or lapping, the more flexible the control.

The eight cylinder engine is commonly known as an engine with eight cylinders placed consecutively in line over a crank shaft having eight "throws" or crank pins.

The simplest arrangement of eight cylinders would be all in line just as the six or the four are arranged. But this would be impracticable, due to the extreme length and also to the abnormally long crank shaft which would be necessary, while the crank case for such an engine would be very heavy. To get around these difficulties the cylinders are arranged in **two sets of four opposite to each other at an angle of 90° in the form of a V.**

Crank shaft: Arranged in this way, the eight cylinder engine is no longer than a four cylinder one of equal bore. As compared with a six, it has about 30 per cent less length, resulting in a shorter crank case—a weight reduction factor. In addition, its **crank shaft is of the same form** as that of a four, the throws being all in one plane; whereas those of a six crank shaft are in three planes, and is a simpler manufacturing job. Furthermore, the shorter shaft is less given to periodic vibration. The cam shaft is also shorter and less prone to whipping.

Cylinder and connecting rod arrangement: Where cylinders are "opposite," this means the conecting rod lower end is attached together as shown on page 129, and termed, "**yoked**" together. The connecting rods on one cylinder in line with connecting rod on opposite cylinder. Where cylinders are "**staggered,**" this means the lower end of connecting rods are not together but are "**side by side**" on the same crank shaft bearing, (fig. 7, page 74). This naturally necessitates the cylinders on one side, being placed a little to the side, or not exactly in line with opposite cylinder, and termed "staggered."

The cam shaft on the eight V engine may be one or two, the majority use one cam shaft. The Cadillac uses a cam shaft with eight cams operating the sixteen valves, whereas the Cole and King eight V engines, use one cam shaft with sixteen cams; one for each valve.

Lap of power strokes of an eight cylinder "V" type engine: The explanation of the lap of the firing impulses is given in chart 58. This shows that during eight periods of 44° travel, there are two cylinders working together on power, whereas on a six, there are six periods of 14° travel, when two cylinders are working together.

This chart also shows eight periods of 46° travel, when only one cylinder is working alone, whereas in a six there are six periods of 106° travel where one cylinder is working alone.

There are eight power impulses or explosions, during each cycle of two revolutions of the crank shaft. In other words the four strokes or two revolutions, is just the same as in a four, but there are **eight** power impulses or explosions during these **two** revolutions. There is a power impulse every quarter turn (90° movement) of the crank shaft, and thus there is no intermission between them, but rather an "overlapping" so complete that the turning effort is practically constant.

In the six cylinder engine, there is a power impulse every one-third revolution of the crank shaft, and though there always is a turning effort upon the crank shaft, it has more fluctuation, due to the longer interval between impulses.

In the four cylinder engine, an impulse occurs every half revolution, and obviously there are periods in the cycle when there is no appreciable force exerted by any of the pistons. The fly wheel then is called upon to carry the shaft over these power lapses.

The Cadillac Eight.

As an example of an eight cylinder engine and its construction, the Cadillac make will be shown in the charts following.

Although a later model Cadillac is model 55, and 57, the model 51 and 53 will be shown in order that the reader may note the variance in construction or improvements. The improvements of the model 55 are mentioned.

*See page 544; "Specifications of Leading Cars," for cars using eight cylinder engines.

Cadillac 1918, model 57 engine; 8 cylinder "V" type engine is same bore and stroke as formerly; 3⅛" bore by 5⅛" stroke; piston displacement 314 cubic inches. Cylinder heads now detachable. It is no longer necessary to remove radiator to take out water strainer between radiator and water pump. See page 40 for Cadillac clutch and pages 180 and 730 for water thermostat and condenser.

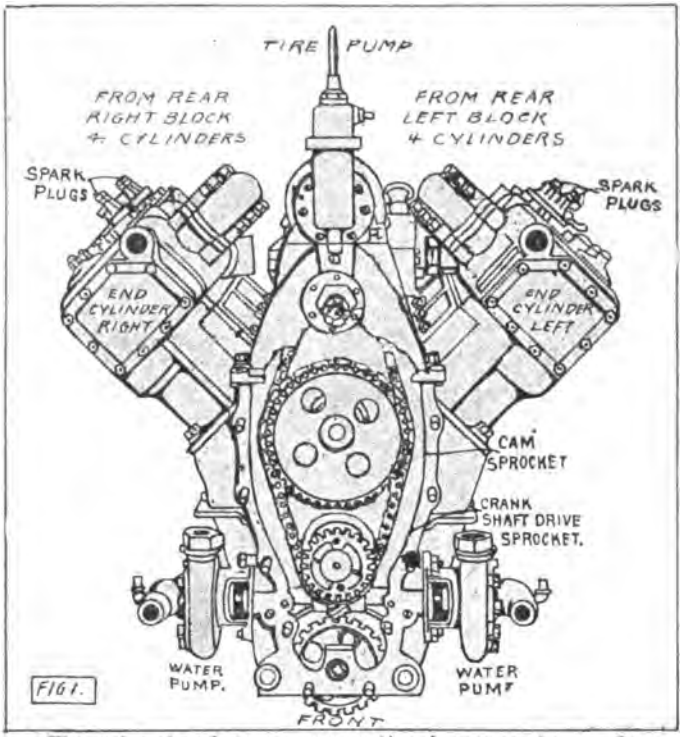

FIG 1.

****Fig. 1. Illustration shows the front end of the Cadillac eight cylinder engine.** There are two groups of cylinders, each a block casting of four cylinders, mounted at 90 degrees to each other on an aluminum crank case. The cylinders are 3⅛ inch bore and 5⅛ inch stroke. The piston displacement is 314 cubic inches; the horsepower rating is 31.25. In dynamometer tests the engine shows 70 horsepower at 2400 r. p. m.. The crank shaft is indentical in design with that used in a four cylinder engine, and the cam shaft carries the same number of cams as in a four cylinder design. This engine weighs approximately 60 pounds less than the four cylinder Cadillac engine of equal horsepower. There is but one carburetor used,—explained further on.

Each of the two cylinder castings contains four L-shaped cylinders. The intake valves are tulip shape*. The exhaust valves are conventional poppet shape. Over each cylinder bore is a removable cap which gives access to the water jacket and to the combustion chamber. Between the second and third cylinder in each block the †breather pipe is brought up through the cylinder casting. In rear of the fan is the power tire pump for tire inflation.††

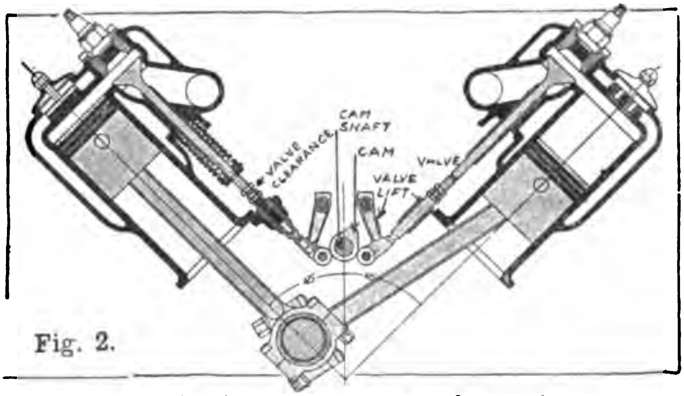

Fig. 2.

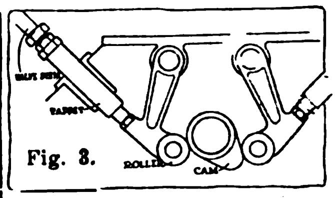

Fig. 3.

Fig. 2. Cross section of Cadillac eight cylinder engine with the cylinder mounted in two groups of four cylinders each at an angle of 90 degrees. The single cam shaft is located direct above the crank shaft, and the means whereby one cam operates the two intake valves for the opposite cylinders is shown.

Fig 3. The valve operating mechanism of the Cadillac engine, showing how one cam operates two opposite valves. The cam bears against the rollers in the ends of the small arms, which are pivoted to the plate above, and which are interposed between the ends of the push rods and the cams, so that the lift will be straight upward instead of having a side thrust component. Adjustment of valve clearance is obtained in the usual way by lengthening the tappet. The upper part of the tappet screws into the lower and the two are locked by a nut. The position of the cylinders, make the valves extremely accessible.

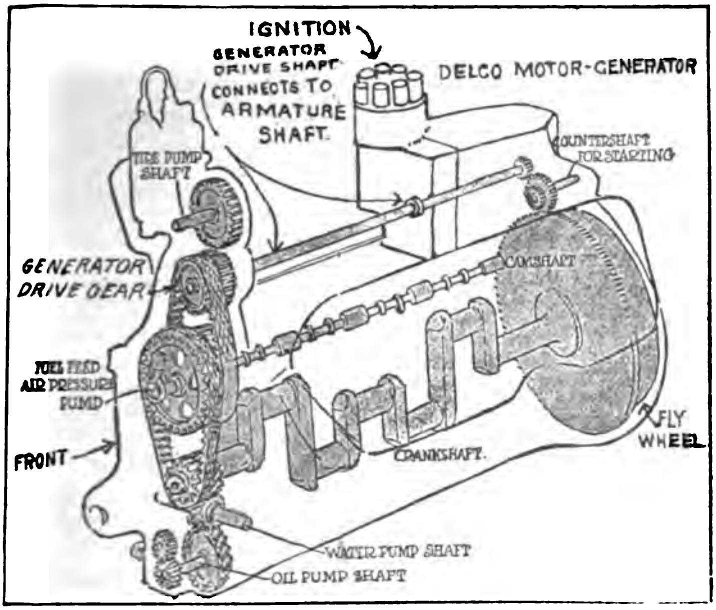
*Note: The tulip shaped inlet valve was used on some of the early model 51 cars, but not on other models.

†On the type 51 and 53 the engine breathers are between the second and third cylinders on each side and serve also as fillers for oil. On Type 55 breathers are on valve cover plates; and oil fillers are as in Types 51 and 53.

††The air compressor is now bolted to right hand side of transmission case and driven by a sliding gear in constant mesh with gear.

CHART NO. 59—The Eight Cylinder "V" Type (Cadillac, model 51).

**See foot note bottom of page 127.



Shafting system in the Cadillac eight cylinder engine, showing the use of two silent chains, one driving the cam shaft and another driving from the cam shaft to the shaft driving the Delco system. The tire pump is driven by spur gear. There are two water pumps on the cross shaft below the crank shaft, and this shaft in turn drives the gear oil pump indicated.

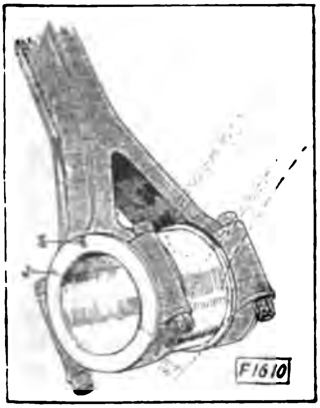
Note the single cam shaft used in eight cylinder Cadillac engines. On it are eight cams which operate the sixteen valves (eight inlet and eight exhaust valves). Each cam works two valves through the rollers shown on opposite sides of it, (fig. 3, page 128.) The shaft is caried on five bearings.

Another make of "V" type engine: The Davis, uses two cam shafts. This permits the direct opening of valves without the rocker arms which are shown in fig. 3 page 128, between cams and tappets. Also permits any desired timing.

The timing of the Davis is as follows:

Inlet opens 10° after top and closes 30° after bottom. Exhaust opens 45° before bottom and closes 5° after top.

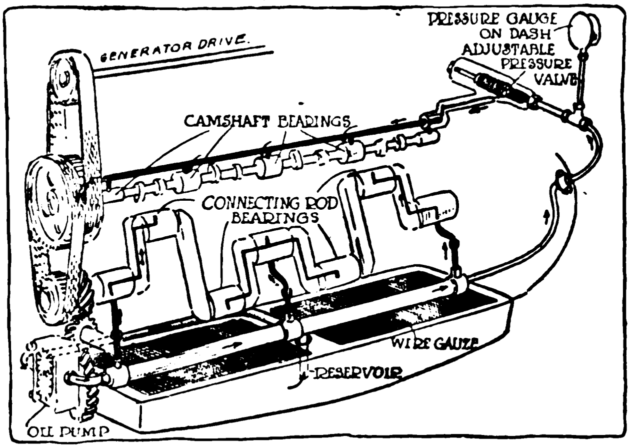
See page 132 for Cadillac ignition timing.



Shewing how the two connecting rods are attached to one bearing. The outer rod fastens to the outer ends of the split bushing (J) with a two-bolt cap for each arm of the yoke.

The bushing is fixed to this rod by pins. The other rod goes between the two arms of the yoke, as shown by the dotted outline. This inner rod is free to move on the bushing. Therefore, the bearing for the yoke end rod is the inner surface of the bushing against the shaft, while that of the inner rod is the outer surface of the bushing.

Crank shaft: A three-bearing crank shaft is used, with the throws at 180 degrees, as in a four cylinder design. (See fig. 5, page 78; connecting rods are "yoked" however.) Two connecting rods attach to each crank pin, this being possible by having one connecting rod with a split or forked lower end, and the other a single end to fit between the forks called "yoked" design.



Lubrication of the eight cylinder Cadillac engine: The pump draws the oil up from the reservoir and forces it through the pipe running along the inside of the crank case. Leads run from this pipe to the crank shaft main bearing and thence through drilled holes in the shaft and webs to the rod bearings. It also is forced from the reservoir pipe up to the pressure valve which maintains a uniform pressure above certain speeds, and then overflows from this valve to a pipe extending parallel with and above the cam shaft. Leads from this latter pipe carry the oil by gravity to the cam shaft bearings and chains. Pistons, cylinders, etc., are lubricated by the overflow thrown from the rods.

CHART NO. 60—Parts of the Eight Cylinder "V" Type Engine (Cadillac); Crank shaft, Connecting rods, Lubrication (model 51). The models 53 and 55 are similar. See separate arrangement of generator and distributor on page 132.

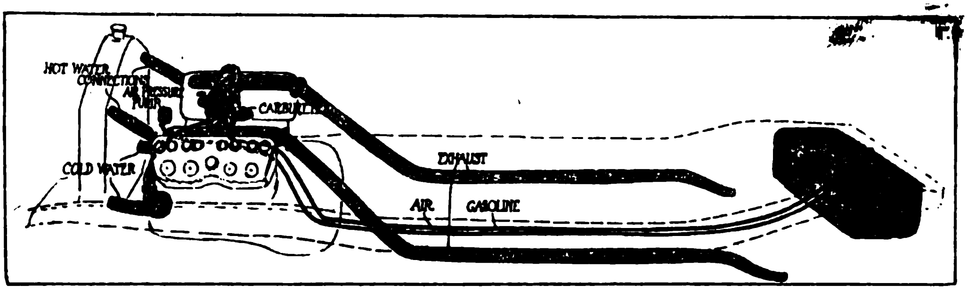


Fig. 3. Diagram showing the general arrangement of the fuel, water and exhaust systems of the Cadillac chassis. There are two exhausts and two mufflers, one for each set of cylinders; while the gasoline is fed by pressure to the carburetor which is between the two cylinder blocks. The air pressure pump for forcing the fuel is at the front of the engine. There are two water pumps and two sets of water connections to the radiator.

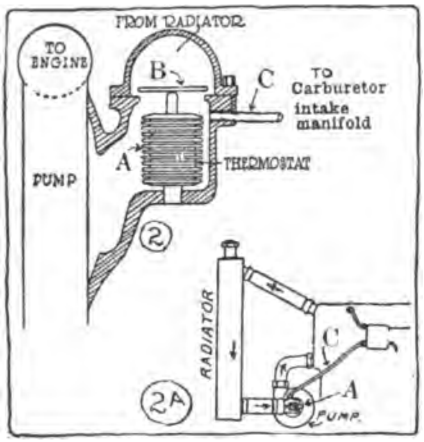

Fig. 2.—*Thermostat principles of water control: A housing containing a syphon thermostat and a valve controlled by the thermostat, are located on the cover of each water pump.

The thermostat (A), fig. 2, is accordion shaped. It contains a liquid which is driven into gas when heated. The resulting pressure elongates or expands the thermostat, forcing the valve (B) from its seat.

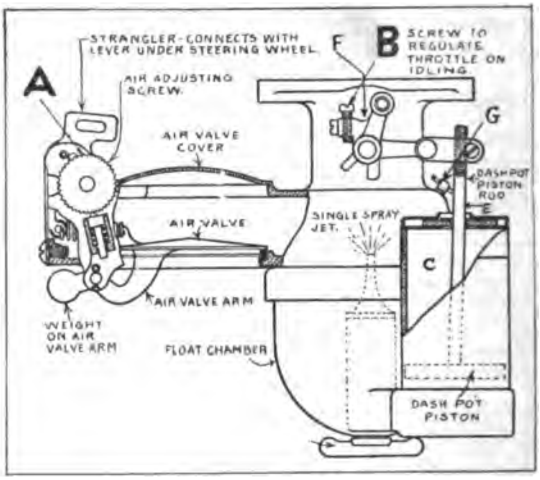
A drop in temperature changes the gas back to a liquid, reducing the pressure in the thermostat and allowing it to contract, thereby bringing the valve (B) back to its seat.

This valve on thermostat is placed in the line of circulation of water, to the side of pump (2A). When cold, the thermostat valve (B) is closed thereby stopping circulation. When warm it expands and opens valve (B) which permits pump to draw water from radiator.

A hand control connected with a shaft extending from cover of pump, is also provided from seat, which can raise this valve, in order to drain radiator.

On the Cadillac model 55 and 57, the water circulation pipe (C) is through jacket of inlet manifold. On the Packard this thermostat is placed directly at top of radiator (rear) and principle is the same.

Condenser as used on Cadillac—see page 730.



To adjust carburetor: 1—Open the throttle about 2 inches on the steering wheel. Place the spark lever in the "driving range' on the sector anl start the engine. 2—Run the engine until the water jacket on the inlet pipe is hot.

3—Move the spark lever to the extreme left on the sector and the throttle lever to a position which leaves the throttle in the carburetor slightly open. Adjust the air valve screw "A" to a point which produces the highest engine speed (see note 2).

4—Close the throttle (move it to the extreme left on the sector) and adjust the throttle stop screw "B" to a point which causes the engine to run at a speed of about 300 revolutions per minute. The spark lever should be at the extreme left on the sector when this adjustment is made.

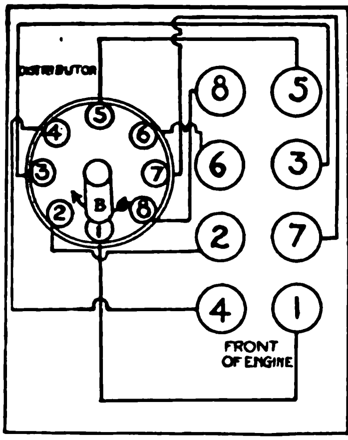
5—With the spark and throttle levers at the extreme left on the sector, adjust the air valve screw "A" to a point which produces the highest engine speed.

Dash pot principle: The cylinder "C" on the carburetor bowl contains a plunger operated by the throttle by means of the connecting rod "F." When the throttle is opened, the plunger is forced into the gasoline in the carburetor bowl. The plunger is drawn out of the gasoline when the throttle is closed. The object of this "throttle pump" or dash pot is to force gasoline through the spraying nozzle when the throttle is opened quickly for acceleration and to assist in starting in extremely cold weather. When the throttle is opened slowly, the plunger has practically no effect on the amount of gasoline passing through the spraying nozzle.

Note 2.—Turning adjusting screws "A" or "G" in a clockwise direction increases the proportion of gasoline to air in the mixture. Turning either in a counter clockwise direction decreases the proportion of gasoline to air.

CHART NO. 61—Cadillac Carburetion. Thermostat. (Model 51, 53 and 55 cars.)

*See pages 187, 189 and also 860.



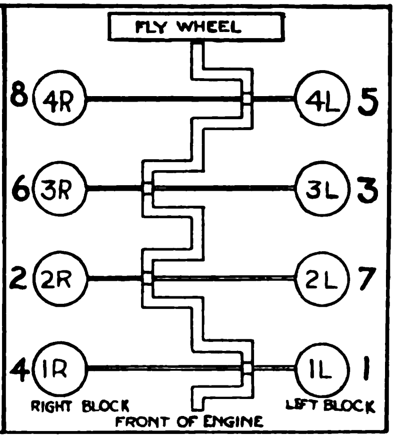


Fig. 1: Distributor connections. **Fig. 2:** Firing order.

Fig. 1: Distributor connections on the model 53, 55, Cadillac—Delco ignition system. The cables lead from connections on distributor to the cylinders in the order which they fire. Note the brush "B" makes contact consecutively, but cables from the distributor are connected to the plugs in their respective firing order.

Fig. 2: Firing order of Cadillac Model 53 and 55. Cylinder marked (IL) fires first, then 2R, 3L, 1R, 4L, 3R, 2L, 4R. Or follow out the black figures on the side of cylinders which show consecutively how cylinders fire.

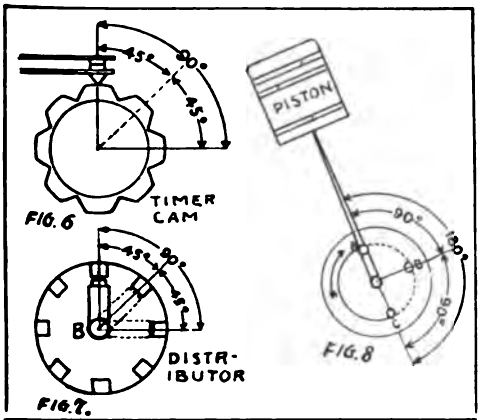

Fig. 6, 7 & 8; Cadillac—Delco distributor and Timer—movement shown in degrees. There is an impulse or firing spark at every 90° movement of crank shaft, which is ½ of a stroke of piston, or ¼ of a revolution of crank.

When crank travels 90°, the timer or distributor brush (B), being run at cam shaft speed, then moves 45°.

When crank makes two revolutions or 720° the timer and distributor brush (B) moves 360° or one revolution. (See Delco system for explanation of the ignition system used on this engine.)

Therefore there are 8 sparks to two revolutions of crank.

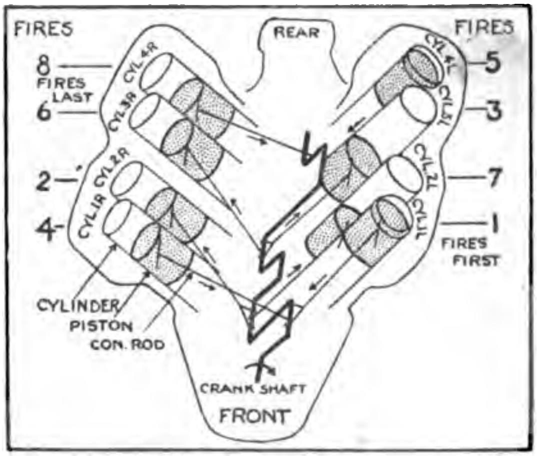

Fig. 10: Relative movement of pistons: By observing piston No. 1, which is now ready to start down on its power stroke or just commencing its working stroke, it can be seen just what is taking place in all the other cylinders, by referring to the following:

1L—Starting to fire.	**2R**—Compressing.
3L—Starting to compress.	**1R**—Suction.
4L—Starting suction.	**3R**—Exhaust.
2L—Starting to exhaust.	**4R**—Working.

Two pistons on the right (when facing engine), are all the way up and two all the way down, while all four on the left are midway.

CHART NO. 62—Cadillac Eight Cylinder V Type Engine. Firing Order and Relative Movement of Pistons, also the Distributor to Crank Shaft. (Model 53 and 55 car.)

*See foot note on page 134 explaining which is the right side of an automobile or engine.

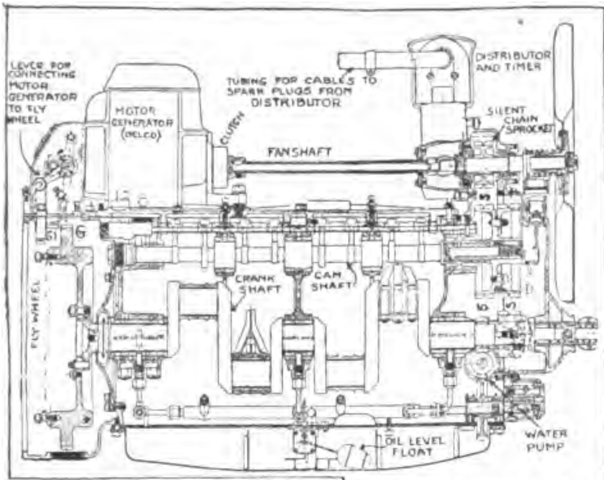

FIG 9 - SIDE VIEW NOTE SEPERATE LOCATION OF MOTOR-GENERATOR AND DISTRIBUTOR MODEL 53

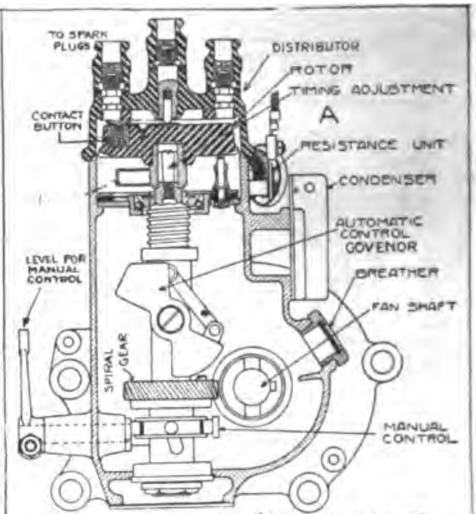

Fig. 10 DISTRIBUTOR AND TIMER

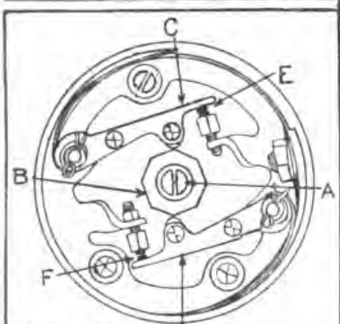

FIG 11-TIMER

Cadillac Ignition System.

The distributor and timer (fig. 10) are carried on the fan shaft housing, and are driven through a set of spiral gears attached to the fan shaft. The distributor consists of a cap or head of insulating material, carrying one contact in the center with eight additional contacts placed at equal distances about the center and a rotor which maintains constant communication with the center contact.

The rotor carries a contact button which serves to close the secondary circuit to the spark plug in the proper cylinder.

Beneath the distributor head and rotor is the timer. The timer cam is provided with a lock screw in the center of the shaft. (See fig. 11.)

A manual spark control is provided in addition to the automatic spark control. The manual spark control is for the purpose of securing the proper ignition control for variable conditions, such as starting, differences in gasoline, weather conditions and amount of carbon in the engine. The automatic control is for the purpose of securing the proper ignition control necessary for the variation due to engine speed alone.

The object for using two contact points on the timer is to distribute over two sets of points the current which would otherwise pass through one. This greatly lessens wear and burning of the points. Interrupter is the closed circuit type.

The timer contact points are set as follows: Turn the engine over until the contact arms "D" & "C" are directly on top of lobes of the cam "B." Then adjust the contact points at "E" and "F" so that they stand twenty-thousandths of an inch apart. Both sets of contact points should be adjusted alike.

To time the ignition proceed as follows: Move the spark lever to the extreme left on the sector; open the compression release cocks on the cylinder blocks, and crank the engine by hand until the piston in No. 1 cylinder is on firing center. (No. 1 cylinder is the one nearest the radiator in the left hand block of cylinders.)

*Next remove the distributor cover; also the rotor, and loosen the lock screw A just enough to allow the cam "B" to be turned by hand after the rotor is fitted. (The lock screw should not be loosened enough to allow the cam to turn on the shaft when the engine is cranked by hand.)

Then replace the rotor and turn it by hand until the distributor brush in the rotor is directly under the terminal marked No. 1 on the distributor cover. Replace the distributor cover, and move the spark lever to the extreme right on the sector.

Then switch on ignition; hold the high tension wire to the spark plug in No. 1 cylinder about one-eighth of an inch away from the cylinder casting and turn the engine slowly by hand in the direction in which it runs. Stop turning immediately a spark occurs between the wire and the casting. (It will be necessary to turn the engine nearly two complete revolutions before the spark occurs.)

If the cam "B" is properly set a spark will occur when a point on the fly wheel one and twenty-one thirty seconds of an inch in advance of the center line for No. 1 cylinder is directly under the pointer or "trammel" attached to the crank case of the engine. This point for each cylinder is marked on the fly wheel by the letter "IG/A."

If the spark occurs before this, rotate the cam "B" slightly in a counter clockwise direction to correct the adjustment. If a spark occurs later than this, rotate the cam slightly in a clockwise direction.

After the adjustment has been properly made, lock the cam securely to the distributor shaft by the lock screw "A."

After locking the adjustment it is a good plan to check the timing by fully retarding the spark lever; in other words moving it to the extreme left on the sector, holding the high tension wire to the spark plug in No. 1 cylinder about one-eighth of an inch away from the cylinder casting, and again turning the engine slowly by hand in the direction in which it runs, stopping immediately a spark occurs.

If the ignition is properly set the spark will occur under these conditions when the center line on the fly wheel for No. 1 cylinder is directly under the pointer attached to the crank case, or has passed the pointer.

Caution: Do not set the ignition so that the spark occurs before center with the spark lever at the extreme left on the sector.

Resistance unit and ignition coil are explained on pages 378 and 246.

CHART NO. 62A—Ignition System of Type 53, 55 Cadillac—see page 396 for wiring diagram which is also wiring diagram of type 57 Cadillac.

*See page 378—adjusting Delco timer. See page 729, fig. 7, "test-light" for ignition timing.

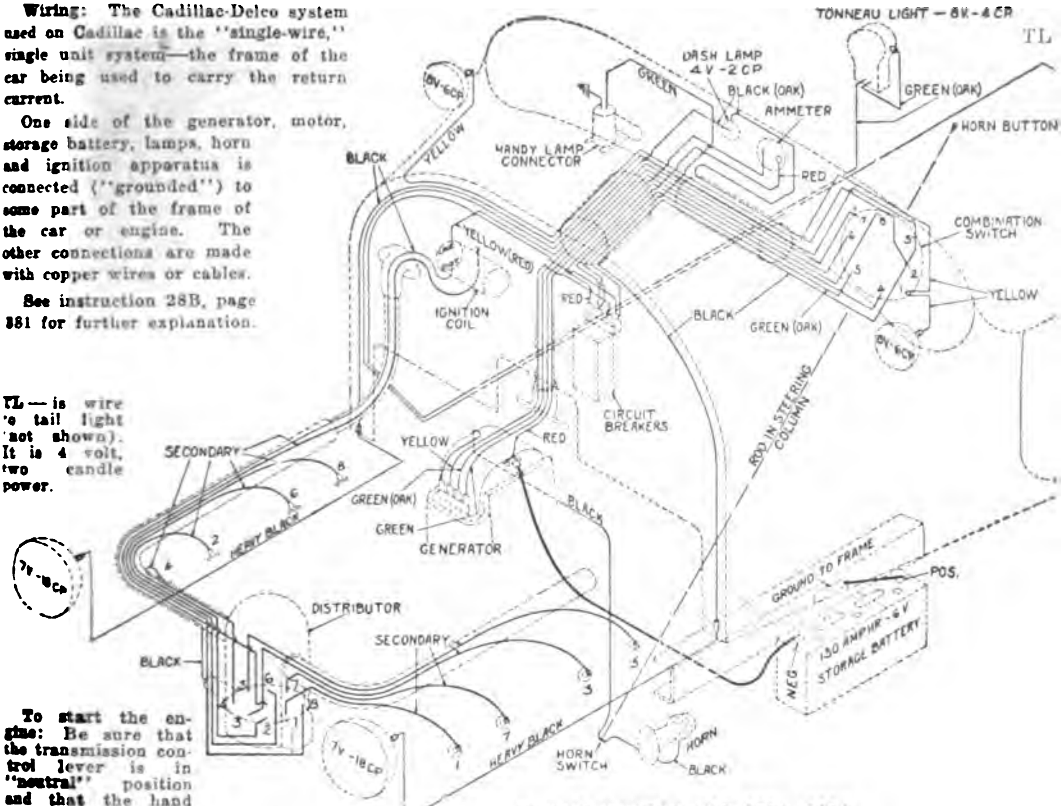
Chart 63 omitted—error in numbering.

Wiring: The Cadillac-Delco system used on Cadillac is the "single-wire," single unit system—the frame of the car being used to carry the return current.

One side of the generator, motor, storage battery, lamps, horn and ignition apparatus is connected ("grounded") to some part of the frame of the car or engine. The other connections are made with copper wires or cables.

See instruction 28B, page 381 for further explanation.

TL—is wire to tail light (not shown). It is 4 volt, two candle power.



To start the engine: Be sure that the transmission control lever is in "neutral" position and that the hand brake is set.

WIRING DIAGRAM FOR OPEN CARS

Note the pressure of air in the gasoline tank. (This is indicated by the "air pressure guage" on the dash.) If the pressure is less than one pound, it should be increased to that pressure by means of the "hand air pump." After the engine is started the pressure is automatically maintained.

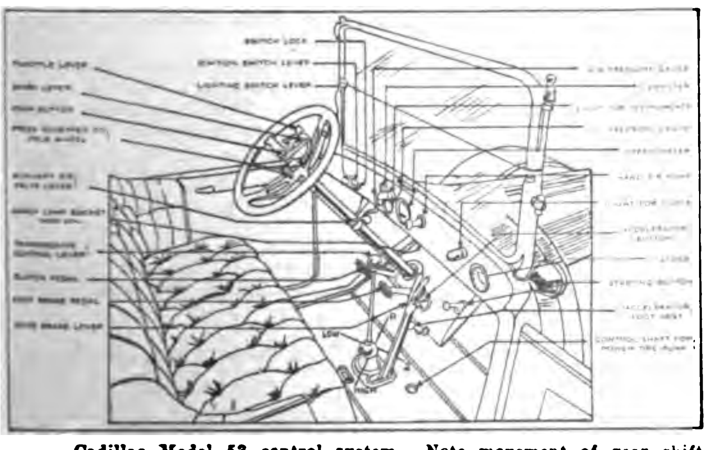
Place the spark lever in the "driving range" on the sector and the throttle lever about two inches from the extreme left (see note). Move the ignition switch lever down, thereby switching on ignition. Then push down on the starting button. This will bring the starter into operation and will cause the engine to "turn over."

In cool weather (also in warm weather, if the engine has been standing for some time), pull up the "auxiliary air valve lever" before you press the starting button.

As soon as the engine fires and commences to run under its own power, which should be in a few seconds, remove your foot from the starting button.

If the "auxiliary air valve lever" is pulled up when starting the engine, it should be "pushed down about one-half the way" immediately the engine is started, and all the way down as soon as the engine is warm enough to permit doing so. Note.—if you crank the engine by hand, place the spark lever at the extreme left on the sector.

In extremely cold weather, if the engine is not started in 15 or 20 seconds, remove your foot from the starting button. This will stop the cranking operation. Now open and close the throttle once or twice with the hand throttle or the foot accelerator. Do not open and close the throttle more than twice.



Cadillac Model 53 control system. Note movement of gear shift lever for speed changes.

The action which causes the engine to "turn over" is produced by a gear of the electric motor sliding into mesh with teeth on the fly wheel; similar to the meshing of the gear teeth in the transmission. When pushing down on the starting button to throw these gears into mesh, if it should happen that they are in just such positions that the ends of the teeth of the starting gear come against the ends of the teeth on the fly wheel instead of the teeth of one sliding between the teeth of the other, do not force them. Simply remove your foot from the starting button and again push down on the button. In the meantime the gears will probably have changed their relative positions sufficiently to allow the teeth to mesh. **Do not press the starting button while the engine is running.**

CHART NO. 64—Cadillac Control System and Wiring Diagram—Model 53, 55 Eight Cylinder Car (See instructions No. 19 and 28A for Delco ignition system.)

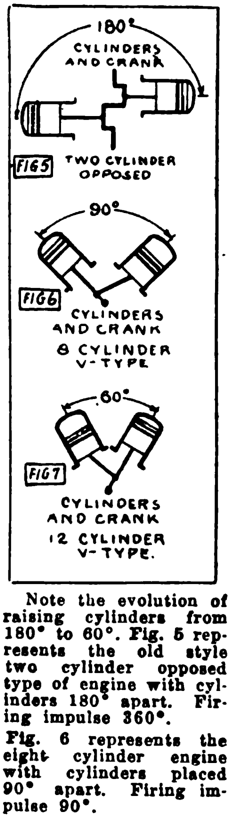
(Chart 63 omitted; error in numbering.)

The Twelve Cylinder V Type or "Twin Six" Engine.

The twelve cylinder engine is referred to in this instruction, as either a "twelve cylinder" or a "twin six." Manufacturers use both terms. Literally, a twelve cylinder engine would mean a type of engine having twelve cylinders placed in line on a crank shaft having twelve throws.

The "twin six" or twelve cylinder V engine term, if we would be exact, consists of two sets of six cylinders placed at an angle of 60° over a regular six cylinder crank shaft with six "throws" of the crank.

Therefore, if the reader thoroughly understands the six cylinder engine, then it will not be a difficult matter to understand the twelve cylinder V type.



Note the evolution of raising cylinders from 180° to 60°. Fig. 5 represents the old style two cylinder opposed type of engine with cylinders 180° apart. Firing impulse 360°.

Fig. 6 represents the eight cylinder engine with cylinders placed 90° apart. Firing impulse 90°.

Fig. 7 represents the twelve cylinder engine with cylinders placed 60° apart. Firing impulse every 60° of crank movement.

Before proceeding with the explanation of the "twin six," refer to the illustration, and note the different angles in which cylinders are placed.

Construction: As previously stated, by placing six more cylinders on a six cylinder crank case and placing them "V" type at an angle of 60°. The same crank shaft and practically the same crank case can be utilized without materially increasing the size or weight of engine. The extra addition being another set of cylinders and connecting rods.

On the eight cylinder "V" type, cylinders are set at an angle of 90° or ½ the distance of firing of the four cylinders. In other words a four fires every 180° and by setting cylinders 90° we get an impulse every 90°.

A six cylinder engine fires every 120°, therefore on a twelve cylinder we would place cylinders at an angle of ½ of 120° which would be 60° instead of 90° and therefore get a firing impulse at every 60° movement of the crank shaft.

The "twin six" engine offers more evenly divided impulses than the eight. Two cylinders are working together at all times and part of the time three are working together.

Firing order: The crank shaft of a twin six is of the type shown on page 122. The crank may be a right hand crank or a left hand, as explained. The firing order would be the same, that is, if you were to consider each block of cylinders on a twin six, as a separate six cylinder engine.

For instance, refer to illustration fig. 8, page 135, refer to the block of cylinders to the left, when facing engine, we will designate these as ***right hand** cylinders and will number them 1R, 2R, 3R, 4R, 5R, 6R and all on the other side we will designate as **left hand** cylinders and will number them 1L, 2L, 3L, 4L, 5L, 6L.

The figures outside of the circles, indicate the order in which the cylinders fire on the Packard twin six. 1R fires first then 6L, then 4R, 3L, 2R, 5L, 6R, 1L, 3R, 4L, 5R, 2L.

Laps of power strokes: If No. 1R fires, and crank pin moves 60°, then 6L fires and moves 60° with 1R, then 4R fires and moves 14° with 1R and 6L, at which time 1R exhaust valve opens. Therefore, making a period of 14 degrees, during which time 3 cylinders are working together.

Then 6L and 4R work together for a period of 46 degrees, after which time, 3L fires and works with 6L and 4R for a period of 14 degrees.

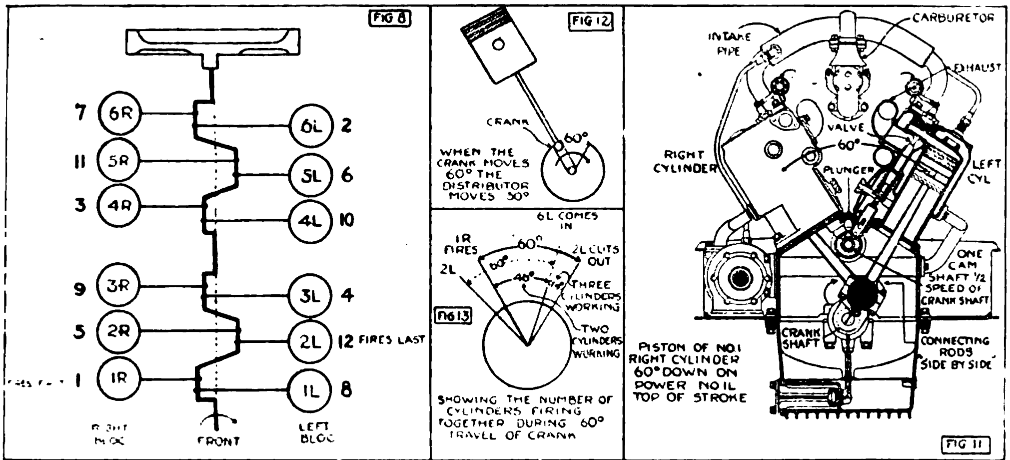
So that with every 60° movement of crank shaft there is a period of 14 degrees, during which time 3 cylinders work together, or in one complete revolution of crank, or 360° movement, there will be 6 periods of 14 degrees when 3 cylinders work together, and 6 periods of 46° alternating with these, when 2 cylinders work together.

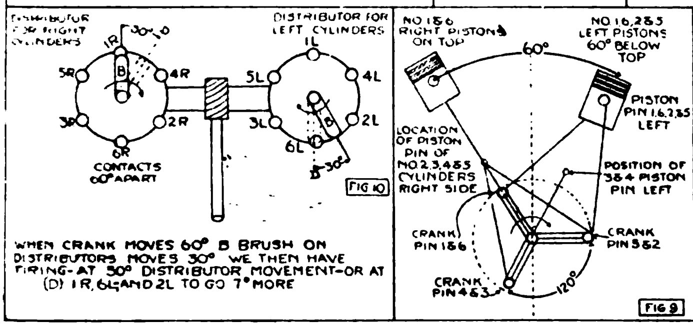
The cylinders on the Packard are staggered, see fig. 8, note left cylinders set ahead of the right. This is in order that the connecting rods can be placed "side by side" on the crank pin instead of being "yoked," see fig. 5, page 78 and fig. 10, page 129.

The cam shaft: On the Packard, one cam shaft with a separate cam for each valve is used. On the National, 2 cam shafts are used.

The ignition: see Packard supplement and page 135.

***The right side of an engine or automobile** is the right side, when seated in the car, that is why we number the cylinders "right" and "left," although it is the reverse when facing the front of engine. See "Specifications of Leading Cars" and "Standard Adjustment of Leading Cars" for cars using twelve cylinder engines.





Twelve Cylinder Firing order: If we considered each side as a separate six cylinder engine, the firing order would be 1, 4, 2, 6, 3, 5.

Note the crank shaft; the throws 1 and 6, 2 and 5, 3 and 4 are in line. This would be a left hand crank shaft, see fig. 2, page 124.

Supposing the firing order was 1, 4, 2, 6, 3, 5, and each bloc separate, the right bloc, starting from front, would fire, **1R, 4R, 2R, 6R, 3R, 5R.** Now start at rear of left bloc, **6L, 3L, 5L, 1L, 4L, 2L.** If the cylinders were numbered from the rear, on the left bloc, as 1L, 2L, 3L, etc.; the firing order would be 1L, 4L, 2L, 6L, 3L, 5L; same as the right bloc, but from rear to front.

In order to see just when three cylinders are working together, refer to fig. 12 and 13. Suppose cylinder 1R fires; 2L will have fired just previous, therefore 1R and 2L firing strokes will run together or "lap," as it is called, for a period of 46 degrees, for this period, note 2 cylinders are working together. Then cylinder 6L will start on its power stroke and will "lap" with 2L and 1R for a period of 14 degrees (3 cylinders working together during this 14 degree period of travel of crank pin), at which time 2L cuts out.

The relation of the movements of the distributor and timer to the crank shaft: The timer and distributor revolve one-half the speed of the crank shaft, or the same speed as the cam shaft. The Packard "twin six" employs two timers and distributors, operated at the same speed as the cam shaft. There is a separate timer and distributor for each bloc of cylinders. See fig. 10 above, which is an exaggerated illustration in order to simplify the meaning.

Now suppose the crank shaft moved 60° (see fig. 12 and 13). During that period of travel we would have had two cylinders on power for a period of 46° and 3 cylinders on power for a period of 14°.

The distributor on each bloc would, each, have moved cam shaft speed (½ that of crank), or ½ of 60° or 30 degrees. We must, however, have had 2 explosions, but 3 cylinders on power, during this period; 2L fired just before 1R, therefore when piston 1R reached top of its stroke and fired, we had then traveled 30 degrees (this means 30° timer and distributor movement or 60° crank pin movement) on the power stroke of 2L. Therefore 2L continues on its power stroke with 1R, 30°; when 6L fires and the three continue to work together for a period of 7° more (timer movement, or 14° crank pin movement), (see fig. 13), when 2L exhaust valve opens and cuts out 2L, leaving 2 cylinders working together for a period of 46° when the next cylinder fires, etc.

Fig. 9: **"Throws" of crank shaft are 120° apart,** note crank pin "throws" 1 and 6, 3 and 4, 2 and 5 are in line. Crank revolving to the right, note cylinder 1R is on top and would fire, then 6L, both being in line, then 4R, then 3L, 2R, 5L, 6R, 1L, 3R, 4L, 5R, 2L.

When No. 1 and 6 right connecting rods move 60°, then 1 and 6L connecting rods will also move 60°, at which point they will be on dead center.

Fig. 11. End sectional view of the Packard twin six; cylinder 1R is 60° down on power, 6L is on dead center—see page 136 for relative position of pistons.

CHART NO. 65—Twin Six Firing Order. Relation of the Speed of Crank Shaft to Distributor

Note word "bloc," used above, is term formerly used, should be block. See also pages 918, 920.

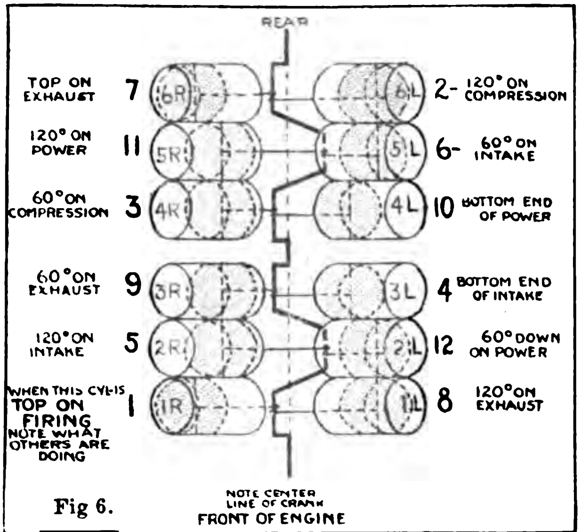


Fig 6.

Twelve Cylinder Piston Positions.

Fig. 6 illustrates the relative position of pistons and what is taking place in each cylinder when cylinder 1R is just starting its power stroke.

Just consider each block of cylinders a separate six cylinder engine and it will be easy to understand the twin six.

The crank pins are 120° apart, whereas the firing impulses are 60° apart.

Note the order in which the cylinders fire is designated by the numbers outside of the cylinders, in heavy type.

Note position of pistons when No. 1R is just ready to go down on power.

Engines with Overhead Valves and Cam Shaft.

The cam shaft on this type is placed overhead and operated usually, by a vertical shaft driven from crank-shaft. See page 137.

The aeroplane engine uses this principle extensively as will be noted by referring to pages 911 to 916. On page 916, note there are two inlet and two exhaust valves to each cylinder.

The "Sleeve Valve" Type of Engine.

The sleeve valve engine differs from any other four cycle engine, only in its method of admitting and exhausting the gas.

The sleeves: Instead of raising and lowering poppet valves, to admit and expel the gas there are two sleeves with ports or slots in them; at certain times, these slots on the same side of cylinder come in line as shown in figs. 2 and 5, chart 69. These sleeves take the place of valves.

The openings occur at the proper time, in a similar manner as any other valves are opened and closed—that is, the exhaust opens once during the four strokes and the inlet opens once during the four strokes of the piston. The sleeves of course sliding up and down cause this opening and closing.

Eccentric shaft: The sleeves are caused to slide up and down by an eccentric shaft (takes the place of a cam shaft), which has eccentrics raising and lowering small connecting rods OS & IS, see figs. 1 and 2. This eccentric shaft is driven by a chain from a sprocket on the crank shaft of engine. It is driven the same speed as any other cam shaft, ie., one-half the speed of engine crank. The eccentric pin operating the inner sleeve is given a certain lead or advance over that operating the outer sleeve.

This lead, together with the rotation of the eccentric shaft at half the crank shaft speed, produces the valve action illustrated in chart 69, which shows the relative position of the piston, sleeves and cylinder ports at various points in the rotation of the crank shaft.

Valve timing: The timing shown is not different from that ordinarily used in poppet valve engines, but the valve area is greater than that of an ordinary poppet valve. The equivalent of increased valve area is gained, also, by the directness of the valve opening and the absence of restrictions in the gas passages.

Valve timing of the Stearns-Knight four cylinder—see chart 69. Valve timing of the Stearns-Knight six cylinder; the same except inlet opens 4 degrees instead of 8 degrees, and exhaust closes on top dead center instead of 4 degrees after.

Setting ignition: Set cylinder No. 1 piston on top of compression. Retard contact breaker box on Bosch magneto. Set points on interrupter just breaking. There is a mark on fly wheel which, when lined up with mark on cylinder, will show when 1 and 6 or 1 and 4 are up. Firng order on six is 1, 5, 3, 6, 2, 4 and 1, 3, 4, 2 on the four.

The "Rotary Valve" Engine.

Is divided into two classes; the "**single**" and the "**double.**" See figs. 6, 9 and 10, chart 70 for description of the "single" rotary valve.

The "Rotary Cylinder" Engine.

In the ordinary motor car engine the cylinders are bolted to a crank case and the crank shaft is made to turn around by the force of the explosions in the cylinders. In the rotary "cylinder" engine the crank shaft is stationary, and the cylinders revolve (used mostly for driving aeroplanes). See chart 70.

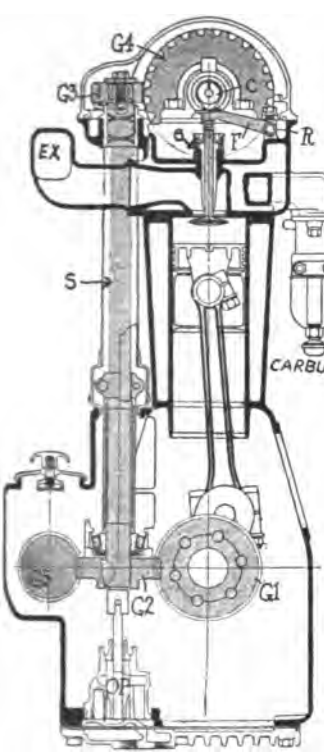

Fig. 2: **Overhead valves operated by an overhead cam shaft;** the Weidley principle.

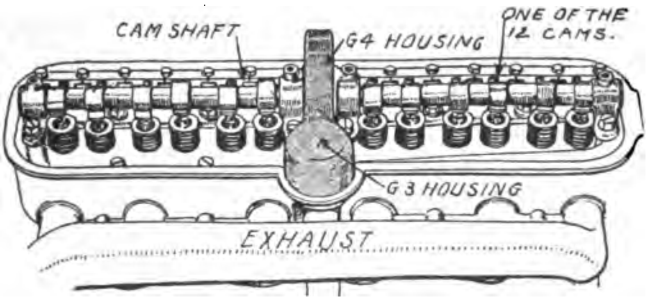

Fig. 7: Note on the cam shaft there are twelve cams operating the twelve valves.

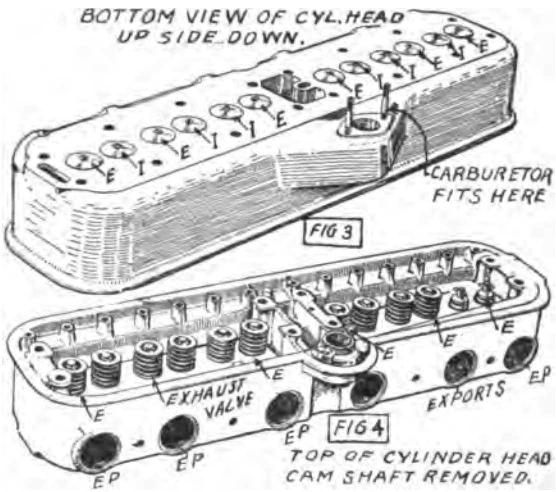


Valves: In the types of engine previously described the valves were either all on one side or opposite, or overhead, but operated by a plunger or tappet or by an overhead rocker arm. In this type the **cam shaft is placed overhead** as per fig. 7, with the cams integral. There are two overhead valves for each cylinder—see figs. 3 and 4, therefore twelve cams, one for each valve.

Cam shaft is operated by a gear G1 on the crank shaft, which operates a gear G2, fig. 2, which is called the lower timing gear; this gear is placed at the lower end of a vertical shaft (S) with an upper timing gear (G3), which operates the cam shaft gear (G4). By referring to fig. 2, it will be seen how the cam C operates the tappet arm (F), which in turn opens the valve against the tension of the spring (S).

While the construction varies, the principle, it will be noticed, is just the same as any other engine. The cam shaft turns one revolution to two of the crank shaft.

The cam shaft mounted on the cylinder head, has four bearings and are 1 3/16 inch in diameter. The end bearings are 1¼ by 1¾ in. long, and the middle ones, which are on either side of the driving gear are 1¾ by 1⅝ inch long. A hole ⅜ inch diameter is drilled through the cam shaft for its entire length, and carries oil to the cams and bearings.

Cylinder head—in this type engine the cylinder head is detachable from the cylinder, and the cylinders are all in one block, therefore to grind the valves or to get to the valves, the cover is removed, then the cylinder head. Fig. 4, shows the cylinder head removed and fig. 3, shows the cylinder head turned up side down, exposing to view the valves seated in the cylinder head casting.

To grind valves: First, remove head. If a single valve is to be ground the valve spring may be compressed and pin holding spring removed, when valve can be dropped out and the seat ground, or the cam shaft may be removed, which is easily done. Springs and pins removed and the cylinder head turned over on a bench, as in fig. 3, and valves ground as any other valves. See index for method of valve grinding.

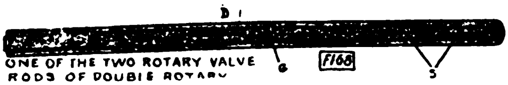
To set the valves: The inlet opens 10° past top and fly wheel is marked "IO." Exhaust closes at 10° after top. Therefore, set the cam shaft with piston No. 1, 10° past top center; cam just leaving exhaust valve (see C, which would be a little further in direction of rotation, as it now has valve open). The gears are then meshed at this point. The timing of both inlet and exhaust is done by one cam shaft, same as on an "L" type cylinder.

CHART NO. 66—The Overhead Valve Operated by an Overhead Cam Shaft—Weidley six cylinder as an example. Note cylinder head is detachable with valves in the head.

Note—Due to error, chart 67, has been omitted and chart 70 follows this. Charts 68 and 69 follow chart 70.

The Rotary Valve Engine.

This type of engine is the same as any other four-cycle principle of gasoline engine, except instead of "poppet type" of valves the "rotary type" is used to admit gas to cylinder and to permit burnt gases to pass out. The Speedwell was one make of car which used the double-rotary-valve.



ONE OF THE TWO ROTARY VALVE RODS OF DOUBLE ROTARY

The rotary-valve is nothing more than a long cylindrical piece of metal with holes in the shape of slots cut in same as per S and D, fig. 8. Instead of valves popping up and down, this rod is placed along side of cylinder and is operated by a chain or gear from crankshaft, and as it turns, the openings in the rods (rotary-valve) performs the same function as the poppet-valves.

There are two types of rotary-valve engines, the double valve and the single valve.

The double rotary-valve, can be compared with the poppet-type-valve engine using the T-head type of cylinder, which has the intake valves on one side and exhaust on the other. On the double rotary-valve we have an "intake rotary valve" on one side and the "exhaust rotary valve" on the other side, per figs. 1, 2, 3 and 4. On a four-cylinder engine, each valve would have four slots.

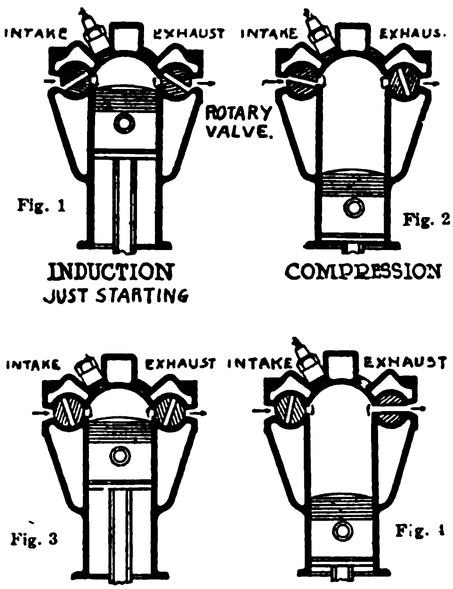


Fig. 1 INDUCTION JUST STARTING — Fig. 2 COMPRESSION — Fig. 3 EXPLOSION — Fig. 4 EXHAUST

Fig. 1 shows suction or induction stroke just starting. As the piston starts down, the opening in intake valve (valve is rotating to the right), will be in line with opening in combustion chamber, therefore gas will be admitted.

Fig. 2, Compression stroke; piston has reached and passed the bottom of intake stroke and is starting up on compression stroke, therefore, intake valve is just starting to close. Note exhaust valve is closed in figs. 1, 2 and 3.

Fig. 3, Power or explosion stroke; opening in both valves are closed, piston will move down.

Fig. 4, Exhaust stroke; piston is now starting up on exhaust, therefore, opening in exhaust valve is open to cylinder, and burnt gases will pass out. Intake valve is closed.

The single rotary valve can be compared with the poppet-valve type of engine using valves-in-the-head, operated by one overhead cam-shaft. Instead of poppet-valves and cam-shaft however, there is one long rotary valve, with openings as shown in figs. 5, 6, 7 and 8. Note the position of these openings during the period of intake, compression, firing and exhaust.

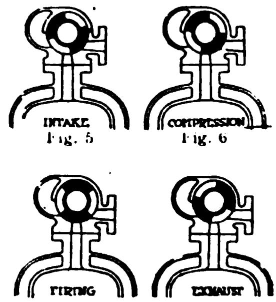

Fig. 5 Fig. 6 Fig. 7 Fig. 8

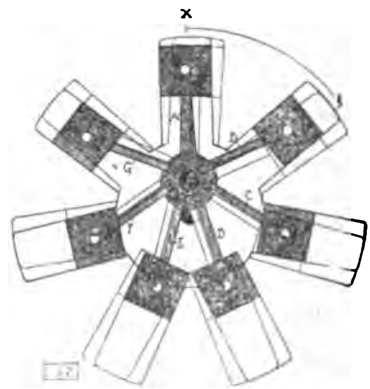
The Rotary Cylinder Engine.

Illustration fig. 2, shows the Gnome seven cylinder engine, see also, page 910 for the Gnome nine cylinder engine.

In the rotary-cylinder engine the crank-shaft is held stationary and the cylinders are mounted on a cylindrical crank-case which can revolve. Connecting rods are fastened to crankshaft-pins, fig. 1.

When an explosion occurs in one of the cylinders the energy can do nothing else but force the piston down. This action turns the rod-holder on the crank-shaft, which causes the rods, pistons and hence the cylinder to revolve as a unit. The crankshaft, fig. 3, remains stationary and due to this fact, the pistons will assume different positions in the cylinders owing to the location of the rods on the crank pin. For instance, in the movement of the cylinder A from X to Y, the piston in the cylinder will travel downward, as shown in the illustration, until it reaches bottom of its stroke.



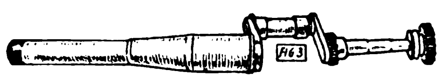


CHART NO. 70—Rotary Valve Engine. Rotary Cylinder Engine.

(Chart 67 omitted; error in numbering.) See page 910 for Gnome rotary cylinder engine.

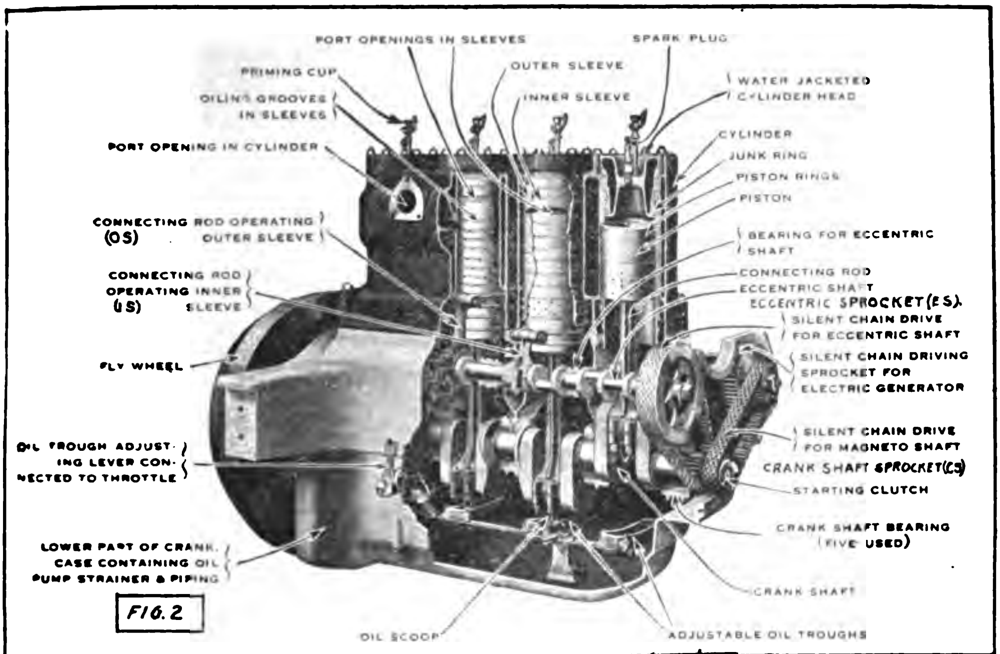

FIG. 2

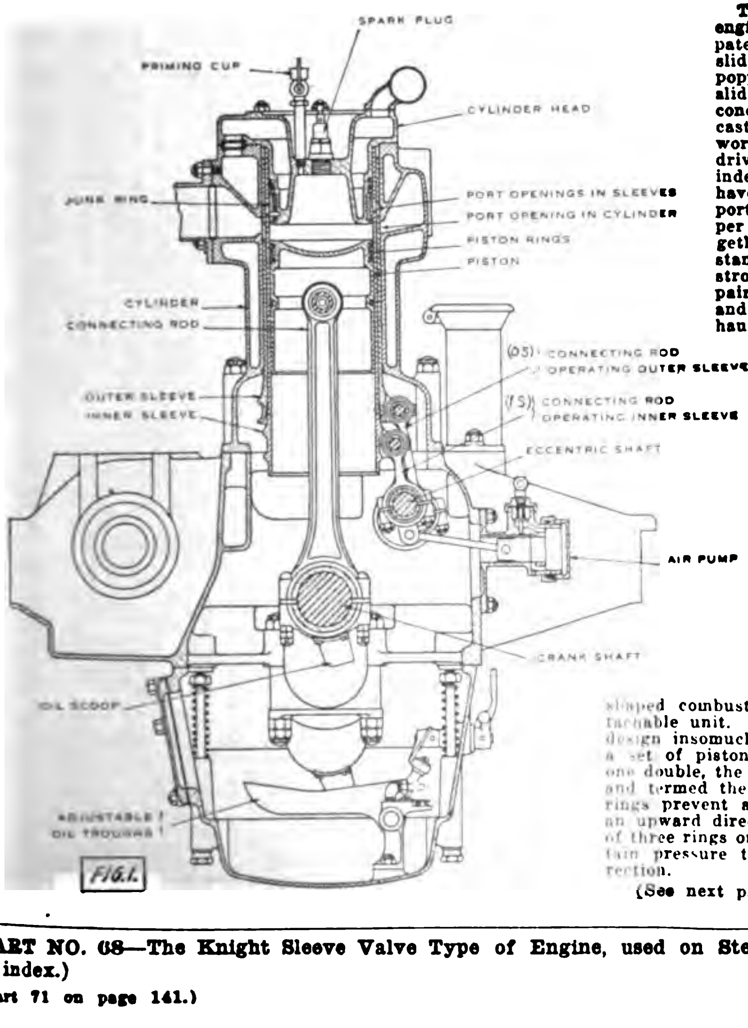

FIG. 1.

The main principle of this engine (made under Knight's patent) is the substitution of sliding valves for the usual poppet or tappet valves. The sliding valves consist of two concentric shells of cast iron accurately turned, working in between the driving piston and the cylinder walls. These shells have two series of large area ports or slots cut in the upper ends, which register together at the required instant in the respective strokes of the piston. One pair of slots form the inlets and the other pair the exhausts.

The sliding shells of each cylinder, which have a relatively short stroke, about 1 inch, are driven by two short connecting rods or side arms working off a lay crankshaft, the cranks having a very small throw, which takes the place of the camshaft in the tappet valve form of engine.

This valve-operating shaft rotates at half the speed of main crankshaft. The sliding shells extend right up into the deep cone-shaped combustion head, which is a detachable unit. This head is of a special design insomuch that it is provided with a set of piston rings, three narrow and one double, the latter being specially wide and termed the compression ring. These rings prevent any escape of pressure in an upward direction, whilst the usual set of three rings on the working piston maintain pressure tightness in the lower direction.

(See next page for further detail.)

CHART NO. 68—The Knight Sleeve Valve Type of Engine, used on Stearns-Knight Car. (Als see index.)

(Chart 71 on page 141.)

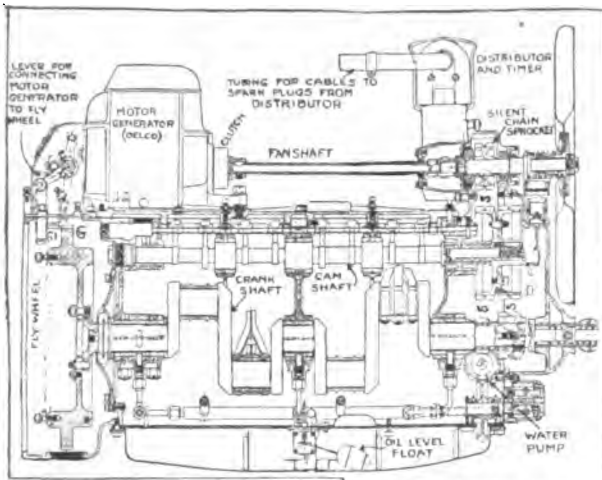

FIG 9 - SIDE VIEW. NOTE SEPERATE LOCATION OF MOTOR-GENERATOR AND DISTRIBUTOR MODEL 55

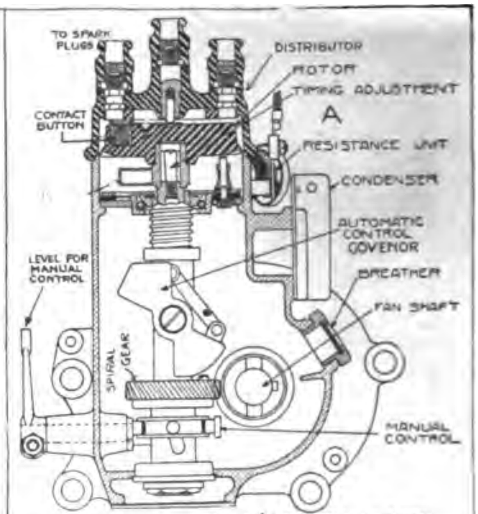

Fig. 10. DISTRIBUTOR AND TIMER

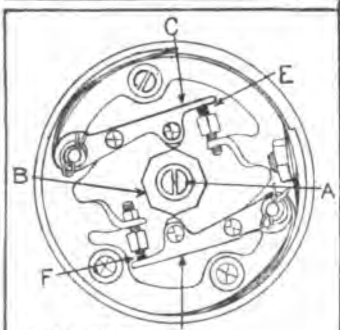

FIG11-TIMER

Cadillac Ignition System.

The distributor and timer (fig. 10) are carried on the fan shaft housing, and are driven through a set of spiral gears attached to the fan shaft. The distributor consists of a cap or head of insulating material, carrying one contact in the center with eight additional contacts placed at equal distances about the center and a rotor which maintains constant communication with the center contact.

The rotor carries a contact button which serves to close the secondary circuit to the spark plug in the proper cylinder.

Beneath the distributor head and rotor is the timer. The timer cam is provided with a lock screw in the center of the shaft. (See fig. 11.)

A manual spark control is provided in addition to the automatic spark control. The manual spark control is for the purpose of securing the proper ignition control for variable conditions, such as starting, differences in gasoline, weather conditions and amount of carbon in the engine. The automatic control is for the purpose of securing the proper ignition control necessary for the variation due to engine speed alone.

The object for using two contact points on the timer is to distribute over two sets of points the current which would otherwise pass through one. This greatly lessens wear and burning of the points. Interrupter is the closed circuit type.

The timer contact points are set as follows: Turn the engine over until the contact arms "D" & "C" are directly on top of lobes of the cam "B." Then adjust the contact points at "E" and "F" so that they stand twenty-thousandths of an inch apart. Both sets of contact points should be adjusted alike.

To time the ignition proceed as follows: Move the spark lever to the extreme left on the sector; open the compression release cocks on the cylinder blocks, and crank the engine by hand until the piston in No. 1 cylinder is on firing center. (No. 1 cylinder is the one nearest the radiator in the left hand block of cylinders.)

*Next remove the distributor cover; also the rotor, and loosen the lock screw A just enough to allow the cam "B" to be turned by hand after the rotor is fitted. (The lock screw should not be loosened enough to allow the cam to turn on the shaft when the engine is cranked by hand.)

Then replace the rotor and turn it by hand until the distributor brush in the rotor is directly under the terminal marked No. 1 on the distributor cover. Replace the distributor cover, and move the spark lever to the extreme right on the sector.

Then switch on ignition; hold the high tension wire to the spark plug in No. 1 cylinder about one-eighth of an inch away from the cylinder casting and turn the engine slowly by hand in the direction in which it runs. Stop turning immediately a spark occurs between the wire and the casting. (It will be necessary to turn the engine nearly two complete revolutions before the spark occurs.)

If the cam "B" is properly set a spark will occur when a point on the fly wheel one and twenty-one thirty seconds of an inch in advance of the center line for No. 1 cylinder is directly under the pointer or "trammel" attached to the crank case of the engine. This point for each cylinder is marked on the fly wheel by the letter "IG/A."

If the spark occurs before this, rotate the cam "B" slightly in a counter clockwise direction to correct the adjustment. If a spark occurs later than this, rotate the cam slightly in a clockwise direction.

After the adjustment has been properly made, lock the cam securely to the distributor shaft by the lock screw "A."

After locking the adjustment it is a good plan to check the timing by fully retarding the spark lever; in other words moving it to the extreme left on the sector, holding the high tension wire to the spark plug in No. 1 cylinder about one-eighth of an inch away from the cylinder casting, and again turning the engine slowly by hand in the direction in which it runs, stopping immediately a spark occurs.

If the ignition is properly set the spark will occur under these conditions when the center line on the fly wheel for No. 1 cylinder is directly under the pointer attached to the crank case, or has passed the pointer.

Caution: Do not set the ignition so that the spark occurs before center with the spark lever at the extreme left on the sector.

Resistance unit and ignition coil are explained on pages 378 and 246.

CHART NO. 62A—Ignition System of Type 53, 55 Cadillac—see page 396 for wiring diagram which is also wiring diagram of type 57 Cadillac.

*See page 378—adjusting Delco timer. See page 729, fig. 7, "test-light" for ignition timing.

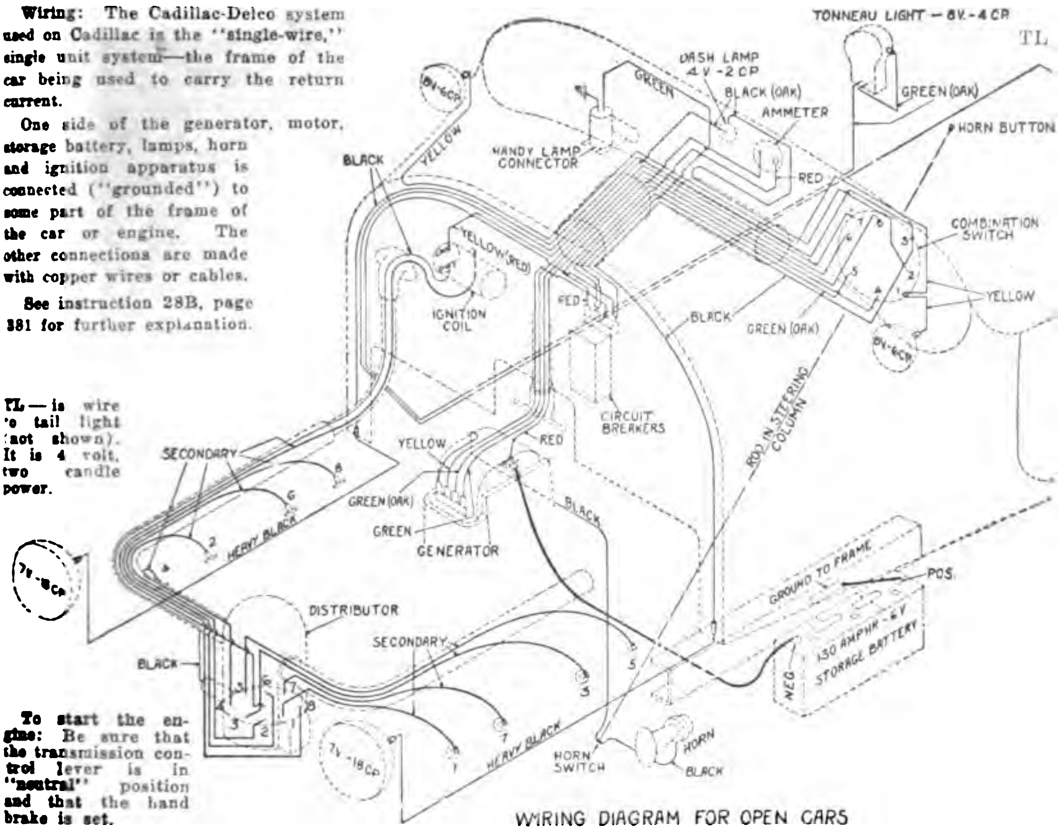
Chart 63 omitted—error in numbering.

Wiring: The Cadillac-Delco system used on Cadillac is the "single-wire," single unit system—the frame of the car being used to carry the return current.

One side of the generator, motor, storage battery, lamps, horn and ignition apparatus is connected ("grounded") to some part of the frame of the car or engine. The other connections are made with copper wires or cables.

See instruction 28B, page 381 for further explanation.

TL—is wire to tail light (not shown). It is 4 volt, two candle power.



WIRING DIAGRAM FOR OPEN CARS

To start the engine: Be sure that the transmission control lever is in "neutral" position and that the hand brake is set.

Note the pressure of air in the gasoline tank. (This is indicated by the "air pressure guage" on the dash.) If the pressure is less than one pound, it should be increased to that pressure by means of the "hand air pump." After the engine is started the pressure is automatically maintained.

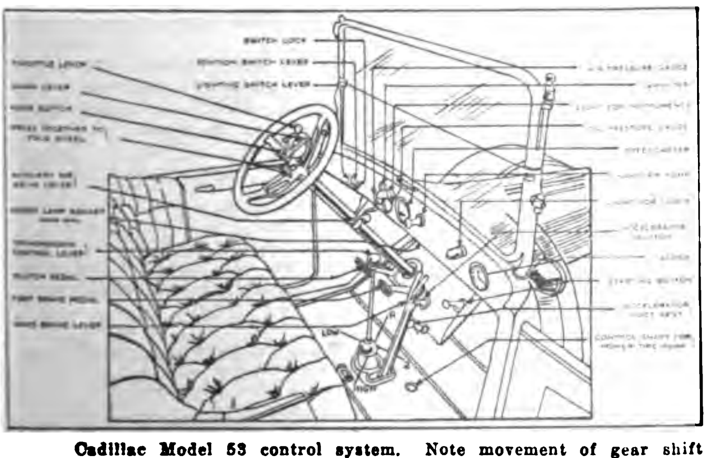
Place the spark lever in the "driving range" on the sector and the throttle lever about two inches from the extreme left (see note). Move the ignition switch lever down, thereby switching on ignition. Then push down on the starting button. This will bring the starter into operation and will cause the engine to "turn over."

In cool weather (also in warm weather, if the engine has been standing for some time), pull up the "auxiliary air valve lever" before you press the starting button.

As soon as the engine fires and commences to run under its own power, which should be in a few seconds, remove your foot from the starting button.

If the "auxiliary air valve lever" is pulled up when starting the engine, it should be "pushed down about one-half the way" immediately the engine is started, and all the way down as soon as the engine is warm enough to permit doing so. Note.—if you crank the engine by hand, place the spark lever at the extreme left on the sector.

In extremely cold weather, if the engine is not started in 15 or 20 seconds, remove your foot from the starting button. This will stop the cranking operation. Now open and close the throttle once or twice with the hand throttle or the foot accelerator. Do not open and close the throttle more than twice.



Cadillac Model 53 control system. Note movement of gear shift lever for speed changes.

The action which causes the engine to "turn over" is produced by a gear of the electric motor sliding into mesh with teeth on the fly wheel; similar to the meshing of the gear teeth in the transmission. When pushing down on the starting button to throw these gears into mesh, if it should happen that they are in just such positions that the ends of the teeth of the starting gear come against the ends of the teeth on the fly wheel instead of the teeth of one sliding between the teeth of the other, do not force them. Simply remove your foot from the starting button and again push down on the button. In the meantime the gears will probably have changed their relative positions sufficiently to allow the teeth to mesh. Do not press the starting button while the engine is running.

CHART NO. 64—Cadillac Control System and Wiring Diagram—Model 53, 55 Eight Cylinder Car (See instructions No. 19 and 28A for Delco ignition system.)

(Chart 63 omitted; error in numbering.)

*Indian Twin-Opposed-Cyl. Motorcycle Engine.

Cylinders; two, opposite or 180° apart instead of 42° as in the V engine. See page 118 explaining firing orders of this type of engine. **Bore** 2 inch; **stroke** 2½ inch; **piston displacement** 15.70 cubic inches; H. P. normal rating 2¼, develops 4. Pistons have two rings; **inlet and exhaust valves** side by side on top of cylinders; **timing gears** in separate housing outside of crank case; **carburetor**; Indian special; **ignition**, Dixie magneto driven at engine speed—fixed or set spark.

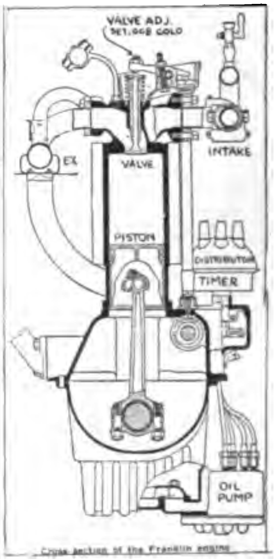
Section of the new Franklin air cooled engine 3¼ in. by 4 in. This is on much the same lines as the former type but is a little smaller, though producing slightly more power. Atwater Kent ignition has been substituted for the magneto and the use of a Stewart vacuum feed allows the carburetor to be placed higher



Cross section of the Franklin engine.

Franklin Engine.

Six cylinder, 3¼x4 inches. **Piston displacement 199 cubic inches. H. P. as per S. A. E. is 25.3, at maximum 31. About 1700 r. p. m. is maximum speed. The gear ratio of car on high gear is 3.9 to 1, wheel being 32 inches, which means 1,950 revolutions of engine per mile.** Weight of car under 2300 lbs. Maximum speed of car 50 m. p. h. or over.

Overhead valve mechanism is used. Atwater Kent ignition. Carburetor of Franklin design.

Pistons—See that the normal working temperature in the Franklin engine is distinctly high, the makers were not very ready to believe in the aluminum piston, but they have now adopted it as stock practice and consider that the better mean effective pressure of the new engine is largely due to the improved piston cooling obtained. At first there was a little trouble from wear on the skirt; it was difficult to get a close enough fit to insure absence of slap without abrasion. The trouble was overcome completely by turning a shallow, square groove of screw thread form from the bottom of the skirt to just beneath the lower ring. This holds oil securely and allows a smaller clearance than is possible with a plain piston.

There is an interesting lubrication system employed, individual oil supply being sent to every point. The oil pump, which is a conventional gear pattern, is mounted on a large plate, and the delivery from the pump is distributed to a number of oil leads by means of passages in the plate. Actually the plate is die-cast aluminum with distributing grooves, and these grooves are made into closed passages by putting a piece of thin sheet copper over the face. This gives direct pressure feed to all bearings on the crankshaft and to various other points.

Valve Clearance.

Is .010 cold and adjustment is made between end of walking beam and adjusting screw. (see page 362 for Franklin electric system and page 189 for air cooling principle. See also page 544 for "specifications.")

"Mixing Valve"—also called "Generator Valve."

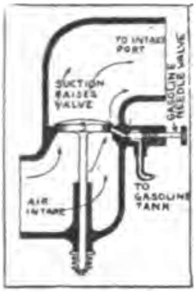

Fig. 1. Mixing valve.

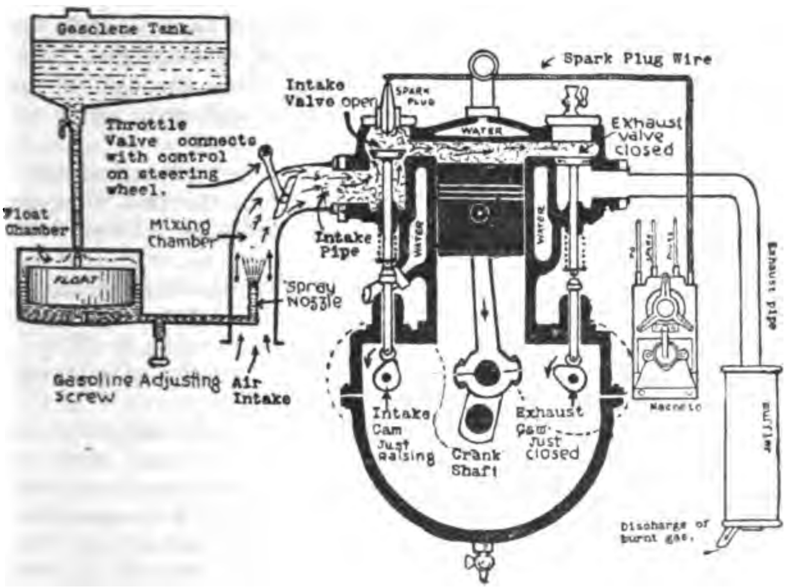
In the early days the method of mixing the gasoline and air in proper proportions was by means of a "mixing valve," figure 1. The air was drawn in at "air intake," through valve (3), being opened by suction of piston forming a vacuum in crank case when going up (on a "two cycle" engine), or when inlet valve was open and piston traveling down on a "four cycle" engine.

When air is drawn in, if gasoline needle valve was open, gasoline would also be drawn in, mixed with the air and pass into cylinder in a partial vaporized condition.

The mixing valve, also called a "generator valve," is still used to a small extent on two port two cycle engines. It takes the place of a check valve, as the valve (3) serves the same purpose.

Note absence of float arrangement. The gasoline is fed by gravity and when engine stops the gasoline needle valve must be cut off, otherwise there will be dripping.

Elementary Principle of the Float Feed (constant-level) Type Carburetor.



The gasoline flows from the gasoline tank to the float chamber of the carburetor through a small brass or copper pipe.

The float chamber immediately fills up until the float (made of cork or hollow copper or brass) rises and cuts off the flow.

The level of the gasoline in the float chamber is slightly lower than the end of the spray nozzle which extends into the mixing chamber, (otherwise gasoline would continue to run out of the spray nozzle or jet when engine is idle). This mixing chamber is connected to the inlet pipe of the engine.

If the throttle valve is opened and engine cranked, the piston will draw in the gasoline, mixed with air, through the inlet valve, (note cam is just starting to raise the inlet valve on the suction or intake stroke).

After the piston makes a complete suction stroke down and gas is drawn into the cylinder the inlet valve closes (usually after bottom, about 36°), and on the next upward stroke of the piston as the gas cannot get out of the cylinder it is **compressed**, then **ignited** by an electric spark at the gap of the spark plug. When the compressed gas is ignited by the spark, the explosive force of the gas forces the piston down. The force depending upon the amount and the amount depending upon the opening of the throttle.

As the piston approaches the bottom of this explosion or power stroke, the exhaust valve begins to open and as the piston starts up again, the burnt gases are forced out. This is called the **exhaust** stroke. (In actual practice the exhaust valve opens about 46° before it reaches bottom, see page 100.)

The same operation is repeated over and over. The momentum of the fly wheel keeps the engine in motion until the next "power stroke."

The speed of an engine is varied by opening and closing the throttle valve.

CHART NO. 71—Explaining how the Gasoline is Mixed with Air and Drawn into the Cylinder of a Four Cycle Gasoline Engine—this is called Carburetion. The device which feeds the gasoline and air to the engine is called a **Carburetor**.

Chart 70 on page 138.

INSTRUCTOIN No. 12.

*CARBURETION: Principle, Construction, Operation, Carburetor Parts. Types of Carburetors. Throttle. Speed Control. Heating or Vaporizing. Gasoline Feed Systems.

Carburetion Principle.

Meaning of carburetion: The mixing together of gasoline vapor and air is called "carburetion," and the device that keeps the two in proportion is called a "carburetor."

To get energy out of the gasoline it is necessary for it to be converted into a vapor and then mixed with a volume of air before it can be exploded in the cylinder.

There are two ways of producing this vapor, one being to expose a considerable surface of this liquid to the air, which is also caused to bubble through it and thus become impregnated with the gasoline vapor. This was the original method and was called the "**surface**" type of carburetion.

The second method is to "**spray**" the liquid gasoline through a fine spray nozzle or jet into the mixing or vaporizing tube and into which air can be drawn to intermingle with the vapor.

The device in which this operation is performed is termed a "**carburetor,**" and the operation itself is known as "**carburetion,**" from the fact that the gasoline largely consists of carbon. The mixture might also be termed "carbureted" air.

Amount of gasoline and air: It has been found that the best explosive mixture with the gasoline commonly used, is a proportion of ***14 parts air to** 1 part gasoline, this when maximum power is desired and ranging to 17 to 1, the latter for maximum economy. (Proportioned by weight of air and gasoline.)

Pure gasoline vapor will not burn; it must be mixed with air before it can be used in an engine. To burn with the greatest rapidity and heat, the air must be in correct proportion to the vapor. The exact amount of air to be mixed with a certain amount of vapor depends on the quality of the gasoline, and other conditions. The carburetor, by which the proportions of the mixture are maintained, is so made that a current of air passes through it when the pisten makes a suction stroke. See chart 71—"air intake."

The air goes through this passage, in which is a small pipe called a "spray nozzle" that sprays the gasoline, so that it comes in contact with the air (see spray nozzle, page 141). The gasoline being volatile, is taken up by the air, and the mixture goes to the cylinder.

The amount of air that may flow through the carburetor, and the quantity of gasoline that may flow out of the small pipe, are adjustable, so that for a certain amount of gasoline the proper proportion of air may be admitted.

When the mixture is not correct; that is, when there is too much or too little air for the gasoline flowing out of the small pipe, the running of the engine is affected, and it will not deliver its full power.

When there is too much air for the gasoline, the mixture is said to be **too poor or lean**; when there is too little air, the mixture is said to be too **rich.**

The carburetor is connected to the inlet pipe, and no air or gas can enter the cylinder through the inlet valve without first passing through the carburetor.

*For Carburetor Trouble and Remedies, see index for "Digest of Troubles," and next instruction.

*That is, 14 to 1 or rich mixture is best for quick acceleration, or 15 to 1 or leaner mixture best for pulling with wide open throttle, and 17 to 1, or still leaner mixture, for high speed work (figures only approximate).

The air drawn through the carburetor on the suction stroke enters it through the "air intake" (see illustration, page 141), and passes around the spray nozzle, drawing gasoline with it; the level of the gasoline in the float chamber then drops, and the float drops also and permits more gasoline to enter the float chamber.

It is in the "mixing tube," or "mixing chamber," as it is sometimes called, that the air is brought into contact with the gasoline. The "spray nozzle," projects into the mixing tube, so that it is in the center of the current of air.

How the gasoline is drawn into cylinder with the air: When the air is not passing through the mixing tube, the liquid gasoline stands just below the open end of the spray nozzle, but as soon as the current of air passes through, it sucks the gasoline out. The current of air sucks up the gasoline, on the order of a child trying to draw the last few drops of soda through a straw, drawing in really more air than soda.

The piston of the engine, on its suction stroke produces the suction effect similar to a squirt gun drawing in water.

The inlet valve must be open to permit the gas to be drawn into the cylinder—which it is, if piston is on the suction or intake stroke, but no other stroke.

***The adjusting screw or "gasoline needle valve" regulates the amount of gasoline to be admited into the mixing tube** through the spray nozzle or jet. The regulation of this needle valve is very important, and after once being properly adjusted, a very slight turn one way or the other will affect the running of the engine.

The throttle valve, usually placed in the mixing tube, above the spray nozzle, governs the amount of gas which enters the cylinder on the suction stroke.

The throttle valve lever on carburetor, connects with the throttle lever on the steering wheel. Moving the throttle lever on the steering wheel, in a certain direction opens the throttle valve on carburetor, which increases the speed of the engine.

The more gas admitted by the throttle lever through the throttle valve, the more gas will enter the cylinder; hence more power or greater force on the power stroke, thereby giving more speed to piston of engine.

Moving the lever in the opposite direction closes the throttle valve on carburetor, reducing the amount of gas which enters the cylinder, thereby reducing the speed of the engine.

The float, in the carburetor is provided merely to prevent the gasoline overflowing and running out of the spray nozzle, when engine is not running. The float is adjusted so the level of gasoline will not quite reach the top of the spray nozzle or jet.

The floats are usually made of cork or hollow metal balls, which float in the gasoline inside of the mixing chamber. A needle point arrangement is connected with the float, which cuts off the gasoline flow when the engine stops.

The reason why engines must first be cranked, before starting, is due to the fact that a charge of gas must be drawn into the cylinder, then compressed. Compressed gas is ignited by the electric spark; this produces the power stroke, and the power from this combustion of compressed gas, together with the momentum of the fly wheel will keep the engine in motion until the next power stroke. The cycle operation of suction, compression, power and exhaust is repeated over and over again. (See page 58 for explanation of the four cycle principle.)

*This adjusting screw has been discarded on some makes of carburetors.

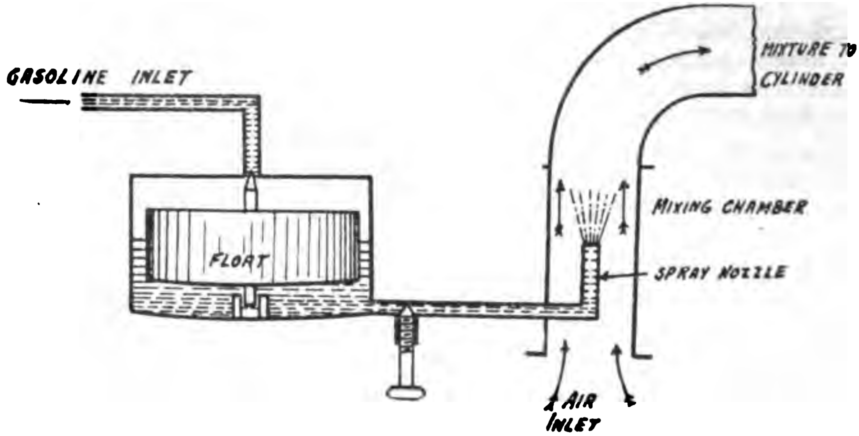


Fig. 1—The principle of a simple float feed carburetor. Note that the gasoline flows from tank through the "gasoline inlet pipe" to chamber of carburetor in which there is a float.

The purpose of the float is to cut the flow of gasoline off when the chamber is full, otherwise the gasoline would overflow at the "spray nozzle."

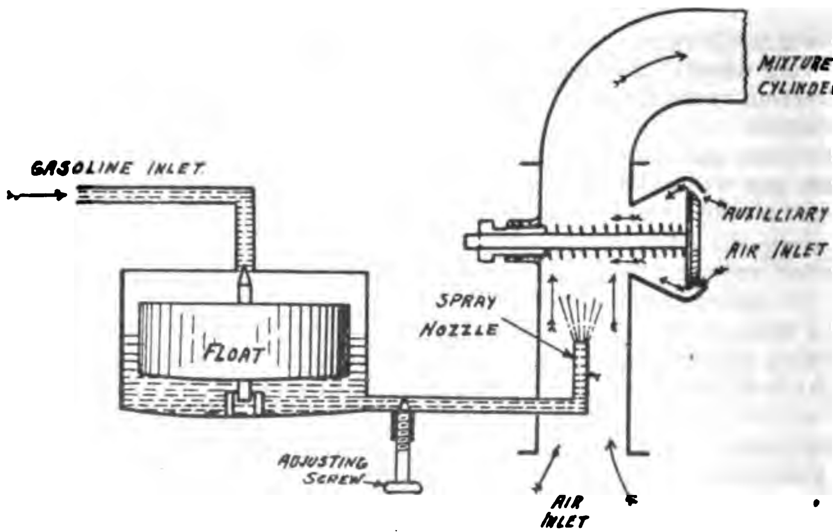
When the float is properly set (usually determined by its weight, or adjustment of float needle valve), the gasoline will not overflow at the nozzle.

When the engine is running the suction of the piston draws the gasoline through the mixing chamber from the spray nozzle, through the intake pipe from carburetor, through the intake valve on engine.

As the gasoline is consumed in the engine, the level of the gasoline in the float chamber drops and thereby causes the float to drop and more gasoline enters the chamber.

There are different methods used on various makes of carburetors for operating the float and cutting off the gasoline, but the principle of practically all carburetors is about the same.

In fig. 1 the main air supply is drawn in at the bottom of the "mixing chamber" but inasmuch as the best power of an engine is obtained by getting exact proportions of air and gasoline, the reader will note that if the speed of the engine varies the air proportion will be too great or not enough, therefore an auxiliary air intake which is automatic in action, is provided on most carburetors.



In fig. 2, note that an "auxiliary air inlet" is placed in the intake pipe above the gasoline outlet; this valve is automatic; if the engine is running at high speed the auxiliary air inlet will open in proportion to the speed of the engine, the suction being greater or less according to the speed of the engine.

Another feature of carburetion is to break the gasoline up into as many fine particles as possible so that the air will more readily mix with the gasoline and form a vapor. There are different methods of doing this which will be shown further on.

There are many different methods of arrangement of the float and air valves, but the fundamental principle remains the same.

CHART NO. 72—A Simple Form of Carburetor.

Fig. 1.—Maybach conceived the idea of using a float to keep the gasoline in spray nozzle at a constant level and to draw air around spray nozzle.

Fig. 2.—Krebs, later, added the auxiliary air valve.

Parts of a Carburetor.

There are various types of carburetors, in fact a score or more; although the construction varies, the principal parts are for the same purpose.

Classified according to structure and operation, we will mention the construction of the parts now in general use.

Floats.

Floats are usually made of light brass or copper in various hollow forms; the joints, if any, being carefully soldered or brazed so that gasoline cannot enter the float itself. Floats are also made of cork, well shellaced so that they will not absorb gasoline and lose their buoyancy.

The sole duty of the float is to maintain a predetermined level of the gasoline in the carburetor. This level is generally a small fraction of an inch below the jet or nozzle opening.

As gasoline flows from the main supply tank through the gasoline pipe or line into the float chamber of the carburetor, the float rises and the needle valve shuts off the further entrance of the fluid into the carburetor.

When the engine is running and using gasoline the float in the carburetor is continually falling and rising slightly, always maintaining the approximate gasoline level in the float chamber.

There are many types of floats and float mechanisms as will be seen in the illustrations of various carburetors in this instruction. By referring to chart 74 the reader will observe several float and float valve arrangements.*

Gasoline leaking into the float would increase its weight, thereby changing the proper gasoline level in the spray nozzle and cause the carburetor to flood.

Float valve mechanism: To the float an attachment is provided which will stop the flow of gasoline when engine stops. This action is obtained by the rising of the float (see fig. 1, page 148), also study the simplified explanation on page 141.

The valve which cuts off the flow of gasoline is called the **float needle valve.**

Side float type of carburetor: The float feed arrangement shown in chart 72, is shown placed to the side of the mixing tube. This form of carburetor is called a **side float type.**

Another side float type is shown in fig. 3, chart 73: The float in this type of carburetor is usually a tight box made of thin brass, the joints being made so there is little danger of leakage. In order to offset the danger of changing the level of the gasoline by tilting, the float and mixing chambers are as close together as possible.

On the float arm is a small collar, in which rests the arm of a rocker, the rocker being pivoted in the center. The other arm of the rocker rests in a similar collar on the stem of the float valve.

As the float rises, it carries with it its rocker arm, the rocker turning on its pivot. This depresses the other arm of the rocker, which closes the float valve and stops the flow of the gasoline into the float chamber.

This is a very usual arrangement of the float valve, as it permits the valve to move downward as the float is moving upward in floating on the gasoline.

The rod through the float forms the primer, or "tickler," because depressing it lifts the float valve and admits gasoline for the purpose of priming, for starting in cold weather.

In another form, the valve stem passes through the float, and is separate from it, the inlet of gasoline being at its lower end (fig. 1, chart 74), left illustration.

A pivoted arm, or sometimes two or more are so set that the ends rest in a collar on the valve stem, and the outer ends, which are heavier, rest on the top of the float. As the float rises it lifts the arms resting on it, which depress the valve stem, closing the valve. When the float falls, the weighted end of the arms fall with it, lifting the valve stem, and thus opening the float valve.

There are several other methods of connecting the float with the float valve, as shown in chart 74, page 148.

The **"gasoline adjustment or needle valve"** on above carburetors are similar to the simple form of carburetor described in chart 72—as is also the "auxiliary air inlet," but they are placed at different positions, yet giving the same results.

The concentric float type: The floats are not always placed to the side; they are quite often placed around the mixing tube as shown in figs. 1 and 2, chart 73. When the float is placed around the mixing tube it is called a **concentric type of float.**

*Dyke's working model explains a type of float mechanism used quite extensively abroad. The throttle on this type of carburetor is called the "sliding or rotary throttle valve type," see page 154.

*For adjustment of floats of various standard carburetors, see next instruction.

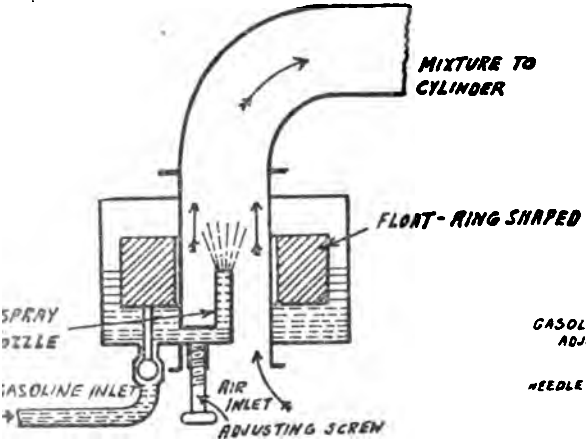


Fig. 1.—Carburetor with the Float Around the Mixing Chamber, called the concentric type of float. Air supply is drawn in at bottom of mixing chamber below the spray nozzle. This illustration shows only the main air supply.

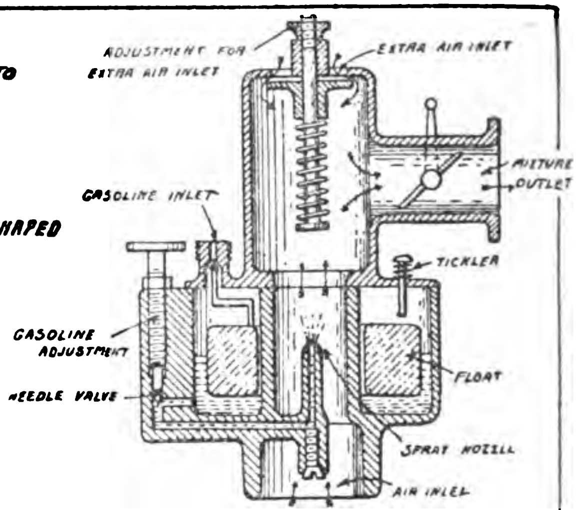

Fig. 2.—Carburetor with the Float Around the Mixing Chamber (also a concentric type). Air supply is at the bottom, below the mixing chamber and is called the "main air supply."

An Automatic Auxiliary Air Supply is shown at the top of the carburetor. This auxiliary air valve is called automatic, because the air is automatically controlled by the spring tension against the valve.

If the Engine is Running Fast the valve will open wider and admit more air, caused by a greater suction.

The Throttle Valve (Butterfly Type), is shown in the outlet tube. This outlet tube connects with the intake pipe of the engine. The opening and closing of this throttle admits more or less gas to the engine and is controlled by hand lever on the steering wheel.

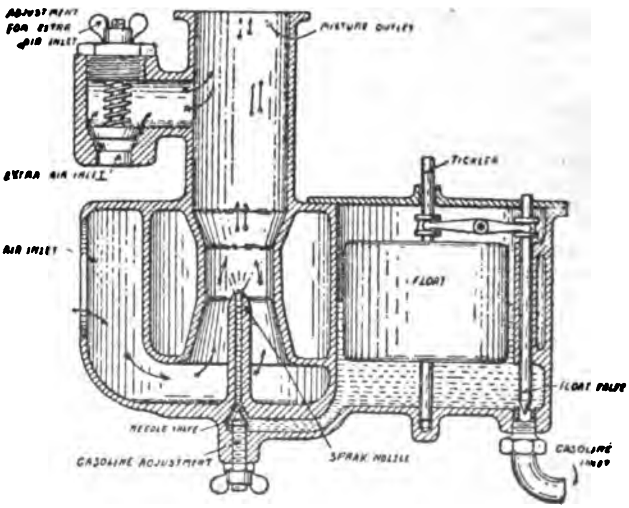

Fig. 3.—This Type of Carburetor has a Side Float Chamber. Note the float valve mechanism attached to the float, to cut off the gasoline. The main air inlet is at the side, but permits the air to enter below the spray nozzle.

The Automatic Auxiliary Air Supply is taken in at the top (over the spray nozzle to the side of mixing chamber), the same principle as the one in Fig. 2, but the arrangment only is different.

CHART NO. 73—Explaining the side Float Type of Carburetor and the Concentric Type of Float Arrangement. Also showing a different arrangement of the Auxiliary Air Intake Valve, which can be placed to the side or overhead.

Concentric means (having the same center), the center of nozzle mixing chamber and of the **float being identical**.

The carburetor with the float passing around the mixing tube is called a "concentric float" type because the float surrounds both the spray nozzle and mixing chamber, all having the same center. This makes a compact carburetor and maintains a constant gasoline level in the spray nozzle regardless of the angle at which the car may be.

The float valve mechanism closing the gasoline inlet is attached to the "float." On almost all concentric float carburetors the float is made of cork.

The gasoline needle valve controls the flow of the gasoline to the spray nozzle, and the correct adjustment of it is necessary for the operation of the carburetor. It is also called the "gasoline adjusting screw." Don't confuse this needle valve with the "float needle valve."

In some carburetors this adjusting screw is placed at the top of the spray nozzle, on others at the bottom and on others, to the side. When placed as shown in fig. 2, page 148, it also helps to break the gasoline into "spray."

The regulation of this gasoline needle valve is very important and likewise very sensitive. After the carburetor is once adjusted by regulating the auxiliary air valve and the opening of this gasoline needle adjustment valve—the slightest turn one way or the other of this valve, will make a difference in the running of the engine.

The type of gasoline adjustment needle valve marked (e), fig. 2, chart 74, is of the **hand operated type**, being adjusted only occasionally. Other types of "gasoline adjustment needle valves" are; the **mechanically operated needle valve**, operated by movement of throttle through a cam arrangement by hand (chart 84), and the **automatic mechanically operated needle valve** operated by action of the auxiliary air valve (chart 82) called "metering pins," which will be treated farther on.

The main air inlet or supply is on all carburetors. See charts 73 and 74. Note, (a), in fig. 2, chart 74, usually placed so the rush of air entering will surround the jet or spray nozzle.

The auxiliary air inlet: The greatest diference in the **air type** of carburetor is in the position and action of the **auxiliary air inlet.** In the one shown (fig. 2, chart 73), there are openings in the top ("extra air inlet"), closed by a valve pressed against them by a "coil spring," whereas in fig. 2, chart 74 it is placed to the side.

The auxiliary air valve is controlled automatically by the vacuum created by engine piston which draws air through the auxiliary air intake, against a spring tension; for instance, see the auxiliary air intake (d) in the carburetor shown in (fig. 2, chart 74).

Another method for automatically opening and closing the auxiliary air intake is shown in fig. 1, chart 75, see the ball (N). Instead of a valve and a spring, balls are utilized instead.

The air valve spring. The weaker the spring the less vacuum it will take to draw the valve open, and it may be adjusted by means of a threaded sleeve (as in fig. 2, chart 74), or in various other ways.

The **stronger** the **spring**, the less air, hence "**richer" mixture.** The **weaker** the spring; **more air, "leaner" mixture.**

Float chamber is that part in which the float operates; it is sometimes placed around the spray nozzle and sometimes to the side, as previously explained.

The float level: In different makes of carburetors, the level of the gasoline in float chamber, and the gasoline in the spray nozzle varies from about one-sixteenth to one-eighth of an inch below to top of the spray nozzle, see pages 166 to 168 "adjusting floats of carburetors."

Spray nozzle: The fuel is discharged into the mixing chamber through the spray nozzle. (Also called "jet tube.")

As its name implies, it is intended to deliver the liquid in the form of a fine spray, which is: (1) vaporized more or less; (2) mixed with the entering air, and (3) carried by the suction into the engine cylinder.

The simplest form of spray nozzle is one having a single opening, as shown at (s) in fig. 2, chart 74. Some carburetors have **two spray nozzles** or jet tubes, as shown in fig. 3. Another type has what is called a "**multiple jet**" spray nozzle, as shown in fig. 4, see also upper right-hand illustration, page 179.

When a carburetor has more than one jet it is particularly adapted to a multiple of cylinders of large size and especially six cylinder engines.

The mixing chamber consits of an enclosure or passageway containing the nozzle. The gasoline and air is mixed within this tube in proper proportions and then drawn through the throttle into the engine.

The venturi tube around the spray nozzle in the mixing chamber, is the accepted type and is now made in almost all makes of carburetors. The principle and purpose of the venturi tube around the spray nozple is in order **to get a greater volume of air through a predetermined sized opening in quicker time.** Explanation of the venturi action is shown in figs. 2 and 3, page 152.

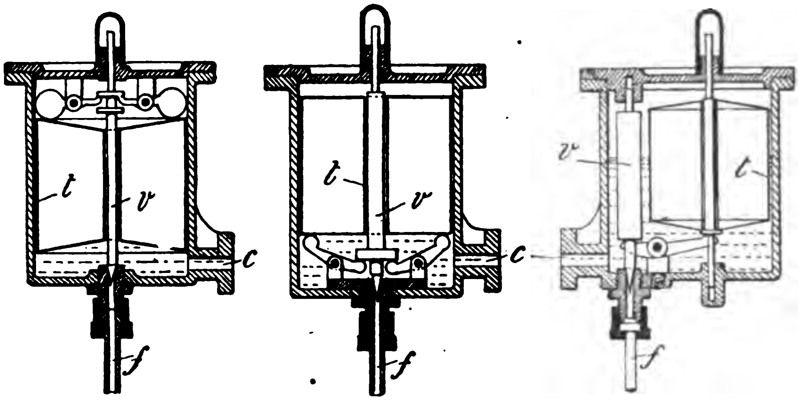

Fig. 1—The Different Mechanisms for operating the float valve on side float type of carburetors—there are several other types in use. T—is the float, usually hollow metal. V— is the float needle valve. C—is the opening leading to the spray nozzle. F—is the pipe from the gasoline tank.

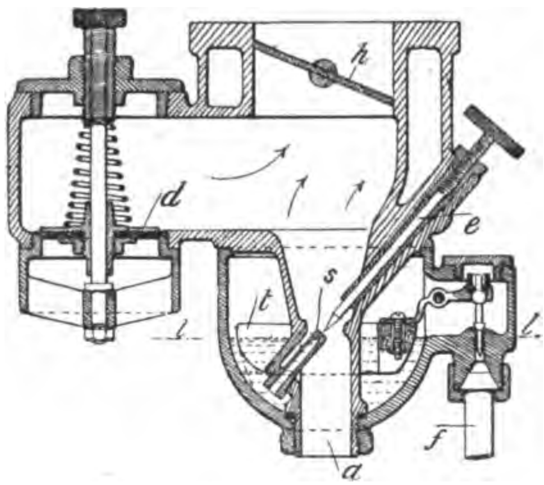

Fig. 2.—Type of carburetor with a concentric type of float. Note the float (t) (made of cork) is constructed so that it surrounds the mixing chamber and the spray nozzle.

The main air intake (a) **auxiliary air intake** (d) **single jet spray nozzle** (s) **and throttle valve** of the butterfly type (h) are shown in this carburetor.

The hand adjusted gasoline needle valve (e) **is also shown.**

A hand controlled mechanically operated gasoline needle valve is shown in chart 84.

An automatically controlled needle valve is shown in chart 82.

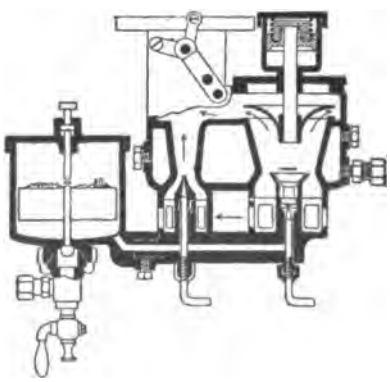

Fig. 3.—A carburetor of the side float and "double jet" type. The hand adjusted needle valves are shown at bottom of carburetor.

Carburetors are also made with three or more jets, see fig. 6, page 149.

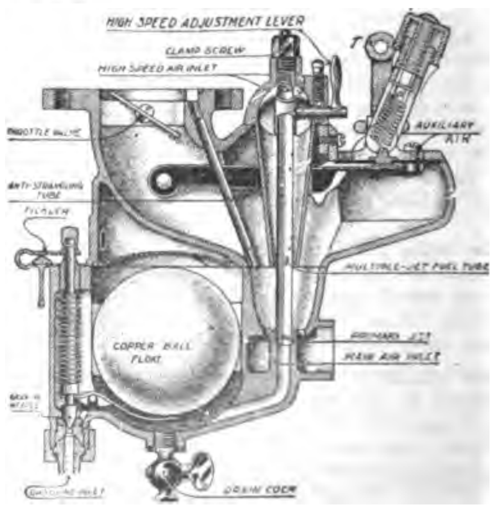

Fig. 4—The Carter; a true Multiple Jet Type carburetor with side float chamber. Seamless copper float. Auxiliary air valve spring subject to control from the car dash. This type is particularly adapted to six cylinder engines.

This illustration is of the old model—see chart 88 for improved model, upper left illustration

CHART NO. 74—Explaining Different Float Mechanisms. Gasoline Adjusting Needle. Double Jet and a Multiple Jet Carburetor.

Carburetor Principles.

Despite tremendous advancement made in internal-combustion engines during recent years, original methods of carburetion are still—broadly speaking—in practice.

The carburetor is still a comparatively primitive instrument, depending upon the suction of the piston during its descent on the inlet stroke to draw from a jet (spray nozzle) or jets—variable or otherwise—the necessary gasoline to mix with the air.

This jet can be a fixed size or it can be variable. This spray of gasoline is at the mercy of the temperature, valve timing, exhaust, inlet and combustion head design.

Carburetors as we know them at the present time, are divided into five classes:

(1) **Air valve type**—In this the fuel issues through a fixed orifice and the additional air required when the throttle is opened is admitted through an auxiliary air valve. (See fig. 2, page 144 and fig. 5, page 150).

(2) **Compensating jet type**—In this an auxiliary fuel jet comes into action as the throttle is opened. (See page 181—Zenith.)

(3) **Metering pin type**—In this the size of the gasoline orifice (jet) is increased automatically to increase the flow of fuel as the throttle is opened. (See page 151 and 178.)

(4) **Expanding type**—In this there are a number of fixed orifices which come in action one after the other as the throttle is opened. See Carter and Master, pages 179 and 180, also 151.

(5) ***The "plain tube" or "pitot" principle:**—Is a modern principle now being adopted extensively. The metering pins, dash pots, auxiliary air valves are dispensed with. The action is to supply an increased supply of gasoline or rich mixture for acceleration and then thin down to an economic mixture for normal engine speed. See page 177 for the Stromberg using this principle, and page 800 for the Schebler, as used on the Ford.

Air Valve Principle.

To properly understand the "air valve" principle we will begin with the first principles.

For a simplified explanation we will use illustration fig. 1, page 144.

The liquid gasoline enters the float chamber from the supply tank through the "float needle valve."

In the "float chamber" there is a "float," made either of cork, well shellaced to keep out moisture, or in the form of an air-tight metal box, which floats on the gasoline.

As the gasoline enters, the float rises, closing the gasoline needle valve, shutting off the gasoline when it has reached a certain depth.

The gasoline runs out of the float chamber to the spray nozzle, the float keeping the gasoline at the same level in both. When the suction of piston draws the gasoline out of the spray nozzle, the level of the gasoline in the float chamber drops, and as the float sinks, the valve is opened and more gasoline admitted.

When the spray nozzle is made with a small opening, the gasoline comes out in the form of spray, instead of as a stream, which makes it vaporize quickly.

In some carburetors, as the gasoline comes out of the spray nozzle it strikes against the end of a head projection, which breaks it into finer spray, and as the object is to make it vaporize as quickly as possible, this is an improvement.

In the simple float feed carburetor shown in fig. 1, page 144, and fig. 4, this page, it is only possible to adjust the amount of gasoline flowing to the spray nozzle. This is called the "Maybach" principle (see fig. 1, page 144).

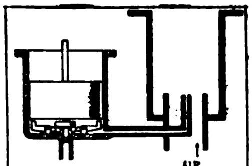

Fig. 4—The Maybach, earliest and simplest of modern carburetors

Therefore the simple form just described is satisfactory only for an engine which runs at a steady constant speed, for the speed of the air current through it does not change, and the **gasoline may be adjusted** to correspond.

The engine of an automobile, however, does not run at a steady speed; sometimes it is running fast and sometimes slow.

The speed of the air current passing through the carburetor depends on the speed of the engine; when the engine is running fast the speed of the air current through the carburetor is much greater than when the engine is running slow.

The greater the speed of the air current, the more gasoline it will suck out of the spray nozzle, and the adjustment of the gasoline flow that will give a correct mixture at a low speed will give a rich mixture when the air current moves at a higher speed. **For this reason the air supply must also be varied in order to give the proper combustible mixture.**

Auxiliary Air Valve.

To vary the air supply, different methods are used, but one used most is the auxiliary air valve, and this is where the "air-valve type" carburetor derives its name.

*The "Pitot tube" is an instrument for measuring pressure in moving streams of gas or liquids. Can be used facing in any direction, but as applied to the carburetor faces down stream.

The Pitot tube has been used for years for measuring fire streams, chimney drafts, etc. In the carburetor it is simply used to provide air at sufficient pressure to force the fuel from the well and be enclosed in the carburetor.

The Auxiliary Air Valve—its purpose.

Maybach conceived the idea of using a float to keep the gasoline in spray nozzle at a constant level and to draw air around the spray nozzle as per fig. 1, page 144. **Krebs**, then added the auxiliary air valve, as per fig. 2, page 144.

The auxiliary air valve was designed for engines which run at changing speeds, so that an extra supply of air was admitted when the air current flows so fast that it would result in too rich a mixture.

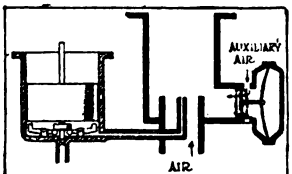

Fig. 5—Krebs added an auxiliary air valve for high speed air

The action of this auxiliary air valve depends on the greater or less suction, that faster or slower speeds of the engine gives.

In this particular type, fig. 2, page 144, and fig. 2, page 146, the extra supply of air, which reduces the rich mixture formed in the mixing chamber, is admitted through the valve placed above the spray nozzle which is controlled by an **adjustable spring**.

The suction produced from the suction stroke of the piston draws the auxiliary valve open, just as an automatic inlet valve is drawn open.

As the rush of air through the mixing chamber becomes greater and greater, because of the increased speed of the engine, the air valve is drawn open correspondingly wider, the spring being adjusted so that the proper amount of fresh air is admitted to bring the rich mixture to the proper proportions.

The float feed and the spray nozzle arrangement in both fig. 1 and fig. 2, page 144, are the same, the difference being in the auxiliary air inlet in fig. 2.

See fig. 2, chart 74 and note the auxiliary air valve as applied to th Schebler model D carburetor.

The disadvantage of this type is that owing to the relieving action of the spring valve, it does not increase the proportion in ratio, and is hardly suitable for the present day high speed flexible engine.

There are several different models now manufactured, based on the principle of the auxiliary air valve only. In these, the problem is worked out in different ways; one manufacturer uses a "**spring-controlled valve**"; another hopes to get better results by regulating the movement of the valve by "**two springs**," instead of one; still another maker adds an "**air dashpot**" with the hope of getting finer regulation and a better functioning of the auxiliary air valve; another uses a "**dashpot filled with gasoline**"; and there are others who use metal "**balls**" to serve as the auxiliary valve; while others use what are known as "**weighted air valves**," in which the suction lifts balls (L), as in fig. 1, chart 75, thus admitting the air which sweeps over the spray nozzle. While they all differ in the details of working out the design they are, nevertheless, based on the basic principle of the **auxiliary air valve** as originally worked out, in fig. 2, chart 72. For simplicity in nomenclature we will refer to this type as the **auxiliary air valve type.**

For air valve types of carburetors, see Kingston, fig. 1, page 152; Schebler model D, page 148.

Relation of Acceleration to Gasoline Consumption.

The rapid advance of high speed and multiple cylinder engines, have demanded "**quicker acceleration**," meaning quicker "get away" or "pick up" of the engine.

Flexibility of control means practically the same thing or the capabilities of the engine to "pick up" from low to high speed and vice-versa. Rapid "acceleration" and "flexibility," both call for a sudden **greater amount or percentage of gasoline to air.** Quick acceleration therefore demands a surplus of gasoline for but **a brief period** after which the normal supply will care for the engine. It may be but a matter of a few seconds, yet it is of importance that this additional supply be ready and in available form for that brief period.

The Dash Pot.

To meet the sudden demand for gasoline, the added nozzle, or multiple jet has been introduced by some makers, so that when the suddenly-opened throttle brings the auxiliary air valve into use, the valve in turn brings more gasoline into the mixture, an added supply. One maker does this by a "**dashpot**" on the auxiliary valve stem, this dash pot performing a regular pump stroke and forcing gasoline into the mixing chamber by way of a separate nozzle as the auxiliary air valve opens. Once open the pumping action ceases, but the nozzle remains open for a more even demand for more fuel.

The Compensating Jet Principle.

As stated, under a heading (2) on page 149; the compensating jet type of carburetor is where an auxiliary **fuel** jet comes into action, as the throttle is opened.

Types of carburetors coming under this heading would be the Zenith, page 181; Stromberg model "H," page 177; Marvel, page 179.

The Metering Pin Principle.

Metering pin type—In this, the size of the gasoline orifice or jet, is increased automatically to increase the flow of fuel as the throttle is opened. For instance, note the connection between the **"throttle" and the "needle valve"** in the spraying nozzle as shown on page 174. By a carefully computed cam action it is possible to give a **sudden lift of the needle** and thus get the desired fuel supply quickly.

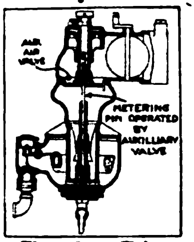

Fig. 1. The Schebler model "T" with metering pin operated by the auxiliary air valve.

The same company in another model-(T), have connected the **"auxiliary air valve" with the "needle valve"** in the nozzle (see above, and page 172), so that as the air valve opens there is a larger nozzle opening for the flow of gasoline. This principle is called the **"metering pin"** method.

Proportion of air and gas: All of those methods of providing "acceleration" are based on the accepted belief that in carburetion, **different mixtures of air and gasoline vapor are needed for different engine requirements.** The days are past when the **uniform-mixture** argument dominated, the argument that the ideal carburetor was one that would give, say, a mixture of fifteen proportions of air to one of gasoline vapor for all speeds, "acceleration," "hard pulling" with open throttle, and high-speed work with open throttle, etc., etc. The new rule is that the amount of gasoline fed into the air volume must be changed according to demands, and that if a twelve-to-one or "rich" mixture might be best for quick acceleration, that a fifteen to one, or "leaner" mixture may be best for pulling with the throttle wide open and a seventeen to-one, or still "leaner" mixture for particularly high speed work. Therefore a **"varying mixture"** must be supplied.

Example of a Carburetor with Both a Metering Pin and Dash Pot.

The Rayfield uses a "metering pin," which pin is lifted as the throttle opens in the main jet N, fig. 2, through a link arrangement, and so establishes a right to be classified as a metering pin type, but it goes further. It incorporates an auxiliary nozzle (AN) which also has a metering pin which is depressed when the auxiliary air valve opens. Thus by having two distinct nozzles it establishes its right also to be classified as an expanding type of instrument.

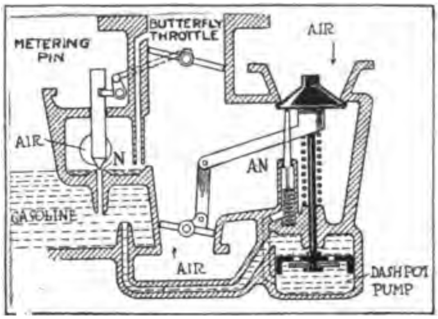

Fig. 2. The Rayfield carburetor principle with "metering pin" connected with the throttle and "dash pot," with auxiliary air intake. (see also page 175.)

But the Rayfield goes still further in that it combines a **pumping** action on the **gasoline** in the auxiliary nozzle AN whereby a very rich mixture is furnished for acceleration whenever the air valve is suddenly opened. This is accomplished by the piston on the lower end of the air valve stem, this piston working in a "dashpot" filled with gasoline. Gasoline enters the dashpot above the piston and is admitted to the space below the piston by the disk valve in the piston. When the air valve suddenly opens, forcing the piston downward, this disk valve is automatically closed, forcing or pumping the gasoline upward through the dotted fuel passage into the nozzle AN, where it is sprayed into the inrushing air. Only when the valve opens is this pumping function occurring and at other times the gasoline issues through this auxiliary nozzle according to the suction of the engine. **Thus the Rayfield is a compound of two metering pins in conjunction with the pumping function** for acceleration.

Other makes of carburetors using metering pins are the "Schebler" and "Stewart" see pages 172, 173, 174 and 178.

Expanding Principle. Plain Tube Principle.

In the expanding principle, there are a number of fixed orifices which come into action, one after the other, as the throttle is opened. Types of this class of carburetors are shown in fig. 6 and in the description of the "Master" carburetor on page 180, also on the "Carter" as described on page 179.

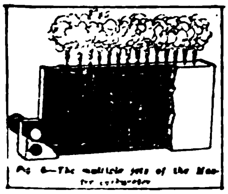

Fig. 6—The multiple jets of the Master carburetor.

Plain Tube Principle

is different from this principle and other principles. It is the principle now being adopted by many carburetor manufacturers. For explanation of the **"plain-tube"** and **"pitot"** principle, see pages 149, 177 and 800.

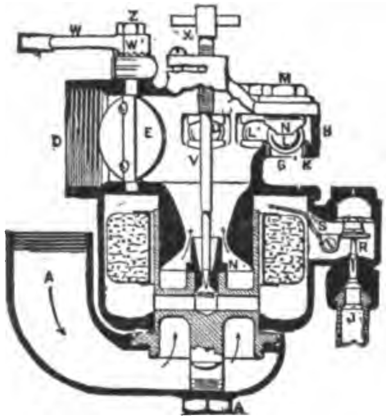

Fig. 1.—The Kingston Carburetor. Instead of using a Spring on the Auxiliary Air Intake; balls (L) Govern the Intake of Air through auxiliary air intake (G). (W) is the throttle. (E) Butterfly valve. (D) Connects to intake pipe on engine. (A) Main air intake. (V) Gasoline needle valve. The float is concentric type. Venturi mixing tube.

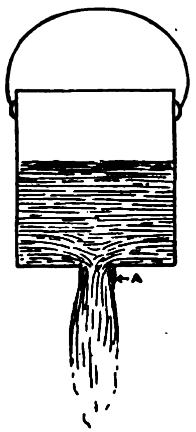

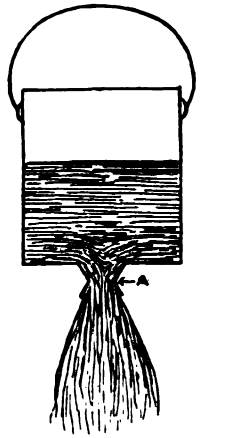

Fig. 2. Fig. 3.

Explanation of Venturi. If two buckets are placed side by side, both filled with water, and for example a one inch opening cut in the bottom of each. One to have a plain opening as in Fig. 2-(A) and the other to have a "Venturi" opening as in Fig. 3-(A), the same volume of water would flow out of the Venturi one-inch opening in Fig. 3-(A) much quicker than through the plain one inch opening Fig. 2-(A).

Note the shape of the Venturi opening (A), Fig. 3—then note a similar shaped tube in the mixing chamber in Fig. 1 of the Kingston Carburetor where arrow points lead from N.

Note a **double venturi** on Stromberg carburetor, fig. 1, page 177. See also page 147 for explanation of "venturi."

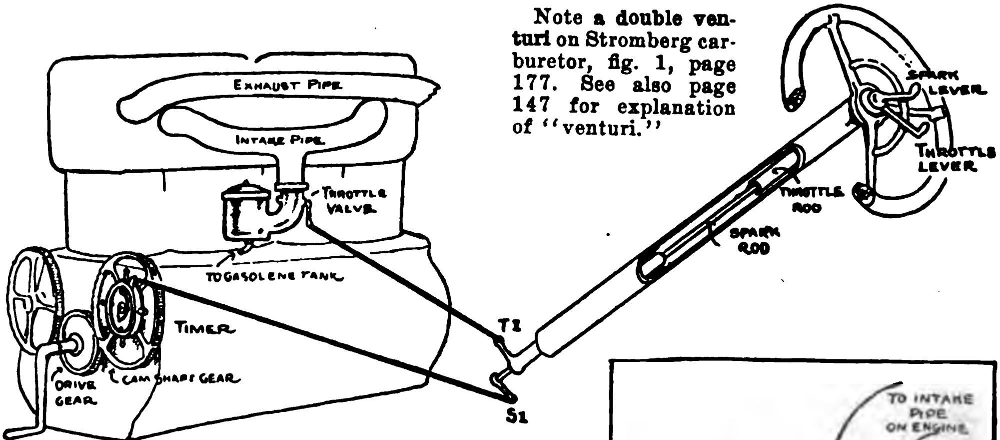

Fig. 4.—Illustrating the Connection between the Carburetor Throttle Valve on the Carburetor and the Throttle Lever on the Steering Wheel. The purpose of this drawing is to explain how the speed of an engine is controlled by hand (the usual method).

The spark must be "advanced" as the throttle is opened. This is done by shifting the timer, and causing the spark at the points of the spark plugs in the cylinder to spark and ignite the gas earlier.

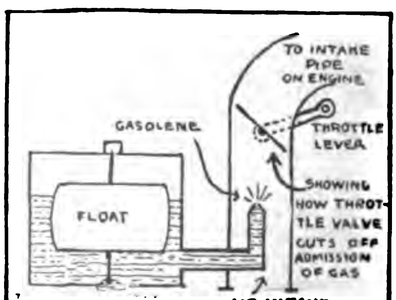

Fig. 5.—The Butterfly Type of Throttle Valve.

:HART NO. 75—Explaining the Ball Type of Auxiliary Air Intake. Explanation of Venturi. peed Control with Throttle on Steering Wheel.

Carburetor Throttle Valves.

There are three types of throttle valves; the **butterfly, rotary** and **sliding** (see chart 76).

The butterfly throttle valve is the type of throttle used on almost all makes of carburetors. This type of throttle is shown in fig. 1, chart 76. The mechanism and method for controlling the throttle is shown in fig. 4, chart 75, also see chart 91. (T).

The throttle is placed in the mixture outlet, and the form that is shown is called a "butterfly valve." It is a disc of metal turning on pivots, so that it acts like the damper of a stove pipe. When wide open, the butterfly valve is edgeways to the flow of the mixture, but even in this position it presents resistance to the flow, which is something that should be avoided.

The "rotary" throttle valve, fig. 2, chart 76, presents no resistance whatever for there is no resistance offered. Also see "**Master**" carburetor, chart 89.

The sliding throttle valve is another type which presents no resistance to the flow of gas. This type is seldom used although it was formerly used quite extensively when governors were used. (See chart 76, fig. 3.)

Engine Speed; How Controlled.

The simplest and probably the acknowledged popular method for controlling the speed of an automobile engine is by **opening and closing the throttle valve** on the carburetor by hand.

A rod leading from the throttle lever on the throttle valve connects with a hand lever on the steering wheel. (See fig. 4, chart 75.) The driver then has the speed of engine under his control at all times.

If running on a level and more speed is desired, the throttle is opened by the throttle lever until the required speed is maintained. By closing the throttle, the speed is decreased.

‡Idling.

The throttle valve is never **entirely** closed; the lock screw (X) shown in (chart 82) prevents the throttle from closing entirely. Therefore engine will run slow or "idle," as it is called, when the throttle valve lever on the steering wheel is closed and car standing. To stop engine entirely; throw off the ignition switch. (see page 171).

The Accelerator.

This is the usual means for controlling the speed of the engine, see chart 76, fig. 4.

Governors.

In the early days the governor was used on a few makes of pleasure cars but discarded. The governor is now **used extensively on truck and tractor engines** as a matter of economy. See index "Governors," and page 154.

There are two types; the "throttling" type which governs the amount of gas entering cylinders and the "hit and miss" type which governs the spark by cutting it off when engine speeds up.

The former is the type in general use and the latter is used to a great extent on small stationary gas type engines. The larger stationary type engines use the "throttling" principle, fig. 5, page 154. (see index "Governors.")

*Remarks on Starting an Engine.

When an engine is started by cranking by hand, which is best done by a **quick** turn of the crank, it is necessary that a charge of vaporized, combustible gas be drawn into the cylinder, which is easy to ignite. It is also necessary to have a **good electric spark** to ignite the gas.

If we attempt to start, depending only on a magneto to supply this spark, it would be necessary to "spin" the crank in order to get the armature of the magneto up to sufficient speed to generate electricity; therefore the magneto is seldom used to start on. The usual method is to **start from coil ignition**—its source of electrical supply is derived from a battery—and after the crank shaft of the engine is in motion, then the switch is turned to the magneto, if a magneto is provided. If a **generator and battery,** then this action is automatic. Explained further on.

The modern method of starting an engine is by an electric motor, which will be explained further on.

In order to facilitate easy starting, by hand or motor, it is advisable to open throttle just before stopping engine; in order to draw in a good charge of gas—by speeding engine up with clutch out; this leaves a charge in the cylinder for starting later.

Priming to Assist Starting.

*When using the low grade gasoline, especially in cold weather, the gasoline does not vaporize freely. Gasoline vaporizes more readily when warm than when cold. The most effective temperature seems to be about 170 degrees Fahr.

Vaporizing really means evaporating, or transforming into vapor. The purpose of heating the mixture before it passes into the cylinder, is to make the gasoline more "volatile" or to evaporate quicker.

When first starting, however, heat is not provided, therefore some method of priming must be resorted to. That is, draw gasoline into the cylinder. (see page 156).

One method of priming is to prime with a "tickler," which means to depress the float by hand so that the float needle valve will open and admit gasoline to the float chamber. A wire is usually run from this "tickler" to the front of the car, where the operator can pull it and flush the carburetor before cranking (fig. 6, page 156).

Another method for priming is called the "damper" or "choke" method, and is shown in chart 78A. Instead of lowering the float, the air intake is closed. This causes an increased suction of gasoline and is called **"choking" the air supply.**

****Too much priming,** however, will fill the float chamber so full, that gasoline will run out of the spray nozzle, giving a rich mixture, on which the engine will not start, therefore it will be necessary to close switch and throttle, and crank engine a few times to draw in more air, then open switch and crank again, at which time engine ought to start if there is a good spark.

After engine is started, then some means for heating the gasoline so it will vaporize more readily should be employed.

***When an engine will not start during cold weather**—an effective method is to pour boiling water over carburetor and inlet pipe. The "**choker**" or "damper" principle however, usually starts engine, per page 159. **See page 489, foot note, "starting an engine by opening switch."

Too much does one of **three things—see page 205, explaining. ‡See also pages 169, 171, 652, 653.

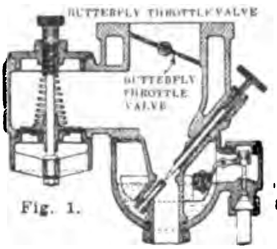

Fig. 1.

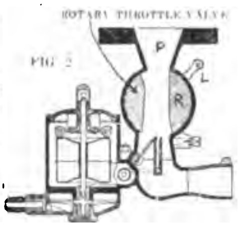

Carburetor Throttle Valves.

There are three types of carburetor throttle valves: (1) the butterfly type as per fig. 1; (2) the rotary type per fig. 2, and (3rd) sliding throttle per fig. 3.

The butterfly type is in general use; it may be placed in position as shown in fig. 1, or as per fig. 1, chart 75. Usually consists of a thin disk with a throttle lever which is connected with the hand throttle lever on steering wheel.

The rotary type is different, but used for the same purpose. In the rotary type, the passage of gas from jet to intake manifold through passage (P), is controlled by a rotary cylinder (R). It is now shown full open, but by moving throttle lever (L), it can be closed or partially opened as desired. This is the principle used on the Master carburetor.

SLIDING THROTTLE VALVE

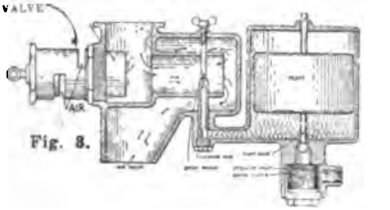

Fig. 3.

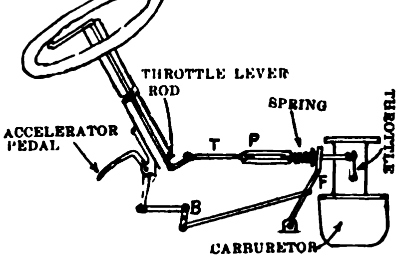
The sliding throttle valve consists of a cylinder type throttle, but instead of being rotated, it is moved in or out of its passage, which controls the amount of gas passing to the intake manifold. As it is moved out, additional air is admitted through port holes. This type was the type formerly used with a governor. It is now practically obsolete.

The Accelerator.

Fig. 4. The accelerator consists of a foot pedal which opens and closes the carburetor throttle valve independent of the hand throttle lever. By referring to the illustration, it will be noted that the accelerator will operate the throttle of carburetor without moving the hand throttle lever by an arrangement as shown. When foot accelerator pedal is depressed, the rod (F) moves against a shoulder which is fastened to the throttle shaft. The end of the shaft (T) works free in a turn buckle (P). Therefore, the throttle can be opened without disturbing the hand lever. Or the hand lever can be operated without moving the foot pedal. The accelerator is used more than the hand throttle lever. Its purpose is the same as the hand throttle lever on the steering wheel; to open and close the throttle valve. (see also page 497, 492.)

FIG 4



The accelerator pedal is the usual means of controlling the speed of the car. When pressed downward for increase or released for decrease of speed, its action is instantaneous. When the accelerator is released, the engine immediately resumes the speed determined by the positions of the hand lever on the steering wheel. Although either the hand throttle lever or the accelerator may be used to control the speed of the car, the use of the hand lever is advised for beginners. After confidence in driving has been gained, the more delicate action of the accelerator will be preferred.

The word "accelerate" means to hasten, therefore the term is applicable here because it is quicker to operate throttling.

The Governor.

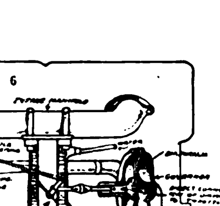


FIG 5 -The centrifugal governor

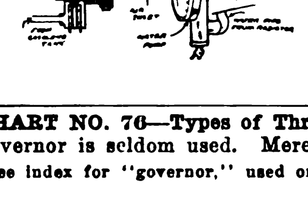
Fig. 5. *There are no pleasure cars using the governor. Nearly all truck, tractor, marine and stationary engines use governors. One type of governor which is a "throttling" type, is the centrifugal ball type as illustrated in fig. 5, and which, no doubt the principle is familiar to all. The "sliding" throttle in carburetor is actuated by the movement of the sleeve controlled by the balls (B). The balls fly out as the speed increases causing the throttle to close.

Fig. 6. The governor formerly used on the Packard: A "hydraulic" governor of the diaphragm type is located directly above the water pump. It is operated by the pressure of the water in the water circulation system and consists of a circular chamber divided by a flexible diaphragm of leather and rubber. On one side of the diaphragm is a water space through which passes the water of the circulating system. On the other side is an air space and a plunger head against which the diaphragm presses. The plunger is directly connected with the throttle valve.

FIG 6



If a decrease in the load on the engine causes its speed to increase, the pressure of the water, circulated by the pump, increases and, consequently, the diaphragm exerts more pressure toward the rear, tending to move the plunger and thereby close the throttle. As the engine speed decreases, the water pressure against the diaphragm is lessened and the throttle may open.

The purpose of the governor is to prevent the engine from racing when the load was removed, as by throwing out the clutch or stopping the car without shutting down the engine, also to prevent driver from obtaining over a set maximum speed.

This, however, was found unnecessary on pleasure automobiles, as high speed is a desirable feature at will of the driver, which is more easily accomplished with the movement of the hand throttle lever.

The governor, however, is a very desirable feature on truck, tractor and marine engines where the engine is supposed to run at one fixed speed, yet the load varied, as the governor would then keep the speed constant although the load did vary and is a saving in fuel, wear and tear.

CHART NO. 76—Types of Throttle Valves. The Accelerator. Governors. The sliding throttle and governor is seldom used. Merely shown to explain the principle.

*See index for "governor," used on truck and tractor engines.

*Vaporizing of Gasoline.

As previously stated gasoline gives off more vapor at about 170 degrees Fahr. It is the vapor mixed with air which is most desired. With the proper mixture there is more uniform power and flexibility.

**Heating Methods.

There are several methods employed for vaporizing, as follows: (1) by passing hot water from the water circulation system around the water jacket of carburetor, or intake manifold; **(2)** by passing exhaust gases from exhaust pipe around the water jacket of carburetor instead of hot water, also around intake manifold; **(3)** by taking the warm air from around the exhaust pipe and passing it through the main air intake of carburetor; **(4)** by heating the mixture as it passes into cylinder.

The above methods can be classified under two headings: (1) heating the air as it passes into carburetor; (2) heating the **mixture** as it passes into cylinder. See pages 159, 157, 160, 187, 855.

†Heat Regulation Methods.

Carburetting means to break up the gasoline into infinitesimally small particles, mechanically, without heating, which is called "spraying." This is the best method, but very difficult to do so, owing to the different amounts of gasoline passing from spray nozzle, and on account of the variation of the throttle or the speed.

‡If a low gravity of gasoline is used, it is necesary to heat and vaporize the mixture, because it is practically impossible to break it up; but if it is a high gravity gasoline, it generates into gas quicker. In other words, it is the **vapor** that we must obtain, which is possible with high gravity gasoline. **But in using high gravity gasoline remember it will not stand as much heating as low gravity,** for if there is too much heat used, then it makes the mixture so rare that the actual amount of gasoline that goes into the cylinder is so small and at such a low flash point, it ignites quicker, and will burn and expand more like powder. It will do its work and cool before the piston gets well under way, furthermore the pressure on piston does not last as long. (see page 161.)

Owing to the low gravity gasoline now being used, the mixture is not a true vapor. Instead of forming a gaseous mixture, it condenses, inside of combustion chamber and manifold—therefore a plentiful supply of heat is required. (see pages 157, 158, 159.)

Air control: Therefore, if some method of heating the mixture is employed, as shown in chart 78A, then the heat must be **regulated,** which is usually done by a dash board or steering column air control (fig. 4, chart 78A), connected with the air intake of carburetor.

Temperature regulator: After engine is well warmed up it ought to have more air, and the more air used, less gasoline required.

If warm air was drawn into the carburetor after engine was **very hot,** then the mixture would be made too rare or lean.

We also know that gas expands in direct proportion to the degree to which it is heated. Therefore, when **heated too much,** the gas is unduly heated or prematurely expanded to such an extent that it loses a certain per cent of its energy.

The best degree for general running appears to be somewhat below the boiling point of water, i. e., between 170 degrees and 200 degrees Fahr.

Therefore some means of admitting cool air must be employed which will mix with the warm air. This would be termed a "temperature regulator," and is very simple. See page 159.

The use of low gravity gasoline requires more heating or vaporizing than a high grade. It might be compared with the firing of a furnace with soft coal.

If soft coal is properly fired and is properly mixed with air, it will produce the most heat without producing very much smoke. Just so with a low grade of gasoline. If properly vaporized it will work fairly well, otherwise carbon deposit and smoke will be the result. (see page 205.)

High gravity gasoline may be compared with hard coal. It is very easy to get the proper mixture of air with the high gravity gasoline, because it is so very "volatile"—meaning: there is more vapor, and less vaporizing is necessary and will "carburet" more readily; therefore it will work satisfactory in most any carburetor construction. Just so with hard coal, it will burn with less smoke and produce an equal amount of heat even though you burn it in an open shovel, and makes very much less smoke and carbon.

On stationary and high duty marine engines as low a gravity of fuel is used, as kerosene and oil, but before it can be used it must be "vaporized."

A correctly heated carburetor runs on less gasoline than an unheated one, therefore a closer adjustment of the gasoline needle valve or a smaller jet is necessary.

An engine requires more gasoline in winter than in the summer as the gasoline does not vaporize and readily mix with the air until warm.

If intake manifold is heated with water, the temperature is not so liable to cause overheating, as the temperature seldom goes above 170 to 200 degrees, especially if a thermostatic principle is used as per fig. 2, pages 180 and 187.

When intake manifold is heated by exhaust, the temperature is liable to increase to a high degree, when engine is run continuously for a long period. The latter system however, will heat the mixture quicker than the water system, when engine is cold. Therefore means for admitting cool air per figs. 1 and 3, page 159, and some means for cutting off the exhaust gases to manifold jacket ought to be provided, for long runs.

*More heat is required in cold weather than warm weather. **See page 855, Packard method for "heating the mixture."

†See also pages 157, 159, 187 and 860.

‡See page 161.

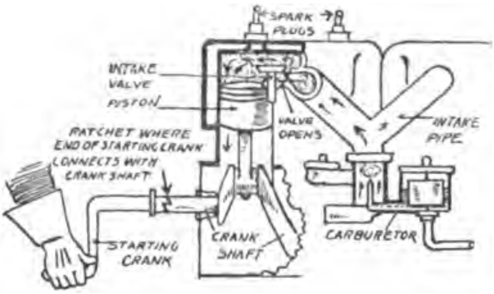


Fig. 1.—When Engine is first Started by hand or by a self-starter, the initial charge of gas must be drawn into cylinder. After it is compressed and exploded or ignited, the engine will then continue to run. Note the starting crank releases after engine is started.

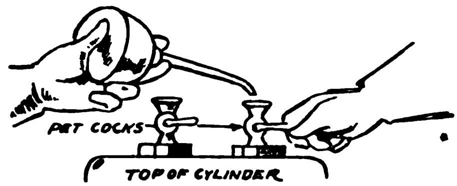

Fig. 2.—Priming by pouring gasoline in top of cylinder, through pet cocks.

Fig. 3.—Priming carburetor, turning adjusting screw.

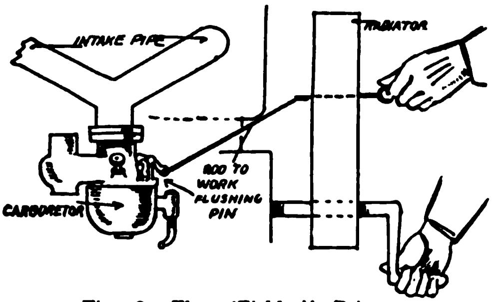

Fig. 6.—The "Tickler" Priming Method; pushing the float down admitting more gasoline.

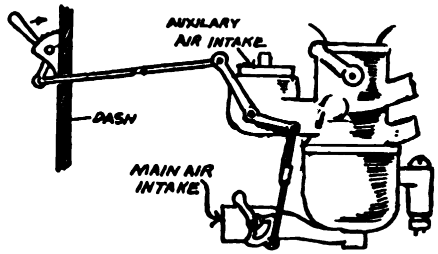

Fig. 4.—A Damper is Provided in the main air intake pipe. When closed the suction of gasoline is more than air Sometimes the tension of the spring on the auxiliary air valve is regulated from the dash or steering post. This regulates the feed of gasoline or air.

DIFFICULT STARTING IN WINTER.

On a Cold Morning after Engine and all parts have Become Chilled, we find that with the ordinary grade of gasoline now in use, the gasoline does not vaporize readily until it is heated; therefore, considerable cranking of the motor is sometimes necessary in order to ignite the cold, damp, unvaporized gasoline.

There are Several Methods of Overcoming this; one being to use a higher grade of gasoline, but even with the higher grade, which is difficult to obtain, on a real cold day the starting will be somewhat difficult, with some makes of carburetors.

A plan quite often used is to have a small machine oil can filled with gasoline, which is squirted into the cylinders through the pet cocks, which are usually placed in the head of the cylinder. By injecting a small quantity of gasoline into each cylinder, then closing the pet cocks. this will give the engine its initial charge, and will often start the engine without further trouble. (See Fig. 2.)

Another Method is to open the Gasoline Adjustment Needle Valve Several Turns before Cranking; this method is not advisable, however, because this adjustment valve is a very sensitive adjusted part of carburetor, and will throw the proper working of carburetor out of order after engine is heated up. If this method is employed be sure and mark a notch on the head of the valve, so that it can be turned back to its original adjusted position (Fig. 3).

Recent Improvements in carburetors to make a motor "easy starting" consist of a mechanism which connects with the main air inlet and the auxiliary air inlet of the carburetor, which closes these openings while cranking. This method causes the suction of the piston to draw into the cylinders a quantity of gasoline, which gives the same effect as if squirted in with the oil can. (See Fig. 4.)

The Usual and Common Method is to connect a wire or rod to a damper placed in the main air intake. When starting is difficult close the damper. (See Chart 79.)

In Either Method Explained, Remember that a Good Hot Spark must be provided in order to ignite this raw gasoline, because it is harder to ignite when cold than after it is warmed up.

It is also Advisable to be sure that no other trouble is the cause of the engine not starting, for instance a leak around the intake pipe. leaky float or some obstruction in the pipe.

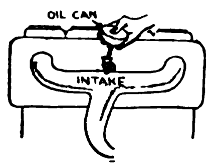

Fig. 5.—The oil can primer where gasoline is injected into manifold—simple and effective when other methods fail.

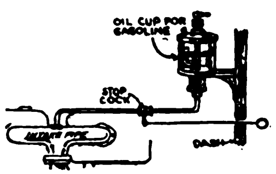

Fig. 7.—A home made primer; a ⅜" glass body oil cup of gas engine type is used.

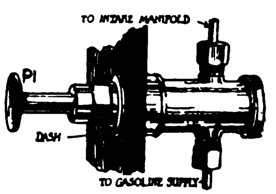

***Fig. 10.— The spray primer;** a small injector pump. The suction part of pump is connected to the gasoline supply pipe between the tank and carburetor. The other part connects to intake manifold; one stroke of plunger sprays a charge into the manifold. Imperial Brass Co., Chicago, manufacture a pump primer of this type, also Bay State Pump Co., 102 Purchase St., Boston.

CHART NO. 77—Different Priming Methods. (Also see Chart 78 for Electric Primer.)

See page 159, for "choker" method, which is the approved method for priming. ***A priming wrinkle which can** be used in connection here, is to have an auxiliary tank on dash under hood—about 1 pint or quart **size and fill** with high gravity gasoline and use for priming mixture. See also, page 579, 788 for **overheating causes.**

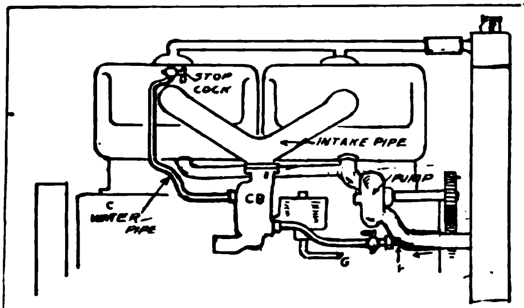

Fig. 1.—Hot water heating of carburetor: The usual method of connecting the hot water to the carburetor water jacket is to connect the upper water connection to cylinder water jacket or pipe, and lower one to suction end of pump (between radiator and pump). See that the connections are made in such a way that water will drain out of the carburetor jacket when system is drained. Place a shut off cock in the line for use in extremely hot weather.

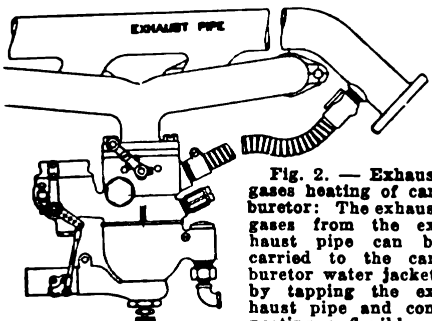

Fig. 2. — Exhaust gases heating of carburetor: The exhaust gases from the exhaust pipe can be carried to the carburetor water jacket, by tapping the exhaust pipe and connecting a flexible or copper tube to water jacket. It is advisable to use as large a pipe as possible—say ½ inch, as it has a tendency to clog up. The other opening of water jacket is left open by a copper pipe connection extending to lower part of engine for emission of gases.

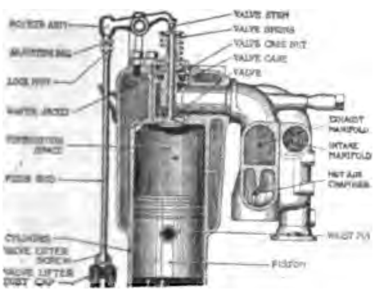

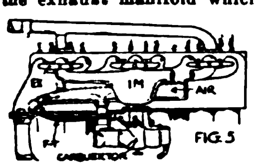

Fig. 5—Buick's exhaust heating of mixture. Note the exhaust manifold which adjoins the inlet manifold (IM). The lower part of exhaust manifold (hot air chamber) is divided from the exhaust (above). Air passes through lower chamber which is heated. Hot air is also drawn into jacket around upper part of carburetor by flexible tube connection (FT). Also see page 179, Marvel carburetor which is used on the Buick.

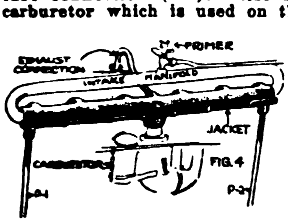

Fig. 4 — Franklin exhaust method of heating the mixture. Note jacket which encloses intake manifold through which exhaust gas passes. A cut off is provided when engine becomes very warm. P1 and P2 pipes are left open.

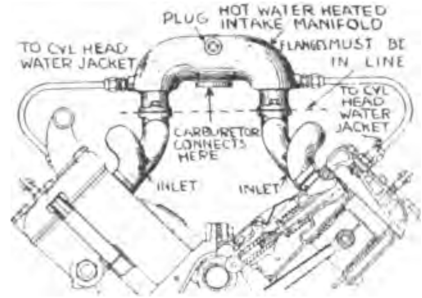

Fig. 1A—Hot water heating of mixture as employed on the Oldsmobile 8 cylinder V type engine. Note the hot water circulates through a jacket around the inlet manifold. This principle is more effective than heat around the carburetor. Exhaust heat can be passed through this jacket instead of hot water, which will heat the mixture quicker. (see also pages 82, 155 and 158.)

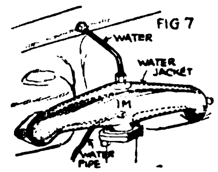

Fig. 7 — Stutz hot water heated intake manifold.

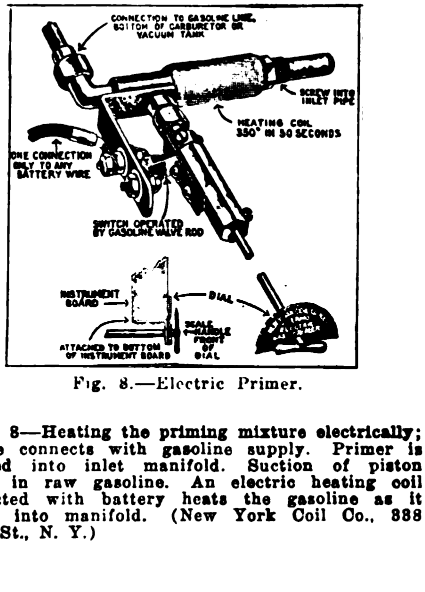

Fig. 8.—Electric Primer.

Fig. 8—Heating the priming mixture electrically; a pipe connects with gasoline supply. Primer is screwed into inlet manifold. Suction of piston draws in raw gasoline. An electric heating coil connected with battery heats the gasoline as it passes into manifold. (New York Coil Co., 888 Pearl St., N. Y.)

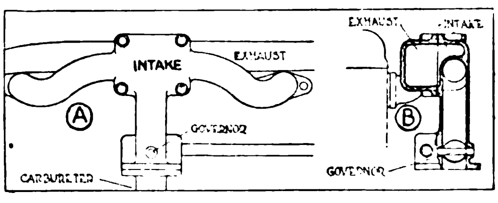

Fig. 9—"Hot-spot" heating of mixture by placing the exhaust manifold adjoining the inlet manifold, but only as part of the inlet manifold is heated; the upper part. The idea here, is to prevent condensation of fuel. The liquid particles, when they reach the top of the vertical passage, do not swing to the left or right with the gas, but go straight, since they are heavier, until they strike the hot spot.

CHART NO. 78—Methods of Heating the Carburetion Mixture. See also page 187, 191.

See page 744 for a home-made heated inlet manifold, and page 735 for "air and water" injection.

See also, Packard Fuelizer, page 855.

**Carburetion Heating Methods.

Hot water heating (see page 157) is probably the most efficient **for heating the mixture** for reasons stated on page 155. When engine is cold after standing all night the water does not heat as quickly as if exhaust gas heated, but when engine is run and warmed up and left standing, the water will remain warm for sometime and will quickly heat again. Therefore a water circulation around carburetor and inlet manifold with a temperature regulator (figs. 1 and 3, page 159) is a very good system. Water heating system can only be used with engines using a force or pump water circulating system (see insert No. 3).

Exhaust gas heating (see page 157) is the quicker method for **heating the mixture,** but overheating may occur. See page 155. The exhaust gases can be passed around the carburetor also jacket around the inlet manifold. For connecting the exhaust pipe with inlet manifold jacket a ⅝ flexible pipe with at least a ⅝" opening should be used. For an outlet a copper pipe with ½ or ⅝" opening should be connected and carried to bottom of engine to emit the gas.

Warm air may be drawn into the main air supply by means of a flexible pipe connection and hot air drum or stove as per page 159, in order to **heat the air** as it is drawn into carburetor. It is advisable that a temperature regulator be provided so cooler air can also be drawn in after engine is warmed up.

Priming by "choking" the air supply, is the method now used to a great extent for starting, which usually consists of a valve in the warm air supply which can be entirely closed thereby causing an increased suction of gasoline. After engine is started the choke or valve is gradually opened as engine is warmed up, at which time as much air as possible to prevent missing, is provided. Priming should be done sparingly. (see page 205).

Carburetor Attachments.

The inlet manifold is attached to the cylinder as explained on pages 159, 160, 164.

The carburetor can be placed **vertically** or **horizontally,** per figs. 4, 5, page 160.

On eight and twelve "V" cylinder engines, a duplex type of carburetor is used and is placed between the cylinders to one inlet manifold. See fig. 1A, page 157.

Air control devices and hot air attachments, see pages 159 and 157.

How To Determine Size Carburetor To Use.

The size of the carburetor should be determined by the area of the valve opening on the engine and not by the cylinder displacement, as the former is a true measure of the engine capacity. A carburetor cannot deliver more charge to a cylinder than the area of the valve opening will allow to pass.

A large carburetor with too much passage area cannot cause an engine to deliver more power than it would with one having a passage equal in area to that of the valve opening. Too large a carburetor would not only waste fuel, but reduce the power of the engine by furnishing a weak mixture.

If the carburetor is too small the engine will not develop its rated power, as it could not deliver a full charge at high speed.

When a carburetor is small for the engine, it becomes very cold while in operation as the amount of heat necessary to effect the vaporization of the gasoline is more than is available from the entering air or than could be secured through the metal carburetor by conduction. The temperature of the metal part of carburetor becomes so low that water condenses on it, and, in some cases, is in the **form of frost.** These results are produced by the use of a carburetor too small for the engine. To meet these conditions, some makers provide means for heating the air supply, as previously treated.

It follows that the carburetor of proper size should have its passage area equal to the valve opening of the engine. In multiple cylinder engines this area is equal to the valve opening multiplied by the number of suction strokes which takes place simultaneously, determined from the sequence of cranks, also see chart 81.

It will spell failure to fit a carburetor with a large jet and opening, to an engine in which the exhaust closes very early, because, the surplus gas cannot be expelled as completely, as with an engine having a very late closing exhaust valve.

Gasoline.

The usual fuel for automobile engines is gasoline. Gasoline is distilled from mineral oil (petroleum).

When petroleum is heated, it gives off gases just as water, when heated, gives off steam. When these gases are cooled, they become liquids, and are called gasoline, kerosene, benzine, naptha, etc.

The chief difference between them is their "volatility." When a liquid turns to vapor, or gas, it is said to be "volatile."

Temperature makes a great difference in the volatility of liquids; for instance, thick, heavy oil is not volatile at the ordinary temperature of the atmosphere, but is volatile when heated.

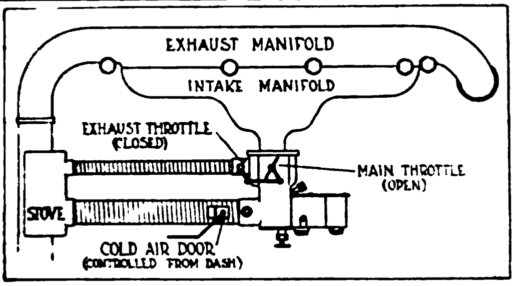
Gasoline is very volatile at the ordinary temperature of the atmosphere. It is so volatile that it must be kept in air-tight tanks, for it would entirely evaporate if left exposed to the air. Because of this volatility, gasoline must be handled with care to prevent fires and explosions. It should never be handled near an open flame.

***Results of using low gravity gasoline:** A low grade of gasoline will produce poor results in any carburetor. Difficulty in starting is the main disadvantage in its use as it is not as volatile as a high gravity.

Inferior, or too much gasoline is generally indicated by a black smoky exhaust and disagreeable odor.

When a low gravity of gasoline is used some method for vaporizing must be employed, as explained on page 155.

*See page 205. See pages 160, 827, 831 on use of kerosene. **See also, pages 187, 855.



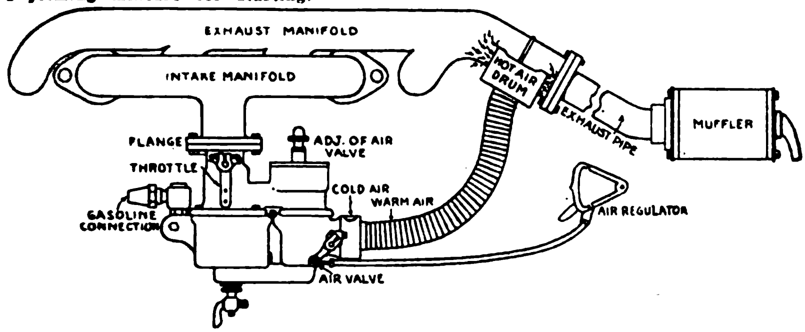
An Ideal Heating System.

Fig. 10.—**Combination of heating the mixture and heating the air;** exhaust manifold adjoins the inlet manifold which **heats the mixture as it enters cylinders.** Warm air is drawn around upper part of carburetor, admission of which is controlled by throttle which keeps upper part of carburetor warm. Warm air is drawn in main air supply which **heats the air.** A temperature regulator controlled from dash, admits **cool air** into main air supply when engine is thoroughly warmed up.

For starting, the lower air opening of carburetor can be closed entirely which "chokes" the air and causes gasoline to be drawn into cylinder until engine starts. This system is used on the Nash trucks and is **an ideal system.**

Air Heating Methods.

In chart 78 methods of heating the mixture as it passed into combustion chamber of cylinder was treated. We will now take up methods of heating the air. Also for "choking" the air entrance, to supply **a priming mixture for starting.**



Hot Air Device.

Fig. 1—illustrates a modern principle of heating the air as it is drawn into the main air supply opening of carburetor. A hot air **drum,** also called a "stove," is fitted around the exhaust pipe. Not close but placed so that air can be drawn in where arrows indicate. A flexible tube then permits the air to flow to air opening of carburetor.

Fig. 1.—Showing how warm air is drawn into carburetor. Also how "choker" or air valve cuts off the air supply causing gasoline to be drawn into cylinder.

A valve is provided, called the "air valve," also called a "damper" or "choker," which can be opened or closed by the "air regulator" lever, usually placed on the steering column or dash. This lever operates a butterfly type of valve in the air opening of carburetor.

Choking Air Supply to Start Engine.

When starting engine, this air valve is closed which cuts off the air supply to carburetor and causes an increased suction of gasoline to enter cylinder (or an extremely rich mixture). This gives the initial priming for starting. Immediately engine is started, the air valve is slightly opened to admit air. As engine becomes warmed up the air valve is opened more and more until full open, or where engine runs without missing or jerking which is common during cold weather. It is well known that engines will miss when first starting, due to the gasoline particles being unevaporated, due to lack of heat, but after engine is warm the gasoline becomes vaporized and the engine runs without missing. *The idea is to run on as much air as possible at all times, therefore open the air valve to the point where missing will not occur.

With this principle warm air will be drawn into carburetor at all times the air valve is open, but after engine is thoroughly warm and especially in summer, cool air can be drawn in—at opening "cold air." This can be closed entirely in the winter or regulated by hand according to the weather.

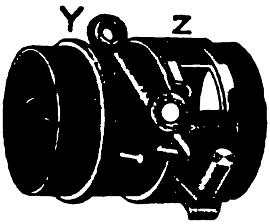


Fig. 2. — A temperature regulator or "air valve" used on the Zenith carburetor.

Temperature Regulator.

Fig. 2.—**Temperature regulator** as used on the Zenith carburetor is shown in this illustration. It is placed on the air opening of carburetor. The air control lever or air regulator operates the "air lever" or "**choke**" valve (Y), admitting more or less warm air.

The temperature of this warm air entering carburetor can be regulated by a band (Z) placed around the opening. The opening **permits** cool air to be drawn in and the use of this opening is governed more or less by the temperature. In summer, the opening (Z) is **usually wide** open, but closed more or less during cold weather.

Another type of temperature regulator is shown in fig. 3—it is the type used on the Holley carburetor. The principle is similar except, this opening (Z) is controlled from the dash.

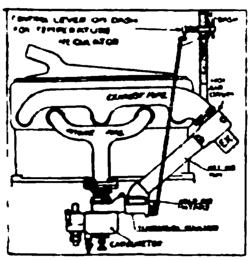

Fig. 3.—Temperature regulator used on the Holley carburetor.

Inlet and Exhaust Manifolds.

This subject is treated on pages 82 and 164, but a few words of explanation will be given here.

The inlet manifold is connected to the port openings of the inlet valves. On a four cylinder engine it is only necessary to have **two** openings to the manifold as there are two inlet ports together (see fig. G, page 64 and fig. 1 above). The carburetor is then connected to the flange as shown above with cap screws.

The exhaust manifold is connected in the same manner. Usually screw studs project from the cylinder and a clamp holds both the inlet and exhaust manifold in place.

For an engine to run slow and pull hard it is necessary that **packing** joint between carburetor and inlet manifold and inlet manifold and engine port openings be absolutely **tight,** to prevent air leaks. See pages 164 and 171.

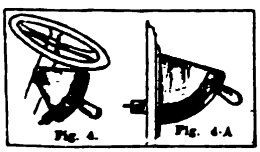

Fig. 4A. — Dash type air control.

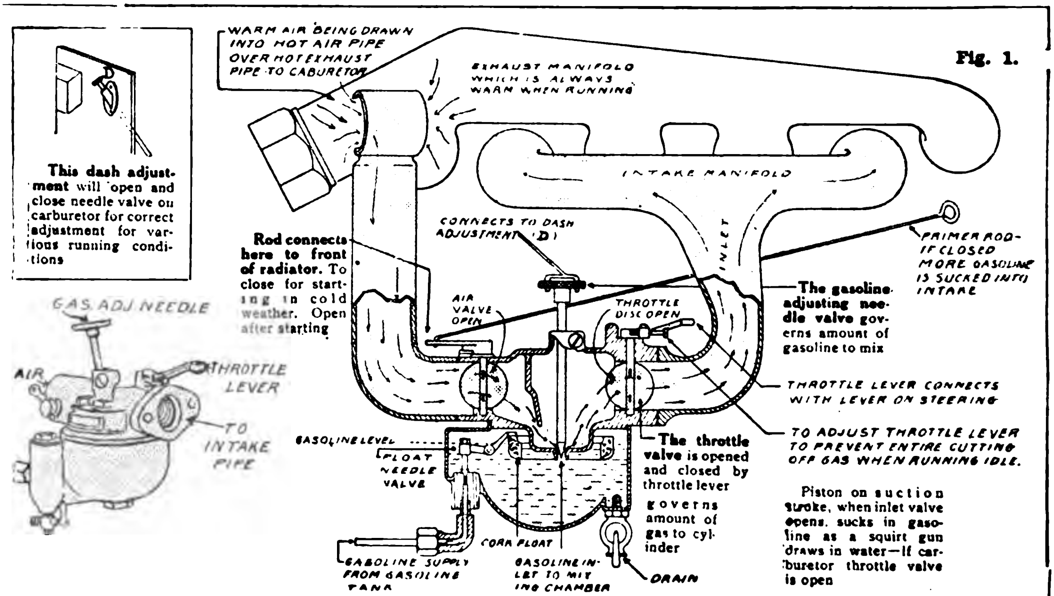
Fig. 4. — Steering column air control.

CHART NO. 78-A—Methods of Heating the Air Entering Carburetor. Starting by "Choking" th Air Entrance.

*See page 735 for a device for admitting water or steam and air into mixture in intake manifold. See also, pag 855 descripti— — — Packard method for "heating the mixture."



Ford Carburetor.

The illustration above is that of the model "Y" Kingston carburetor used on the Ford.

Float Principle.

When gasoline and air is drawn into cylinders by suction of piston, the float automatically lowers, thereby opening the float needle valve permitting more gasoline to enter the float chamber. When engine is not running the float chamber fills up, causing the float to rise, thereby closing the float needle valve. This prevents more gasoline entering which would cause overflowing and dripping. If the float happens to become loose or lowered more than intended, it would not cause the needle to cut off the gasoline supply—hence dripping would result. (note dotted lines indicate the gasoline level.)

Priming Method.

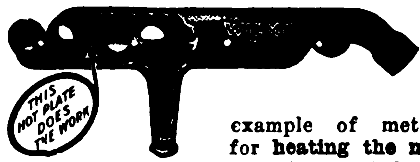
The damper or "choker" or "primer" method for priming or feeding the engine more gasoline for starting in cold weather, is operated by closing the damper or "air valve." This is used principally during cold weather. See Ford carburetor, pages 798, 802.

Heating the Air.

The air is taken in at the "air-valve" opening. A hot air pipe is shown connected which admits warm air to be drawn in from around exhaust pipe. This is a good example **of how the air is heated before being drawn** into cylinders. It will be noted that there is no auxiliary air valve on the carburetor.

Heating the Mixture.

This illustration (fig. 3) is that of the Wilmo exhaust heated intake manifold, designed for Fords and other cars. It is a good



example of method **for heating the mixture** just before it passes into cylinders.

The carburetor connects with the lower, or inlet part of the manifold—exhaust is upper part, with a plate between. By completely vaporizing the gasoline no residue is left to seep into crank case to thin the lubricating oil. The Whittier Co., 2415 So. Mich. Ave., Chicago, Ill., mnfgrs.—who claim an increase in mileage on a Ford.

A Ford Kerosene Burning Carburetor.

The principle of using kerosene is similar to that of using low gravity gasoline. It should be **heated** in order to obtain vapor which will mix with air. Kerosene, being of lower gravity (thicker) than gasoline, it must be heated more. However the gasoline we are now being supplied with requires heat also and this principle will explain a very good type of **exhaust heated intake manifold,** which would also be satisfactory for present day low gravity gasoline.

The hot-pin manifold, this particular one is termed, because the pins as shown, which are inside of the inlet manifold, turn the wet gasoline or kerosene into a vapor as it strikes the hot pins.

Fig. 2—A kerosene carburetor for the Ford.

The inlet manifold is cast directly into the exhaust manifold, but of course, the exhaust gases do not pass into the intake manifold, but around it which soon warms the intake manifold.

To use **kerosene** it is first necessary to use gasoline to start on. Therefore with this system there are two carburetor bowls. One on the left is for gasoline, and one on the right for kerosene. The engine is started on gasoline, from a small auxiliary gasoline tank with which it is connected. After starting on gasoline and running for a few blocks, in order to give manifold time to heat, the gasoline is cut off and the kerosene side of carburetor is turned on. An operation controlled by a special designed throttle lever. Manufacturers are Kerosene Burning Carburetor Co., 2015 Michigan Ave., Chicago, Ill.

CHART NO. 79—Principle of Carburetor Action and Hot Air System for the Ford. Wilmo Exhaust Heated Manifold. A Ford Kerosene Carburetor—see also pages 827, 754.

—continued from page 158.

A test by hand: To ascertain how near kerosene you are getting, pour a little gasoline in the hand. When it evaporates slowly and leaves a greasy deposit, it is a very low grade. When it evaporates rapidly and leaves the hand dry and clean, it is a higher grade. This furnishes a fairly reliable test.

Testing gasoline with a hydrometer was the method used a few years ago. It was used as follows: Fill the glass tube with the gasoline, insert the hydrometer, which will float. The gravity of the gasoline is determined by the depth the hydrometer sinks in it. A scale is graduated on the upper portion of the hydrometer and the level of gasoline indicates the specific gravity. The scale usually runs from 60 to 80. Gasoline under 60 test ought not be used. It averages about 64 to 68 and the better grade 72.

Gravity is no longer an accurate test of the merits of the fluid, the only really accurate test being from a maximum and minimum boiling point. It is, of course, not practical for the average owner to make such tests and the best rule is to purchase from a reliable distributor, who handles goods manufactured by responsible distillers.

Most of the gasoline today sold for motor car use differs from that of several years ago in that it is not all of one grade, but is a compound or blend of the different petroleum elements; some of it being very light and volatile, while about one-fourth of it may have a boiling point higher than that of water, and is correspondingly difficult to convert into a vapor.

To use this fuel it is necessary that the whole carburetor and intake manifold system be thoroughly heated. Without this heat the carburetor setting will have to be changed and made richer than necessary, while the extra heavy part of the fuel, not vaporized, will burn slowly in the cylinder, forming carbon, sooting up spark plugs, etc.

There is, of course, a period of time just after starting the engine cold, when the rich mixture will be necessary (and can be furnished by the dash control), but the control should be released as soon as the engine becomes warm.

It is also advisable, while the engine is cold, to avoid opening the throttle full, as the fuel vaporizes much more readily in the suction or partial vacuum which exists in the manifold while the throttle is partly or completely closed.

In very cold weather it is advisable, instead of readjusting the carburetor or using the dash control continuously, to cover part of the radiator surface so that the normal temperature is maintained under the hood.

In some parts of the country there is so great a range in the constituents of the gasoline sold that the lighter or more volatile fractions may, in warm weather, boil in the carburetor, under normal operation of the car. In this case, the hot air supply to the carburetor may be disconnected, while care should be taken that the gasoline supply line from the tank to the carburetor does not approach the exhaust pipe, cylinder walls or other heating influence.

If the gasoline should catch fire, do not try to put it out with water, for as the gasoline will float on water, it will only spread the flames. Damp sand, flour or a wet blanket will smother the fire.

*Low Gravity vs. High Gravity Gasoline.

The proper gravity of gasoline to use is governed by conditions. In the summer a low gravity vaporizes much easier than in the winter; therefore the engine starts easier.

A great many claim the low gravity gives as good or better results than high grade—probably it does, as there are more †heat units per gallon, **but as a matter of easy starting and absence from carbon deposit, the high gravity is preferable,** unless the carburetor has been properly adjusted and priming and heating methods provided. (see page 155.)

With the high gravity we have a high "flame" rate (mixture burns rapidly), whereas, with the **low gravity** we get a higher combustion heat, but **slower** "flame" rate. With a high flame rate **the mixture** burns rapidly—pressure rises quickly and imparts a powerful push at commencement of stroke, but falls away equally quick as the stroke progresses.

With low gravity gasoline, the reverse occurs. The explosion generates slowly and does not impart a violent shock, but with a retarded flame rate, the pressure predomniates through a much greater proportion of the stroke. The results are obvious, with high speed, as racing, the high gravity is best. For medium speeds, where steam-engine like power is required, combined with fuel economy, low gravity is best—providing the carburetor has been readjusted for the low gravity fuel and proper heating arrangements provided.

Owing to the great amount of carbon in low gravity gasoline it is very necessary that the carburetor be properly adjusted.

The starting will be more difficult with low gravity, but with the use of a primer and hot air arrangement, this trouble can be overcome.

It is a well known fact that an engine, especially an old one with loose bearings and slack pistons, will run much more quietly on low gravity gasoline. The reason is due to the slow flame rate; the pressure is gradual on the piston head and presses rather than slams.

Fuel Troubles.

Water in gasoline: Is indicated generally when the engine runs irregularly and finally stops. This will often prevent starting of the engine. Water is frequently present in gasoline, and particularly when the tank is low, is liable to get into the pipes and carburetor. The drain cock at the bottom should be opened occasionally to let off the water.

In cold weather, this water is liable to **freeze,** preventing the action of the carburetor parts. Ice in the carburetor can be **melted** only by the application of hot water, (or some other non-flaming heat), to the outside of the float chamber.

Gasoline ought to be strained: Many carburetor troubles would be avoided if more care were taken to free gasoline of all dirt before its entrance into the tank. When filling the tank use a strainer funnel; chamois skin makes an excellent filter; if a wire gauze be used it should have a very fine mesh. In the absence of a strainer, funnel or chamois use three or four layers of fine linen fitted inside an ordinary funnel. Never use the same funnel for both gasoline and water. (See chart 80.)

Old gasoline: Left in carburetor for some time, when car is not in use, will lose its strength. If the engine should not start easy, then drain the float chamber.

A strainer should be on all gasoline tanks or lines as water and sediments being heavier, always settle at the bottom.

Addresses of carburetor manufacturers classified under the type carburetor they manufacture is given on page 162. For detail information catalogs are of value.

*It is important that the low gravity gasoline be heated, otherwise condensation takes place in cylinders, see page 205. †See pages 861, 909, meaning of B. T. U.

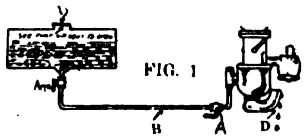
Gasoline Troubles.

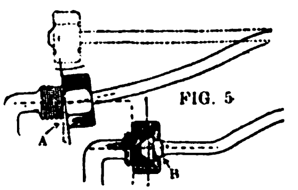
The tank of a fuel system is always provided with a small hole, usually drilled through the filling cap, as per V, fig. 1, by which air may enter to replace the gasoline as it is drawn off.

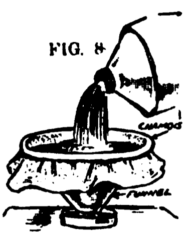
If this hole becomes clogged with dirt the gasoline in flowing out will tend to create a vacuum, and the flow will stop.

The outlet pipe should project slightly above the bottom of the tank, so that water and dirt may settle, and not be carried to the carburetor—a filter screen should also be provided.

If gasoline drips from feed line, examine connections A and if **it drips from carburetor** it is likely due to float needle valve not seating properly, see page 166, 167. Gasoline leaks are sometimes difficult to locate.







If gasoline fails to flow to carburetor, see that V, fig. 1, is open. If this is open, then examine filter screen at bottom of tank. If this is open, then remove pipe B and blow it out. If this is open then take carburetor apart and see if clogged up with waste, or sediment.

Gasoline feed pipe connections should use special unions as shown in fig. 5 and page 608. The threads are very fine and can easily be crossed. Therefore use precaution to not "cross-thread" when joining a gasoline pipe coupling as at (A). In B the threading is straight and correct.

Gasoline rots rubber rapidly and should not be conveyed through a rubber hose, nor should joints be packed with rubber. Shellac or soap may be used when screwing joints together, as it helps to make them tight.

Draining. The lowest point of the gasoline line on a vacuum feed system is the bottom of gasoline tank. On a gravity feed system it is at the carburetor. Strainer made of brass wire gauge is usually at the lowest point and should occasionally be removed and cleaned.

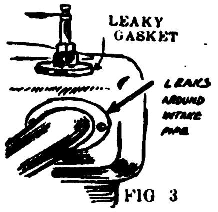
To prevent water getting into the gasoline and freezing during cold weather, thereby clogging flow, strain through a chamois.

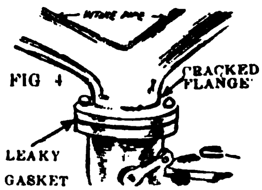
It is said that static electricity will be generated when straining through a funnel and chamois and a spark is liable to ignite the gasoline. If funnel is grounded to tank this cannot occur.

Broken gasoline pipe can be temporarily repaired by wrapping with tape.

Air leaks cause missing: If engine persists in missing and is not the fault of ignition, then look **for air leaks** in the inlet manifold (per figs. 3 & 4 and page 717) examine gaskets and see if a crack is in the intake casting—providing the trouble is not in the ignition.

Leaks in the intake pipe gasket is a very common cause for missing at low speeds, and is best detectel by letting the engine run at the missing speed. Take a squirt can full of gasoline and squirt around all the intake pipe joints. If you detect any difference whatsoever in the running of the engine there is a leak.





Cracked flanges (per fig. 4) can be repaired by having welded by oxy-acetylene process. See page 164 and 717, for kind of gasket to use.

Gasoline Tank and Gauge.

Fig. 27. Shows the gasoline tank used on the Studebaker-six. Note the connection to vacuum tank, also the **gasoline gauge** mechanism. As the tank is filled the float rises which causes bevel gear on float-rod to turn rod connected with gauge needle. See also, page 514 and 828 for other type of gauges.

CHART NO. 80—Gasoline Feed Troubles. Gasoline Tank and Gauge.

Gasoline Feed Methods.

There are five systems: (1) gravity; (2) pressure; (3) combined gravity and pressure; (4) gravity and pumping; (5) gravity and vacuum. (see page 164.)

The Stewart Vacuum and Gravity System.

Is explained on page 165. A few pointers as to the installation and care will be given here.

Installation.

The top of vacuum tank must be above level of gasoline in main gasoline tank when full, even when car is going down steep grade.

The bottom of vacuum tank must be not less than 8 inches above carburetor, 5/16" copper pipe is used.

Do not install directly over generator or wiring terminals, on which gasoline could leak.

Never tap through a water jacket if intake manifold is provided with one. Always tap intake manifold at point as close to the **intake of** one of the cylinders as possible. Be careful in bending tubing. **The air vent must be placed at as high a point as possible under the hood. Best** location for tank is on engine side of dash.

On 8 or 12 cylinder, "V" **type engines with** two inlet manifolds, a "Y" connection is **made** at (D) on top of tank and both manifolds **tapped.**

Care and Repair of Stewart System—page 165.

Vent Tube Overflow.

The air vent allows an atmospheric condition to be maintained in the lower chamber, and also serves to prevent an overflow of gasoline in descending steep grades. If once in a long while a small amount of gasoline escapes no harm will be done, and no adjustment is needed.

However, if the vent tube regularly overflows, one of the following conditions may be cause:

(a) Air hole in main gasoline tank filler cap may be too small or may be stopped up. If the hole is too small or if there is no hole at all, the system will not work. Enlarge hole to 1/8 inch diameter, or clean it out.

(b) Vacuum tank may not be installed quite high enough above carburetor. If bottom of tank is not 8 inches above carburetor, raise the tank.

Gasoline Leakage.

If gasoline leaks from system, except from vent tube, it can only do so from one of the following causes:

(a) A leak in outer wall of tank may exist. If so, soldering up the hole will eliminate trouble.

(b) Carburetor connection in bottom of tank may be loose. If so, it should be tight.

(c) There may be leak in tubing length D or C.

Failure to Feed Gasoline to Carburetor.

This condition may be due to other causes than the vacuum system. To test; after flooding the carburetor, or "tickling the carburetor," as it is commonly called, if gasoline runs out of the carburetor float chamber, you may be sure that the vacuum feed is performing its work of feeding the gasoline to carburetor.

Another test is to take out the inner vacuum tank, leaving only the outer shell. If you fill this shell with gasoline and engine still refuses to run properly, then the fault clearly lies elsewhere and not with the vacuum system.

If the trouble of failure to feed is in the vacuum tank, one of the following may be the cause:

(a) The float (G), which should be air-tight, may have developed a leak; thus filling up float with gasoline and making it too heavy to rise sufficiently to close vacuum valve. This allows gasoline to be drawn into manifold, which in turn will choke down the engine.

(b) Flapper valve may be out of commission.

(c) Manifold connections may be loose—allowing air to be drawn into manifold.

(d) Gasoline strainer or tubing clogged up (below K, fig. 2, page 165). Look to this first.

Remedies for Above Troubles.

(a) To repair float; remove top of tank (to which float is attached). Dip the float into a pan of hot water, in order to find out definitely where the leak is. Bubbles will be seen at point where leak occurs. Mark this spot.

Next, punch two small holes, one in the top and the other in the bottom of the float, to permit discharge of the gasoline. Then solder up these holes and the leak. Test the float by dipping in hot water. If no bubbles are seen, the float is air-tight.

In soldering float, be careful not to use more solder than required. Any unnecessary amount of solder will make the float too heavy.

To overcome the condition of a leaky float temporarily until you can reach a garage, remove plug (W) at the top. In some cases the suction of the engine is sufficient to draw gasoline into tank even with this plug open, but not enough to continue to be drawn into manifold. If, however, you are not able to do this, close up plug (W) with engine running. This will fill tank. **After** running engine until tank is full remove plug (W) until gasoline gives out. Continue repeating same operations until a repair station or garage is reached, when the leaky float can be remedied.

(b) **A small particle of dirt getting under the flapper valve (H), might prevent it from seating air-tight, and thereby render tank inoperative.**

In order to determine whether or not the flapper valve is out of commission, first plug up air vent; then detach tubing from bottom of tank to carburetor. Start engine and apply finger to this opening. If suction is felt continuously then it is evident that there is a leak in the connection between the tank and the main gasoline supply, or else the flapper valve is being held off its seat and is letting air into the tank, instead of drawing gasoline.

In many cases this troublesome condition of the flapper valve can be remedied by merely tapping the side of the tank, thus shaking loose the particle of dirt or lint which has clogged the valve. If this does not prove effective, remove tank cover, as described below. Then lift out the inner tank. The flapper valve will be found screwed into the bottom of this inner tank.

To Fill Tank.

To fill the tank, should it ever become entirely empty; with the engine **throttle closed and the** spark off, turn the engine over a few revolutions. This takes less than ten seconds, and will create sufficient vacuum in the tank to fill it.

If the tank has been allowed to stand empty for a considerable time and it does not easily fill when the engine is turned over, this may be caused by dirt or sediment being under the flapper valve (H).

Or, perhaps, the valves are dry. Removing the plug (W) in the top and squirting a little gasoline into the tank will wash the dirt from this valve, and also wet the valves, and cause the tank to work immediately. This flapper valve sometimes gets a black carbon pitting on it, which may tend to hold it from being sucked tight on its seat. In this case the valve should be scraped with a knife.

To Clean Tank.

Remove the top of tank and take out inner shell or vacuum chamber. This will give access to lower chamber from which dust or dirt may be removed. Clean tank every three months.

To Remove Top.

After taking out screws, run the blade of a knife carefully around top, between cover and body of tank, so as to separate gasket without damaging it. Gasket is shellaced.

Auxiliary vacuum pump; on some cars (Hudson), a small hand vacuum pump is provided on dash, which if vacuum tank should become empty, it would not be necessary to turn engine over, but merely operate pump connected by check valve to pipe C, page 165, which will create sufficient vacuum to draw gasoline from main tank.

Engine primer; see foot note, page 165.

Additional pointers: suction valve (A) and atmospheric valve (B), fig. 2, page 165, can easily be ground if necessary. The spring (E) may be weak. There is a fibre washer at bottom of stem on float—this sometimes swells and causes trouble—always look for air leaks first—if tank will not fill.

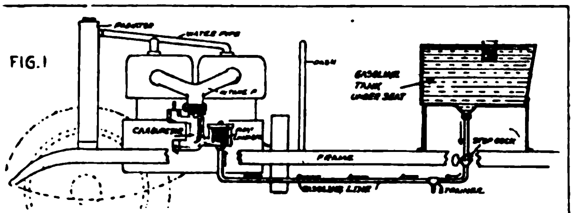

FIG. 1

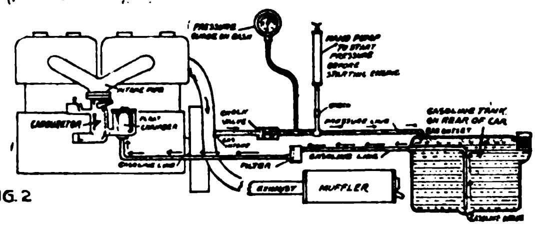

FIG. 2

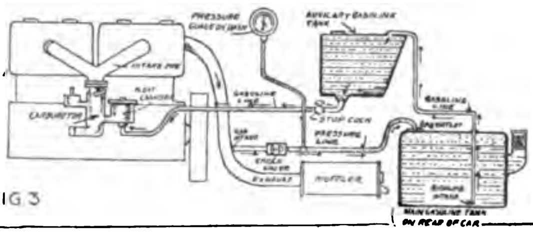

FIG. 3

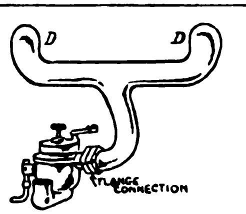

Fig. 4 —Carburetor Attached Horizontally

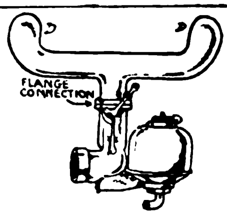

Fig. 5 —A Carburetor Attached to the Intake Manifold Vertically

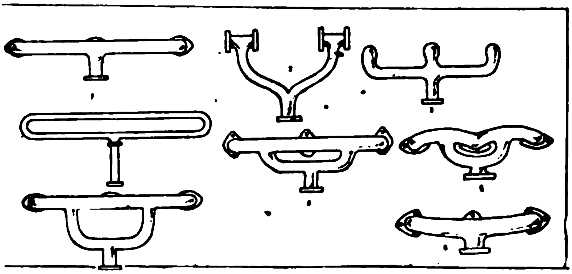


Some of the methods which have been employed for x cylinder engine inlet manifolds. A modern construction is shown in lower illustration, page 82.

Gasoline Feed Systems.

Fig. 1.—Gravity feed tank is placed above the level of carburetor so that the gasoline flows from tank to carburetor by gravity. The tank can be placed at any point on the car, just so it is above the level of carburetor.

The disadvantage on large cars where tank is not close to carburetor; when ascending hills, or on the side of an incline the gasoline may fail to flow through pipe.

Fig. 2. Pressure Feed—With this system the tank is placed in the rear and is air tight. A hand air pump is connected to obtain the initial pressure in tank. After engine is started the exhaust gases pass through check valve to tank, creating a pressure, which forces the gasoline to carburetor.

A small pipe is used for the exhaust passage. The pipe being exposed to the air, the gases are cooled and prevent a flame. The check valve prevents the gas passing back, as it can pass but in one direction.

Disadvantage—The pressure is liable to interfere with the proper operation of the float.*

Fig. 3. Combined gravity and pressure feed— gasoline is forced by exhaust pressure from tank to an auxiliary tank, placed above the level of the carburetor—the gasoline then flows to carburetor by gravity.

The auxiliary tank is small and is placed close to carburetor, so the gasoline will always feed.

The modern gasoline feed system is explained in chart No. 81A.

Carburetor Gaskets.

When fitting a carburetor, a gasket must be placed between the carburetor flange and the flange on intake pipe.

The best form of gasket is copper, interlined with asbestos. Multibestos or similar material can also be used and coated on each side with shellac. Leather could also be used here but would not answer elsewhere, because it would get too hot. If material is used which has a rough edge, it is important to watch that none of it gets into the carburetor pipe.

At the point (D) where inlet manifold covers the inlet ports, a copper gasket must be used and drawn tight to prevent air leakage. Be sure there are no air leaks where carburetor joins the intake pipe, and where the intake pipe connects to the engine.

The air inlet of the carburetor, if exposed to dust and dirt, should be placed so that dust may not be drawn in.

The inlet manifold, connecting the carburetor to the inlet valve port chamber, should present no resistance to the flow of the mixture. Sharp bends or turns will make it harder for the mixture to pass.

When fitting a carburetor be sure there is no vibration, if there is, the result will probably be a broken flange as shown in chart 80. If there is vibration, place a small iron hanger from a nut on engine frame to carburetor, to steady it and also to take strain off intake pipe.

Inlet Manifolds.

Engine manufacturers endeavor to make a manifold which will have the least number of **curves,** and as straight and as short a path for the gas to travel through as possible.

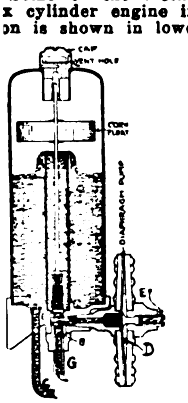
The ideal inlet manifold is easily specified. It is one in which no unnecessary resistance is offered to the flow of the mixture.

An inlet manifold for a six cylinder engine which will deliver an equal mixture to each cylinder has been a problem with manufacturers. If the distance is too great the gas tends to condense.

The inlet manifold in use today, is smaller in diameter than formerly, owing to the poor grade of gasoline. The fuel is harder to "break up" and will not vaporize readily—therefore it condenses and clings to the inner walls of manifold. By having smaller intake manifolds, the mixture is sucked through at a greater speed, which in a way prevents this condensation.

With too large an intake, using present low grade fuel, after a hard pull, the engine tends to "choke" and miss until it runs a short distance on a closed throttle.

Water jacketed manifolds are now the approved method. See (lower illustration), page 82. On many engines the intake manifold is cast right into the cylinder. (see also page 157.)



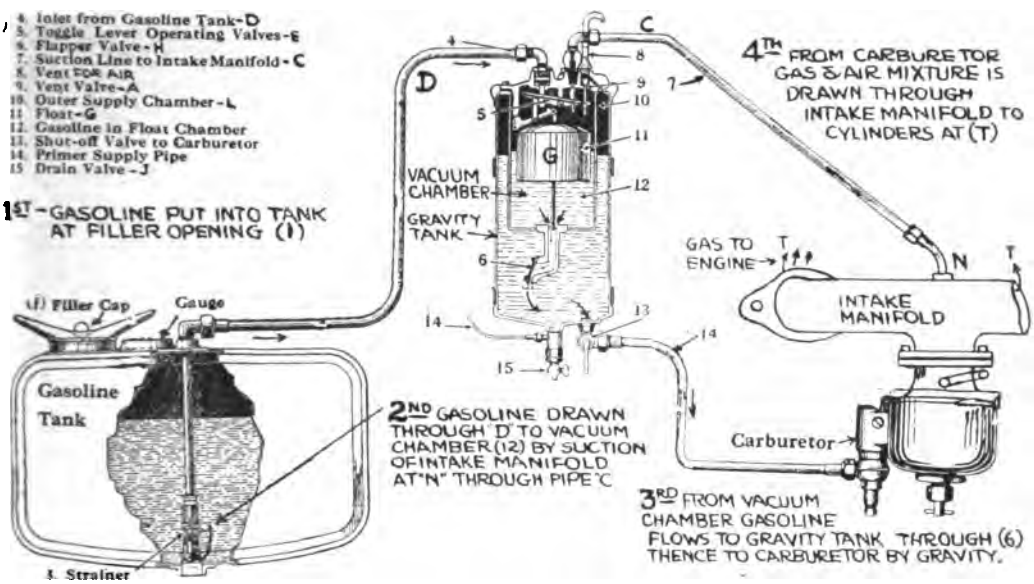
Carter Gasoline Pumping System.

Instead of drawing gasoline to the tank by a vacuum, the diaphragm pump (D) **pumps the gasoline.** E—connects with combustion chamber of cylinder by small copper pipe.

Compression causes diaphragm (D) to work in and the spring forces it back, causing a pumping action.

CHART NO. 81—Gasoline Feed Systems—simplified. Attaching the Carburetor. Inlet Manifolds.

index for "Air Pressure Gasoline Feed System." *When air pressure is used, if carburetor has a small float pressure should not be over 2½ or 3 lbs. With a larger float, the greater area will withstand more variation in pressure.



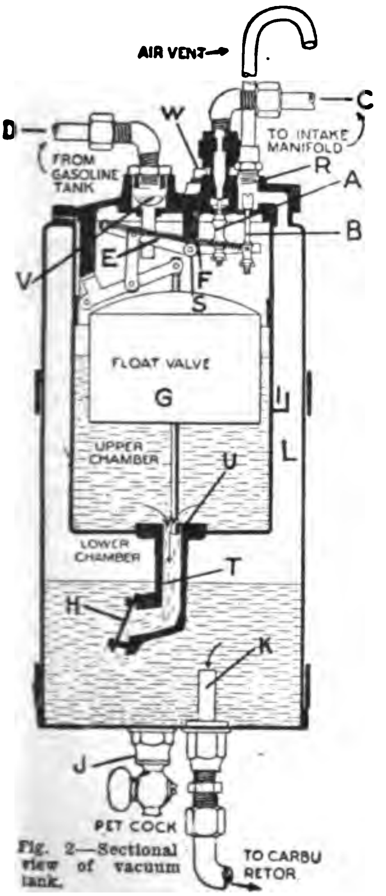


Fig. 2—Sectional view of vacuum tank.

The Stewart Vacuum Gasoline System.

Referring to upper illustration it will be noted that gasoline is fed by gravity to carburetor in the usual manner, by a gravity tank, which is combined with a vacuum system of drawing the gasoline from the main gasoline tank. In other words the same gravity principle of feeding gasoline to the carburetor is utilized but the auxiliary or gravity tank and the vacuum suction system is placed on the inside of the dash (usually) above and near the carburetor, so that the gasoline will feed to the carburetor at all times regardless of the angle or position of car.

The difference in this system is that of drawing the gasoline to this tank, as the main gasoline tank is below the level of the gravity tank. Instead of air being applied to the gasoline in the main tank to force the gasoline to the gravity tank, **it is sucked by a vacuum process through pipe (D)** to the vacuum chamber (12), thence it flows through trap or flapper valve (6) to the gravity tank, thence to carburetor.*

This vacuum is created by suction at intake manifold through pipe C, connected at N.* We know that a great suction takes place in the intake manifold when pistons are working. Therefore this suction is utilized to create the vacuum as will be explained below.

Principle of Operation.

There are two chambers; the upper or vacuum chamber and the lower chamber or gravity feed tank.

When there is no gasoline in either chamber, the float and levers E and F, to which float is connected, **closes** the valve B which admits air into the vacuum chamber and at the same time **opens** the valve A connected with the suction pipe C which is connected with the intake manifold.

If engine is working, (by crank or power), a vacuum is then created in the upper chamber which closes the flapper H (by suction), thereby making upper chamber absolutely air tight, which creates a vacuum and causes the gasoline to be drawn from main gasoline tank to vacuum or upper chamber.

As the gasoline enters upper or vacuum chamber the float rises, and through lever E and F, connected to float, the valve A to intake manifold **is closed,** thereby cutting off further suction and at the same time valve B is **opened,** which permits air to enter the vacuum chamber, through air vent tube.

Air entering vacuum chamber causes flapper H to open which action permits the gasoline in vacuum tank to flow into the lower chamber or gravity tank, thereby causing the float to lower as the gasoline flows out.

As the float lowers, the operation of levers E and F is again brought into action, and valve A is **again opened** and B **closed,** which again causes H to close, and the vacuum and suction takes place again, as explained above. **It will be noted that the lower chamber is always open to air circulation** through the "air vent tube," otherwise the gasoline would not flow by gravity to carburetor.

***Note—although connection of pipe (C) is shown in center of manifold at (N), the usual plan is to connect it near end of manifold,** as the vacuum is greater at a point closer to one of the cylinders.

Primer (14) above, is a connection used by some of the car manufacturers for connecting with hand pump on dash, similar to fig. 10, page 156, for priming engine to start during cold weather.

CHART NO. 81-A—The Stewart Vacuum Tank and Gravity Feed to Carburetor. Manufacturers are Stewart-Warner Speedometer Corp., Chicago, Ill.

INSTRUCTION No. 13.

*CARBURETOR ADJUSTMENTS: Parts to Adjust. Carburetor Troubles. Adjustments of Leading Carburetors.

The principle of carburetion is treated in instruction No. 12, and it will be advisable to start at the beginning of the subject and master the fundamental principles before taking up the subject of adjustments in this instruction.

Kerosene carburetors for marine and stationary engines, are described elsewhere in this instruction (see index). And motorcycle carburetors are described in **Dyke's Motor Manual.** Ford carburetors are described under Ford instruction.

A Few Words on Adjustments.

First and most important thing to learn about any carburetor is to let it alone as long as it is working properly. Never tamper with the carburetor until you are quite sure that it is at fault.

Test engine for compression, see that there is a good **hot spark** occurring in each cylinder at the right time, and **gasoline in the tank.** The carburetor should be the **last** thing to touch.

If the engine refuses to start, first flood the carburetor by holding down the tickler above the float chambr; if gasoline does not appear, look for a leak or an obstruction in the pipe; a closed shut-off valve or a dirty strainer.

If the tickler shows gasoline in the float chamber look for trouble in the clogged spray nozzle.

If the carburetor floods or leaks gasoline when the car is standing, look for an obstruction under the float valve or a leak at one of the connections.

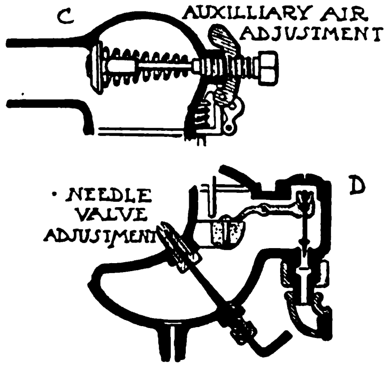
If the engine starts, but a "popping" noise occurs in the carburetor when the throttle is suddenly opened, it indicates a **lean** mixture. Open the needle valve slightly or put in a larger jet if there is no needle valve.

If the engine runs sluggishly with a black smoke at the exhaust, it indicates too rich a mixture. Close the needle valve slightly.

If the engine refuses to idle properly, or lacks "ginger" or "pep" at the higher speed, close the air adjustment slightly, and if not already too rich at low speed, the gasoline needle valve may also be opened slightly by turning to the left.

Parts to Adjust—Air Valve Type.

The three principal parts of a carburetor used for making adjustments are: the **auxiliary air valve,** the gasoline **needle valve** and the **float** mechanism.



Three principal parts of an air valve type carburetor for adjustments.

Some carburetors do not have auxiliary air valves, but depend upon the main air supply opening and a "gasoline needle valve" for adjustment. For instance; the Kingston Model "Y" on the Ford (page 160); the usual method of adjusting this carburetor is to start the engine, advancing the throttle lever to about the sixth notch with the spark retarded.

The flow of gasoline should now be cut off by screwing down the needle valve until the engine begins to miss-fire; then gradually increase the gasoline feed by opening the needle valve until the engine picks up and reaches its highest speed, and until no trace of black smoke comes from the exhaust. Having determined the point where the engine runs at its maximum speed, the needle valve is left adjusted at this point. There are other carburetors which do not have "auxilia y air valves" or "needle valves" to adjust. This and other types will be explained further on.

*Float Troubles and Adjustments.

When a carburetor drips this usually indicates the float or float valve mechanism is out of adjustment. This prevents the float needle valve from properly closing. For instance, the float may be loose, as shown in illustration, at the float screw, the gasoline then reaches a higher level than the spray nozzle or jet— result, overflowing at the spray nozzle.

—continued next page.

*See index for "Digest of Troubles;" for carburetor troubles, in addition to pages 170 and 171

Carburetor repair bench. A space should be set aside in every shop for testing and repairing carburetors.

A suggestion for a repair bench is to place a galvanized iron pan over one part of the work bench. Then place a 4" machinists vise opening 5¼" on the bench to hold the carburetor being tested. Place a pan under vise to catch gasoline drippings. Place a small tank with shut-off cock and tube about 6" above level of carburetor. The carburetor is held in vise while testing the float level and to see that it does not leak. The vise is also necessary for other repairs.

There are several causes for a dripping carburetor; either the float needle valve does not seat; due to sediment under it, or perhaps it is worn. If sediment is the cause, the needle valve can be turned a few times on its seat and probably clear the obstruction. On some carburetors, the float-needle-valve is in the form of a rod running through the float, as in fig. 1, page 148.

If the leak is not in the float-needle-valve, then it is likely due to the float being set so that it does not cut off in time to prevent overflowing at the jet. Or if a metal float; there may be a small hole in it preventing it from floating; another cause might be due to the mechanism being too loose.

Float adjustment: There is usually an adjustment provided directly above the gasoline float needle valve, which will regulate the height of the float. If not, then on some makes of carburetors, as the Schebler, for instance, the float arm can be bent up or down which will regulate the height of float, which in turn governs the float needle valve cut off.

If the leak is due to a faulty seating of the float needle valve, then it will be necessary to put in a new needle valve or to reseat the float valve seat or both.

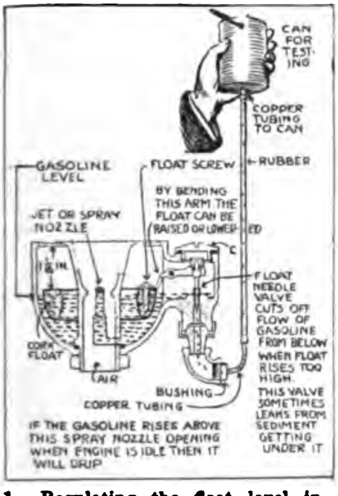


Fig. 1. Regulating the float level in a carburetor; gasoline must stand in the jet barely below level of jet or spray nozzle, when the float cuts off.

By slightly lowering the float the adjustment can be made to cut off early. Raising float will cut off later.

Testing the Float Height.

On most makes of carburetors, the float valve is intended to cut off the gasoline when the level of gasoline in the float chamber reaches a level of about 1/8 of an inch below the top of the nozzle or jet tube. Therefore this height or the height recommended by the manufacturer ought to be maintained.

A simple method to test a carburetor float mechanism is shown in the illustration.

In making this test, unscrew the part of carburetor which will permit access to the float and float-mechanism. Then prepare a device consisting of a can with a wire handle, a piece of copper tubing soldered to the bottom of the can to form an inlet, a piece of rubber tubing, and a nipple or short piece of metal tubing with a coupling adapted for attachment to the carburetor. The gasoline flows to the carburetor from the can, when it is held above the carburetor. By watching the float chamber fill with gasoline, the height the gasoline reaches at the time the float valve cuts off can be seen. If the height of gasoline in carburetor is not sufficient, then the float is slightly raised so it will cut off later, if the height is too great, which can be determined by gasoline flowing out of the jet, then the float must be slightly lowered, so it will cut off earlier.

Owing to the variation in the suction of different engines on a carburetor, it often is found that a slight variation of the fuel level or a slight change in the size of the spraying nozzle will add greatly to the efficiency of the engine. The first thing to do then before attempting the adjustment of a float is to learn whether or not the float needs adjustment, by seeing if the gasoline is at the proper height in the jet when the float cuts off the gasoline.

To locate a suspected leak in a float of the hollow metal type:

If the float is immersed in very hot water, the gasoline will be vaporized sufficiently to force its way out through a puncture and the spot may be located by watching the bubbles. The float should, of course, be removed from the water the instant bubbles cease appearing. The remedy is to solder the hole. (see page 163.)

Gasoline Level in the Jet.

Stromberg: Note level of gasoline in float chamber in the Zenith, fig. 2, page 168. This illustration will give the reader an idea as to the relation of the level of the gasoline in the float chamber to that in the jet. On the Stromberg (H) it should be about one inch from the lower edge of the glass. This can be adjusted by removing the dust cap and loosening the nut; if gasoline is too low, screw adjustment up; if gasoline is too high, screw adjustment down.

†The adjustment on the Stromberg "K" type can only be adjusted by "bending the arm," as previously explained, which governs the float level.

Rayfield: The float level is correctly set at the factory and does not require adjustment, but if it should, then the correct gasoline level should be maintained in the middle of the window in the side of the float chamber.

*It is advisable to not tamper with the float unless you know positively it is out of adjustment. This can be determined if continually leaking and test as above. Carburetors with floats as per type "H" Stromberg are provided with float adjustments.

†On models L & M Stromberg carburetors, page 176-177, the height of gasoline should be 1 inch below the top of the float chamber.

Cork floats are coated with varnish but after long periods of time this coating may come off and cork become gasoline soaked making it heavy thus causing float needle valve to not cut off properly. A mixture for coating is as follows: 1 lb. of glue, 1 teaspoon glycerine, 1 quart water, let this come to a boil and add formaldehyde for quick drying. When coated suspend by a string until dry.

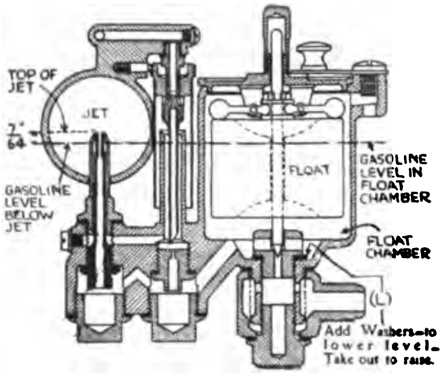

Fig. 2. This illustration shows the level of gasoline in the float chamber and in the jet of the Zenith carburetor. If the float level was above the jet, the gasoline would run out the jet.

Zenith: The level of gasoline is maintained in the float chamber so that the gasoline stands 3 millimeters below the top of the jet, or about 7/64". To regulate the level, note the washers (L), fig. 2.

Master: The float weights are set about 1/32 inch from bottom of the float lid.

Schebler: Model "L" (chart 84); the top of the cork should stand 1 1/16 inch from the top of the bowl in the 1-inch, 1¼-inch, 1½-inch and 1¾-inch. In the 2-inch—model L carburetors this measurement is 1⅛-inch and in the 2½-inch model L, 1⅝-inch. These measurements should be made when the float valve is seated.

Model R; the height of the cork float should be 23/32 inch from the top of the bowl when float valve is seated.

Models D & E; the cork float should be level and rest 1/16 inch above the top of the nozzle in the ½ inch, ¾ and 2 inch sizes, and 1/32 inch on the 1, 1¼, and 1½ inch sizes. Model H; is 19/32.

Note, when changing float level, great care must be taken to bend the arm in such a manner that the float will be at the proper height, yet perfectly level.

Auxiliary Spring Tension Adjustment.

In the air valve spring lies the chief difficulty in making carburetor adjustments, if carburetor is provided with automatic auxiliary air valve. This spring should be of such length and of such gauge wire, diameter and number of convolutions as to provide the requisite progressively increasing resistance to opening, while at the same time exerting little or no pressure upon the valve when it is against its seat.

Adjustment: The needle valve should be set for slowest running with the air valve held lightly against its seat, and then the spring adjustment should be backed off until the slightest further increase in throttle opening causes the valve to leave its seat.

From this point on the only proper adjustment for the air valve becomes a series of tests for spring strength without alterations being made in its normal length. That is, with the adjustment backed off as per the above instruction; if the spring tension with increased throttle openings is too light and "spitting back" in the carburetor continues in spite of increased opening of the gasoline needle valve adjustment; it is a pretty sure indication that the air valve spring is too weak and a stronger one should be obtained from the factory. These can usually be obtained in several sizes or degrees of tension to suit varying engine and climatic conditions.

Too strong a tension on the auxiliary air valve spring will cause **too much gasoline** and not enough air (too rich a mixture), because the valve will be more difficult to open by suction. **Too weak a spring tension** will give too much air or too lean a mixture.

The hand air adjustment operated from the seat is very popular. See pages 159, 155. The warmer the engine the more air needed and less gasoline. By merely opening the air intake more and more, by hand, the proper mixture can be obtained.

**A Few Words About the Mixture.

***At low speeds** the mixture should be richer than at high. At low speeds more heat is lost to the cylinder walls, more compression is lost by leakage, and the combustion can therefore be slower, thus sustaining the pressure. **At high speeds** the compression is higher, due to less leakage and less loss of heat. A lean and highly compressed charge burns faster and hence gives better pressures and fuel economy than a richer one.

The quantity of mixture an engine will take, varies greatly with the speed and pull. At slow speeds the volume, at carburetor pressure is equal to the cubic content of the cylinders, multiplied by the number of power strokes.

At high speeds of one thousand revolutions or over, the quantity may drop to less than one-half the amount, depending on the design of the valves, inlet piping and passages. This reacts upon the compression, and hence on the mixture desired for best results.

****The plug points or gaps should be carefully set;** about .025 of an inch apart. **If too close** engine will operate unevenly at idling speeds and miss at higher speeds; **If too wide,** will miss when accelerating at very low speeds or hard pulls. A weak spark causes late combustion. See index for "Spark Plugs."

****Atmospheric conditions have much to do with action of carburetor.** An engine seems to run better at night (see page 585)—likewise, taking an engine from sea level to an altitude of 10,000 feet, involves using air in the engine cylinders at atmospheric pressures ranging from 14.7 lbs. down to 10.1 lbs. to the square inch.

The design of the engine has a bearing on the carburetor design, which explains the well known but seemingly mysterious fact, that a carburetor giving good results on one engine sometimes fails to maintain its reputation when applied to one of different design. The system of ignition used also has a marked influence on the proper working of an engine as a hot spark is most essential.

To Test the Mixture.

If there are doubts in the mind of the operator as to whether the mixture is too rich, **an excellent way to ascertain the correct proportion of air and gasoline is to shut off the fuel at the tank and open the throttle.**

If the mixture passing into the cylinder is too rich, the engine speed will increase as the level of the gasoline in the float chamber is lowered, since this operation weakens the mixture considerably.

If the mixture is thought to be too weak, the float chamber can be flooded while the engine is running, and if this causes the engine to speed up, it may be taken as an indication that the mixture is not rich enough.

The proportionate amount of gasoline to the proportionate amount of air is essential.

The novice usually gives the carburetor too much gasoline by opening this adjustment valve too wide, thereby causing "too rich a mixture." Too much gasoline will not run the engine any better than not enough. It must be remembered that only a very little gasoline is required in proportion to the air.

‡Smoke Tests.

If the engine is fed too much gasoline, **black smoke**, smelling of raw gasoline, will usually be in evidence, issuing from the exhaust. Care should be taken to distinguish this from the excess of heavy **blue smoke** which is indicative of too much engine lubrication.

Whenever any considerable quantity of smoke of either color come from the exhaust, the engine may miss explosions due to fouled spark plugs.

***If the mixture is too rich, the engine will have a tendency to slow up and "choke" or "load up" when the throttle is opened wide, and will run at a higher speed when it is partially closed.**

Another indication of the mixture being too rich will be shown in its speeding up perceptibly, if the auxiliary air valve of the carburetor is held open, or additional air is admitted in any way between the carburetor and the cylinders.

Such being the case, the exhaust gases, if ignited by holding a piece of burning paper near the end of the exhaust pipe, will burn with a large red flame similar to that of a bunsen burner when the air is mostly cut off.

****Loping**: Another indication of too rich a mixture is when "**idling**;" the engine will run in a loping manner as if actuated by a governor; **more air**, less gasoline is needed.

Flame Test of Mixture.

Another method is to open the relief cocks in the cylinder heads (if provided), while the engine is running and judge from the color of the flame when the mixture is correct. At each explosion a jet of flame will shoot out of the cylinder through this relief cock.

If the mixture is too poor—too much air for the gasoline—the **flame will be light yellow.**

If the mixture is too rich—not enough air for the gasoline—the **flame will be red and smoky.** Black smoke will also come out of the muffler, smelling of raw gasoline.

If the mixture is correct, the flame will be **light blue or purple**, and hardly visible. See also, page 855.

†Rich and Lean Mixture.

A rich mixture is one in which the proportion of gasoline abnormally exceeds the amount of air. It may be due to faulty adjustment of the gasoline needle valve, float, or air valve.

An overrich mixture will cause an engine to overheat and thereby give rise to a number of troubles such as; preignition, accumulations of carbon on the pistons and cylinder heads, steaming water in radiator and loss of power and "**loping**" **or choking up on slow speeds.**

A mixture is poor or lean when it contains too much air and not enough gasoline, a condition often due to a faulty adjustment of the needle or air valve float, a leak in the inlet pipe, the supply cock partly shut off, the spray nozzle, float valve or feed pipe partly clogged, or water in the gasoline.

A poor mixture will make the engine miss when running idle at slow speeds, and at high speeds it will not only cause misfiring, but the missing will be accompanied by coughing and "**popping**" in the carburetor. Both this and explosions in the muffler may also be due to faulty ignition.

Cause—mixture too rich: Too much gasoline at needle valve. Punctured float. Float valve not working properly, owing to bent needle, or presence of foreign matter in valve seat. Too much priming. Primary air passage clogged or partially obstructed. Air valve not open enough, spring too strong or air opening choked.

Cause—mixture too weak: Too much air, not enough gasoline. Carburetor passages or jet clogged. Throttle valve out of adjustment. Insufficient flow of gasoline. Tank valve closed. Break in gasoline supply. Bad gasoline; originally, or from standing. Water in gasoline. Carburetor too cold. Gasoline supply exhausted.

*Mixture "too rich" means too much gasoline in proportion to air, or technically, there is insufficient oxygen to support its combustion.

**See page 171. ‡See also pages 652, 653. †See page 623, "relation of carbon to combustion."

"**Loading up**" **when running slow or idling** is due to the fact that the air comes into the carburetor so slowly that the gasoline particles are not broken up fine enough and condensation takes place. Thus the gasoline is taken in, in a more or less liquid form and combustion is very poor. That is one reason why as much heat as possible should be applied to the air intake of the carburetor. Also do not let your engine tick over slowly for any length of time when the car is standing idle. It not only wastes fuel but the manifold will load up with raw fuel and your acceleration will be anything but good when you attempt to get under way. See also page 652.

INSTRUCTION No. 13.

*CARBURETOR ADJUSTMENTS: Parts to Adjust. Carburetor Troubles. Adjustments of Leading Carburetors.

The principle of carburetion is treated in instruction No. 12, and it will be advisable to start at the beginning of the subject and master the fundamental principles before taking up the subject of adjustments in this instruction.

Kerosene carburetors for marine and stationary engines, are described elsewhere in this instruction (see index). And motorcycle carburetors are described in **Dyke's Motor Manual.** Ford carburetors are described under Ford instruction.

A Few Words on Adjustments.

First and most important thing to learn about any carburetor is to let it alone as long as it is working properly. Never tamper with the carburetor until you are quite sure that it is at fault.

Test engine for compression, see that there is a good **hot spark** occurring in each cylinder at the right time, and **gasoline** in the **tank.** The carburetor should be the **last** thing to touch.

If the engine refuses to start, first flood the carburetor by holding down the tickler above the float chambr; if gasoline does not appear, look for a leak or an obstruction in the pipe; a closed shut-off valve or a dirty strainer.

If the tickler shows gasoline in the float chamber look for trouble in the clogged spray nozzle.

If the carburetor floods or leaks gasoline when the car is standing, look for an obstruction under the float valve or a leak at one of the connections.

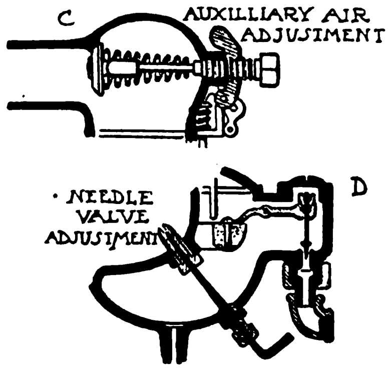
If the engine starts, but a "popping" noise occurs in the carburetor when the throttle is suddenly opened, it indicates a **lean** mixture. Open the needle valve slightly or put in a larger jet if there is no needle valve.

If the engine runs sluggishly with a black smoke at the exhaust, it indicates too rich a mixture. Close the needle valve slightly.

If the engine refuses to idle properly, or lacks "ginger" or "pep" at the higher speed, close the air adjustment slightly, and if not already too rich at low speed, the gasoline needle valve may also be opened slightly by turning to the left.

Parts to Adjust—Air Valve Type.

The three principal parts of a carburetor used for making adjustments are: the **auxiliary air valve,** the gasoline **needle valve** and the **float** mechanism.



Three principal parts of an air valve type carburetor for adjustments.

Some carburetors do not have auxiliary air valves, but depend upon the main air supply opening and a "gasoline needle valve" for adjustment. For instance; the Kingston Model "Y" on the Ford (page 160); the usual method of adjusting this carburetor is to start the engine, advancing the throttle lever to about the sixth notch with the spark retarded.

The flow of gasoline should now be cut off by screwing down the needle valve until the engine begins to miss-fire; then gradually increase the gasoline feed by opening the needle valve until the engine picks up and reaches its highest speed, and until no trace of black smoke comes from the exhaust. Having determined the point where the engine runs at its maximum speed, the needle valve is left adjusted at this point. There are other carburetors which do not have "auxilia y air valves" or "needle valves" to adjust. This and other types will be explained further on.

*Float Troubles and Adjustments.

When a carburetor drips this usually indicates the float or float valve mechanism is out of adjustment. This prevents the float needle valve from properly closing. For instance, the float may be loose, as shown in illustration, at the float screw, the gasoline then reaches a higher level than the spray nozzle or jet— result, overflowing at the spray nozzle.

—continued next page.

*See index for "Digest of Troubles;" for carburetor troubles, in addition to pages 170 and 171

Carburetor repair bench. A space should be set aside in every shop for testing and repairing carburetors.

A suggestion for a repair bench is to place a galvanized iron pan over one part of the work bench. Then place a 4" machinists vise opening 5¼" on the bench to hold the carburetor being tested. Place a pan under vise to catch gasoline drippings. Place a small tank with shut-off cock and tube about 6" above level of carburetor. The carburetor is held in vise while testing the float level and to see that it does not leak. The vise is also necessary for other repairs.

There are several causes for a dripping carburetor; either the float needle valve does not seat; due to sediment under it, or perhaps it is worn. If sediment is the cause, the needle valve can be turned a few times on its seat and probably clear the obstruction. On some carburetors, the float-needle-valve is in the form of a rod running through the float, as in fig. 1, page 148.

If the leak is not in the float-needle-valve, then it is likely due to the **float being set so that it does not cut off in time** to prevent overflowing at the jet. Or if a metal float; **there may be a small hole in it** preventing it from floating; another cause might be due to the **mechanism being too loose.**

Float adjustment: There is usually an adjustment provided directly above the gasoline float needle valve, which will regulate the height of the float. If not, then on some makes of carburetors, as the Schebler, for instance, the float arm can be bent up or down which will regulate the height of float, which in turn governs the float needle valve cut off.

If the leak is due to a faulty seating of the float needle valve, then it will be necessary to put in a new needle valve or to reseat the float valve seat or both.

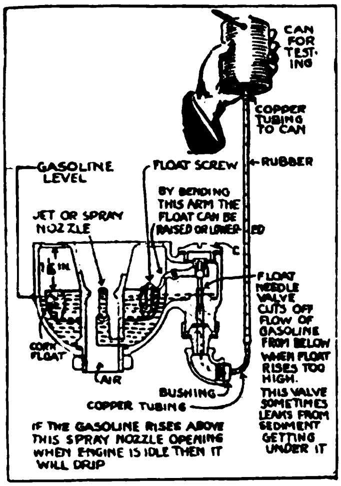


Fig. 1. Regulating the float level in a carburetor; gasoline must stand in the jet barely below level of jet or spray nozzle, when the float cuts off.

By slightly lowering the float the adjustment can be made to cut off early. Raising float will cut off later.

Testing the Float Height.

On most makes of carburetors, the **float valve is intended to cut off the gasoline** when the level of gasoline in the float chamber **reaches a level of about 1/8 of an inch below the top of the nozzle or jet tube.** Therefore this height or the height recommended by the manufacturer ought to be maintained.

A simple method to test a carburetor float mechanism is shown in the illustration.

In making this test, unscrew the part of carburetor which will permit access to the float and float-mechanism. Then prepare a device consisting of a can with a wire handle, a piece of copper tubing soldered to the bottom of the can to form an inlet, a piece of rubber tubing, and a nipple or short piece of metal tubing with a coupling adapted for attachment to the carburetor. The gasoline flows to the carburetor from the can, when it is held above the carburetor. By watching the float chamber fill with gasoline, the height the gasoline reaches at the time the float valve cuts off can be seen. **If the height of gasoline in carburetor is not sufficient,** then the float **is slightly raised** so it will cut off later, if the **height is too great,** which can be determined by gasoline flowing out of the jet, then the **float** must be **slightly lowered,** so it will cut off earlier.

Owing to the variation in the suction of different engines on a carburetor, it often is found that a slight variation of the fuel level or a slight change in the size of the spraying nozzle will add greatly to the efficiency of the engine. The first thing to do then before attempting the adjustment of a float is to learn whether or not the float needs adjustment, by seeing if the gasoline is at the proper height in the jet when the float cuts off the gasoline.

To locate a suspected leak in a float of the hollow metal type:

If the float is immersed in very hot water, the gasoline will be vaporized sufficiently to force its way out through a puncture and the spot may be located by watching the bubbles. The float should, of course, be removed from the water the instant bubbles cease appearing. The remedy is to solder the hole. (see page 163.)

Gasoline Level in the Jet.

Stromberg: Note level of gasoline in float chamber in the Zenith, fig. 2, page 168. This illustration will give the reader an idea as to the relation of the level of the gasoline in the float chamber to that in the jet. On the Stromberg (H) it should be about one inch from the lower edge of the glass. This can be adjusted by removing the dust cap and loosening the nut; if gasoline is too low, screw adjustment up; if gasoline is too high, screw adjustment down.

†The adjustment on the Stromberg "K" type can only be adjusted by "bending the arm," as previously explained, which governs the float level.

Rayfield: The float level is correctly set at the factory and does not require adjustment, but if it should, then the correct gasoline level should be maintained in the middle of the window in the side of the float chamber.

***It is advisable to not tamper with the float unless you know positively it is out of adjustment. This can be determined if continually leaking and test as above. Carburetors with floats as per type "H" Stromberg are provided with float adjustments.**

†On models L & M Stromberg carburetors, page 176-177, the height of gasoline should be 1 inch below the top of the float chamber.

Cork floats are coated with varnish but after long periods of time this coating may come off and cork become gasoline soaked making it heavy thus causing float needle valve to not cut off properly. A mixture for coating is as follows: 1 lb. of glue, 1 teaspoon glycerine, 1 quart water, let this come to a boil and add formaldehyde for quick drying. When coated suspend by a string until dry.

Use air: It is advisable to run the engine with as much air as possible, which means a "lean" mixture. This not only means economy of gasoline but prevents soot deposit and pitted valves (providing good lubricating oil is used).

Of course, when first starting or when cold, more gasoline is absolutely necessary, but as soon as the engine warms up, cut down on the gasoline and run on **more air.**

Most carburetors now-a-days, are fitted with air regulators and heated intake manifolds, as shown on pages 157 and 159, for this purpose.

An engine will run on less gasoline, and more air, the warmer it gets. Therefore the reason for the air adjustment.

"Back Firing" or "Popping" in the Carburetor.

Back firing: There seems to be much confusion in the use of the terms "back kick" and "back fire," the latter being very often used to describe what happens when, in starting an engine, it suddenly reverses its direction of rotation to give a "back kick."

Generally speaking, "back-firing" is caused by weak mixture which burns so slowly that the flame continues until the opening of the admission valve again, when it ignites the incoming charge in the intake pipe and shoots back to the carburetor. While an over-rich mixture will also burn slowly, it rarely ever will cause back-firing.

Another cause of back-firing is, of course, the faulty timing of the valves, or, in fact, a badly leaking valve. As a general rule, back firing is due to one or more of the following causes: (1) very slow explosion or weak mixture, (2) very late explosion; (3) a spark occurring during the intake stroke; (4) the intake valve partially open during the power stroke; (5) premature ignition.

Slow combustion is caused by a lean mixture, late combustion is caused by a weak or retarded spark.

Nos. 1 and 2 are the usual causes, while Nos. 3 and 4 happen infrequently.

Back-kicking is usually caused by preignition in starting the engine, which is due usually, as is well known, to too much "advance" in the spark timing.

"Popping back" or "spitting" in the carburetor is quite a common occurrence with carburetors when first starting the engine on a cold day. But after engine has been run for a brief period it will become warmed up and the gasoline will begin to vaporize properly and run without popping back.

If the "popping back" continues then the mixture is too weak and more gasoline is required. By giving the auxiliary air valve spring a slight increase of tension or opening the gasoline needle valve a notch or so, to close the "damper" or air intake, thereby causing more gasoline supply until the popping stops, which it will probably do when engine is warmed up.

Carburetion During Cool Weather.

Now that low gravity gasoline is being used, the engine will have a tendency to miss explosion and run in jerks or uneven explosions, especially when starting.

The reason is due principally, to the **lack of heat** to properly vaporize the gasoline to prevent condensation. After the engine becomes thoroughly warmed up, the missing usually disappears. When weather is warm the engine starts easier, because gasoline will vaporize more readily and is easier ignited. Therefore during cool weather **three things are essential;** a good **hot spark** and a **quick method of heating** and a **choker** or **primer** for enriching the mixture to start on.

****For starting**—There are different methods employed to inject a rich mixture into cylinder in order to start engine at all on a cold day. The common method is to close the main air intake, which causes raw gasoline to be drawn into cylinder, which would be termed "choking" the air supply. **After engine is started,** it is then a matter of running engine until warm enough to vaporize the gasoline, at the same time gradually opening the choke or air valve, until the regular amount of air is being used.

Warm air, of course should be drawn into the carburetor as per fig. 1, page 159. **If a** temperature regulator is also provided, as per fig. 2, page 159, then less cool air should be drawn in at (Z) in winter, than in summer.

There is a disadvantage however, in this system, and that is, the raw gasoline drawn into a cool cylinder is not all utilized for combustion, but part of it forms carbon, due to lack of oxygen which is not being supplied, as the air is choked, result, as per page 205. Therefore the air should be supplied as quick as possible. **The problem is then, to heat the gasoline as quickly as possible,** so that vapor and **air** is used **instead of raw gasoline.**

The exhaust heated intake manifold, explained on page 155 and 157, **will assist considerably.** With a jacket around the intake manifold, and hot exhaust gases passed through same, as per page 157, the mixture will become heated quicker.

The **choker** or some method of supplying a richer mixture however, is usually necessary for starting. If the "choker" principle is used, it is closed **only** until engine starts, then gradually opened. **In fact, by using an exhaust heated intake manifold to heat the mixture, and also drawing warm air through air passsage of carburetor** as per fig. 1, page 159, the amount of raw gasoline injected into the cylinders will be considerably less than if same is not heated. Therefore this system will provide a quicker vaporizing or heating of mixture and a saving of fuel and less carbon deposit in cylinders.

Additional Pointers on Cold Weather Starting.

Don't expect the engine to warm up in a minute any more than you expect a kettle to boil as soon as it is set on the stove. It takes time to heat.

Take into consideration the fact that cold solidifies the lubricant in the transmission, rear axle, and other parts of the car. Therefore, it requires greater energy on the part of the self-starter to revolve the engine.

If the clutch is in, you of course revolve most of the transmission gears. After a car has been standing over night in a cold garage or sufficiently long at the curb to become thoroughly chilled, throw out the clutch when cranking. This eliminates the drag of the transmission gears plowing through the solidified grease.

A good hot spark is important, especially in winter. Remember it is more difficult to charge a battery in winter than in the summer, so be particular to see that the battery is always charged. A quick method of starting should be provided in order to save current.

*See page 576 "Digest of Troubles," also foot note, page 153.

**See page 798 for starting Ford carburetor in cold weather. The method employed here is to open gasoline needle valve slightly in extreme cases and close damper also. See also page 160.

Carburetors are usually adjusted to the best advantage when the engine has been run and all parts are warmed up. If a carburetor is adjusted when the engine is cold, it will be noticed that it will need readjusting when warm, that is, in order to get a perfect adjustment.

When carburetors are adjusted when warm, sometimes, especially on a cold day, the engine will not hit just right when first starting; it will miss and not run even or smooth until it has run a few moments and is heated up, then it runs satisfactorily.

***Another point to remember, be sure the ignition is right and you have a good hot spark, and spark plug gaps set about .025 of an inch** (see index for "adjusting spark plug gaps"). Also be sure the trouble is in the carburetor and not due to other troubles. See "Digest of Troubles," how to diagnose troubles.

For the average carburetor, having an "auxiliary air valve" and a "needle valve" adjustment, the following rule for adjusting will apply.

First, run the engine at what will be nearly its maximum speed in ordinary use with the throttle open considerably and the spark rather late. This speed, of course, will be considerably less than the maximum speed of the engine when running idle.

Second: Then turn the main gasoline adjustment, until the mixture is so weak there is popping in the carburetor.

Third: Note this position and then turn the adjustment until so much gas is fed that the engine chokes and threatens to stop.

Fourth: Set the adjustment half way between these two points, which will be very near the correct position. Turn the adjustment slightly in one direction and then in the other until the point is found where the engine seems to run the fastest and smoothest.

Fifth: Gently and gradually cover the auxiliary air inlet of the carburetor by placing the hands over the valve, if necessary, in order to exclude the air. If the engine slows down, the spring should be weakened, since not enough air is allowed to enter the carburetor.

Sixth: Next try opening the air inlet slowly and gradually by pushing the poppet off its seat with the finger or the end of a pencil. If the engine speeds up, there was not enough air and the spring should be loosened, while if it slows down, the mixture is correct or a little too lean, according to the degree to which the speed is affected. If it is found to be too lean, the spring needs tightening.

Seventh: After the air inlet has been adjusted, open the throttle again and adjust at high speed, as this adjustment may now require to be altered.

When adjusting carburetors for speed, racing, etc., the mixture is cut down much more than for ordinary use. One method is to cut off the supply until the engine m'sses when idling at low speed. Then give it just a trifle more and test the adjustment by trying the car on a hill.

Some time ago the writer was told by an ex-tester that whenever he was beaten in a "brush" he was in the habit of stopping and adjusting his carburetor until the engine missed, and then give just a slight turn more on the gasoline needle valve. Then, in a good many cases, he was able to catch up with and pass his opponent.

The best way to adjust a carburetor is to arrange so that the engine may be run loaded while the adjustment is being made. One way to do this is to adjust the carburetor while the car is in motion on the road,
tor while the car is in motion on the road.

To test carburetor for adjustment; run throttled down for two blocks. When there is a clear space ahead, suddenly press accelerator pedal down. The engine should pick up smoothly, to as high speed as you care to run. If engine chokes, stalls, misses or labors, or backfires at carburetor, or muffler explosions, it shows the carburetor is out of adjustment.

To Obtain a Slow Even Pull of Engine Without Missing.

(1) **Retard the ignition.** If this does not overcome the missing and it is not due to other causes mentioned below, it may be due to the ignition being set too far advanced at retard position. Setting back a tooth will often help to run slow, if this is desirable.

(2) **Air leaks is a common cause.** Be sure there are no leaks at intake manifold and carburetor gaskets, valve caps and above all, use good ****spark plugs** (see page 235) and see that they do not leak at bushing and where screwed into cylinders. See that gaps are about .025. This is important. Wide gaps and weak magnets on magneto ignition will cause missing.

(3) **Interrupter points** must be set correctly. A clear flat surface is important.

(4) **Be sure there is a good hot spark from the battery,** which means a fully charged battery.

(5) **A coil has been known to have a short circuited internal connection** which would give a spark at high speeds but miss on low speeds.

(6) **The carburetor should be adjusted** which does not permit loping (too much gasoline). The hot exhaust heated manifold is an advantage here.

(7) **Engine should have good compression;** valves ground, and proper valve clearance, being sure valves are not held open too long. Rings free of leaks.

All this is esential to secure a flexible and smooth running engine.

Leading Carburetors,—Principle and Adjustment.

Are treated on pages following.

Owing to the fact that innumerable improvements are constantly being made in carburetor construction, it is impossible in this instruction to describe all the actual adjustments of all the carburetors

Repairmen are advised to secure instructions for adjustment of all the leading makes of carburetors from the manufacturers and keep them on file (see page 162 for list of the leading manufacturers).

†See "Digest of Troubles" for carburetor troubles and remedies, page 576.

*See page 543 for "Specifications of Leading Cars" to find the type of carburetor used on different makes of cars.

**See page 233 for testing spark plug leaks.

†When adjusting "V" type engines, adjust each block of cylinders separate, by disconnecting one block.

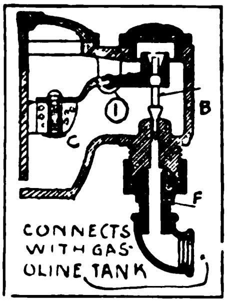

Fig. 1.

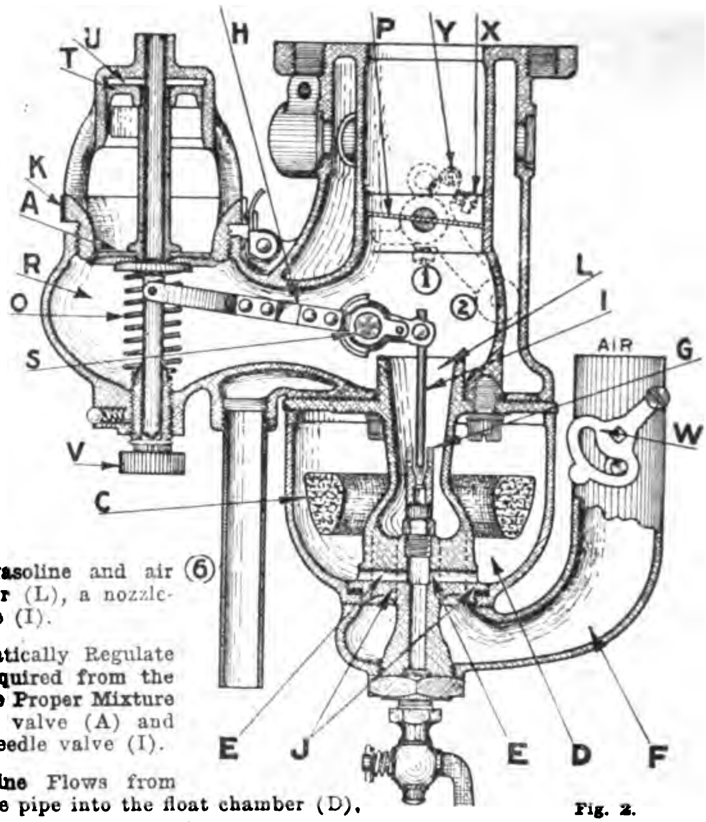

Fig. 2.

The parts consist of a float chamber (D), the cork float (C), and a float needle valve (B).

These three parts control all flow of gasoline into the carburetor as it is needed by the motor.

That part of the carburetor which mix . the gasoline and air (6) consist of a mixing chamber (L), a nozzle (G), and a needle valve (I).

Parts which Automatically Regulate the Amount of Gasoline Required from the Float Chamber to Provide the Proper Mixture consist of an auxiliary air valve (A) and lever (H), connected with needle valve (I).

OPERATION; the Gasoline Flows from **the Tank through** the gasoline pipe into the float chamber (D).

As the Gasoline Rises in the Float Chamber (D) it raises the cork float (C) with it, which, through a lever connection, automatically closes the needle valve (B) and shuts off the flow of gasoline from the tank to the carburetor. Of course as the gasoline is drawn from float chamber (D) the float (C) drops and raises valve (B), admitting more gasoline.

The Suction of the Pistons Draws the Gasoline from the Float Chamber (D) through the Passages (E) into the Nozzle Well (G), and past the needle valve (I) into the mixing chamber (L). As the needle valve (I) is raised and lowered as hereafter described, more or less gasoline is allowed to spray into the mixing chamber (L). At the same time the suction of the pistons draw from the warm air intake (F) and the passages (J), warm air into the mixing chamber (L). As the suction of the swiftly moving pistons is very strong, the air is drawn through the mixing chamber (L) with great velocity, and there, coming into contact with the gasoline spray from the nozzle well (G), it vaporizes the gasoline.

This Vaporized Mixture is then drawn by the suction of the pistons past the throttle valve (P) into the cylinders. The quantity of combustive vapor flowing past the throttle valve (P) is regulated by the position of this throttle valve, and the position of this throttle valve is regulated by the driver either from a pedal called the "accelerator" or a throttle lever on the steering post. Opening the valve (P) admits more combustive vapor to the cylinders, and consequently increases the speed and power of the motor. Closing it has the reverse effect. At high speed it is obvious that the suction through the mixing chamber (L) and the warm air passages (J) greatly increases, and as it increases beyond the capacity of these passages to supply air, a strong suction is brought to bear upon the auxiliary air valve (A). At a certain speed this suction is sufficient to draw this valve down against the coil spring (O). As the valve is drawn down, air rushes into the auxiliary air passage (R), and from thence past the mixing chamber (L) into the cylinders.

Auxiliary Air Valve. To take care of this extra supply of air there must be an extra supply of gasoline automatically furnished. This is taken care of as follows. As valve (A) is depressed against the spring (O) it operates the lever (H), which is hinged at the point (S). As the lever (H) is depressed by the valve (A) it opens needle valve (I) admitting more gasoline to the mixture. It can be seen that this extra supply of gasoline is always directly in proportion to the air supply through the valve (A).

Dash Pot Action. It is obvious that if means were not taken to prevent it the valve (A), which is under the tension of the spring (O), would close very abruptly if the speed of the engine was suddenly checked. It would also tend to open very abruptly if the speed of the engine was suddenly increased, as for instance, when the accelerator was suddenly opened. Furthermore, the suction of the cylinders is to a certain degree intermittent between the strokes of the pistons and this intermission between the strokes would ordinarily tend to cause the valve (A) to flutter or vibrate if means were not taken to prevent it, and the fluttering or vibratory action of the valve (A) would result in an unsteady flow of gasoline vapor to the cylinders, which would cause a vibratory or jarring effect in the engine. Any such action is prevented by a device (U) called a dash pot. Its function is to automatically insure a steady and staple supply of gasoline vapor to take care of varying engine speeds under all circumstances. To hold the valve (A) steady and to check its sudden closing or opening and to overcome its tendency to vibrate, it is attached directly to a plunger (T), which operates on a cushion of air in the dash pot (U).

CHART NO. 82—Model "R" Schebler Carburetor. Note the gasoline needle valve is automatically operated by movement of auxiliary air valve (A). (See Specifications of Leading Cars for users.)

—model R continued.

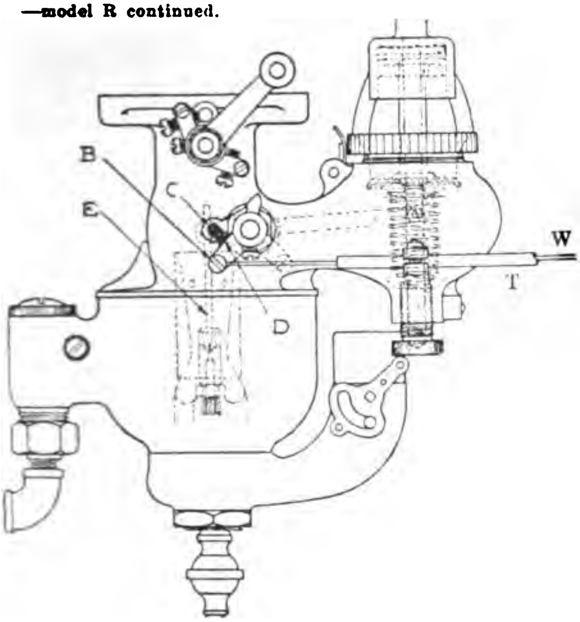

Fig. 3. When carburetor is installed see that lever "B" is attached to steering column control, or dash control, so that when boss "D" of lever "B" is against stop "C" the lever on steering column control or dash control will register "Lean" or "Air." This is the proper running position for lever "B."

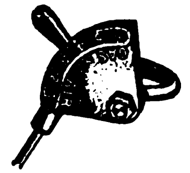

Fig. 4 and fig. 5, show two types of hand controls for "choking" air supply of carburetor controls. Fig. 4 shows the **dash** type and fig. 5 the **steering column** type.

Auxiliary adjustment—enables the driver to give the carburetor a very "rich" mixture without leaving the seat.

This adjustment is connected directly with the needle valve by means of an eccentric in the mixing chamber (see "S," chart 82) to which is connected lever (B), fig. 3. This lever is connected as shown, to the dash or steering column control by a flexible shaft (W) consisting of a piece of spring steel wire **running through a brass tube** (T) which is anchored firmly at the carburetor and soldered to the body of the dash or steering column control. By moving lever of the control the steel wire moves the lever (B) **when the lever on the dash adjustment is pulled all the way up it moves** the lever (B) to the right, or away from the stop (C).

The lever (B) turns the eccentric ("S," chart 82), **thereby lifting the needle valve** and increasing the tension on the air valve spring (O). This gives a very **rich mixture** for starting in cold weather and by gradually moving the dash control lever downward the **adjustment can be brought back to normal while the engine is running and getting warmed up.**

This adjustment is entirely separate from and independent of the main adjustments on the carburetor, which must be properly set before the dash or steering column adjustment is used.

In other words the carburetor **adjustments proper** are made at (K) and (V—chart 82) and after they are properly set, then the auxiliary adjustment can be used to get a rich starting mixture.

To adjust the carburetor (fig. 2), turn the valve cap (K) clockwise, or to the right (right means rich) until you can turn it no farther. Then turn to the left or anti-clockwise, (left means lean) through one complete turn. Start the engine and then continue to turn (K) to the left or anti-clockwise until the engine hits perfectly on all cylinders, at the slowest speed possible. Advance the spark lever two-thirds or three-fourths the way on the sector and then suddenly open the throttle lever or accelerator wide. If the engine back-fires on this quick acceleration, turn the spring adjusting screw (V) up until the carburetor works perfectly.

By turning the screw (V) up o inward, you turn it against the spring (O) (fig. 2), which increases its tension thus preventing valve (A) from admitting air into the carburetor too freely.

Turning (K) to the right or clockwise, lifts the needle valve (I) out of the nozzle well (G) and permits more gasoline to spray into the mixing chamber.

When you turn (K) to the left, or anti-clockwise it lowers the needle in the nozzle and shuts off the gasoline. It should be remembered that it is desirable from both the points of economy and power, **to drive the car with the leanest mixture possible.**

The throttle valve should be adjusted so that when the hand throttle is closed, the engine will just run evenly on all cylinders. This can be ascertained by the regularity of the impulses in the exhaust when both the spark and throttle levers are set at their lowest positions. If the engine, however, should run too fast, or should stop when the throttle is at lowest position, adjustment is necessary, directions for which are as follows:

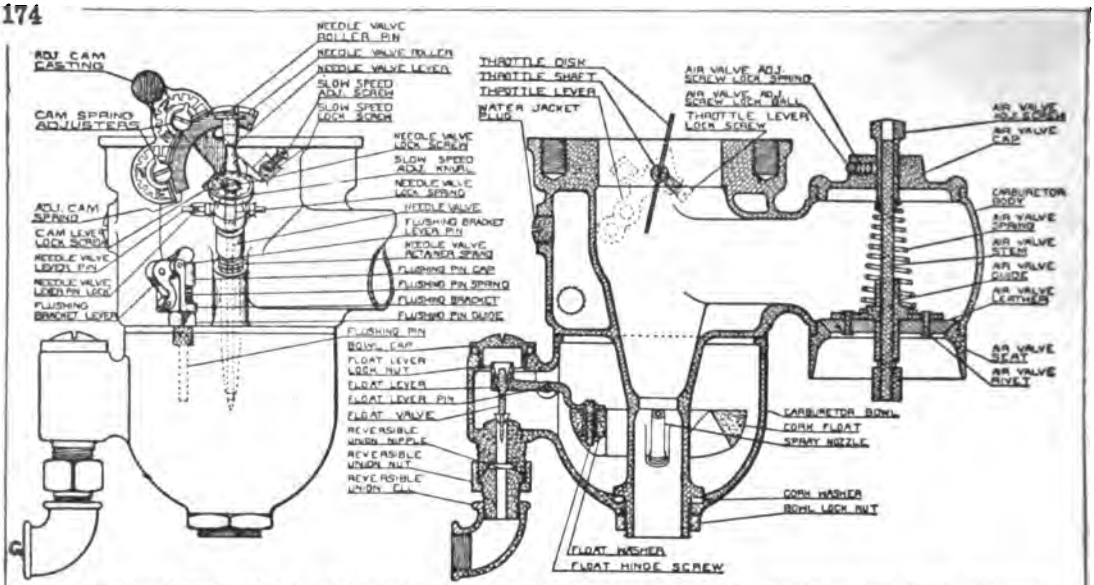
Loosen the set screw (X) which locks the adjusting screw (Y) where throttle shaft enters carburetor. Place throttle in lowest position.

If engine runs too fast, unscrew adjusting screw (Y) so that butterfly valve in carburetor is closed a little tighter.

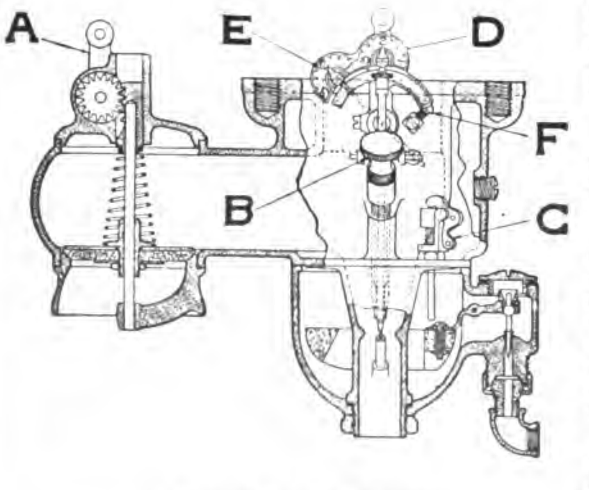
If engine runs too slow, screw in the adjusting screw so that valve is held a little more open. Lock adjusting screw (Y) with set screw (X) after adjustment.

Note: Warm air pipe as shown in fig. 4, chart 78A is connected with (F), fig. 2. **The exhaust gas can** be connected with (6), fig. 2, similar to fig. 2, page 157.

CHART NO. 83—Air Control and Adjustment of Model "R" Schebler Carburetor. (Wheeler and Schebler, Indianapolis)—see page 167 for "adjustment of floats."



Sectional View Model "L" Schebler Carburetor—Concentric type float, single jet and spring adjusted **auxiliary** air intake valve. Mechanically operated needle valve with **three speed adjustments; low, medium and high.**



Model L. Schebler Carburetor.

Connect carburetor to intake pipe so that it sets about six inches below bottom of gasoline tank, that the bowl may be filled by gravity. For best results, the carburetor should be as close to the cylinder as possible, and in case of multiple cylinders, equidistant from each one. Connect a pipe or tube from gasoline tank to union "G." Pipe to be brass or copper and not less than ¼-inch hole.

Be sure pipe is free from dirt—blow it out. Connect the hot water jacket with water circulation if there is a force circulation, otherwise a hot air pipe. See Chart 78.

Before adjusting the carburetor, make sure that your ignition is properly timed and that you have a good hot spark at each plug; that your valves are properly timed and seated, and that all connections between your intake valves and carburetor are tight, and that there are no air leaks of any kind in these connections.

In adjusting the carburetor, first, make your adjustments on the auxiliary air valve "A" so that it seats firmly, but lightly; then close your needle valve by turning the adjustment screw, "B," to the right until it stops. Do not use any pressure on this adjustment screw after it meets with resistance. Then turn it to the left about a turn and a half and prime or flush the carburetor by pulling up the priming lever "C" and holding it up for about five seconds. Next, open your throttle about one-third, and start the motor; then close throttle slightly and retard your spark and adjust throttle lever screw "F" and needle valve adjusting screw "B," so that the motor runs at the desired speed and hits on all cylinders.

After getting a good adjustment with your motor running idle, do not touch your needle valve adjustment again, but make intermediate and high speed adjustment on the dial "D" and "E." Adjust pointer on the first dial, "D," from figure No. 1 toward figure No. 3, about half way between. Advance spark and open throttle so that the roller on the track running below the dials is in line with the first dial. If the motor back-fires with the throttle in this position, and the spark advanced, turn the indicator a little more toward figure No. 3; or if the mixture is too rich, turn the indicator back or toward figure No. 1 until you are satisfied that your motor is running properly with the throttle in this position, or at intermediate speed. Now, open the throttle wide and make your adjustment on your dial "E" for high speed in the same manner as you have made your adjustments for intermediate speed on dial "D."

Note:—We find in the majority of cases in adjusting this carburetor the tendency is to give too rich a mixture. We suggest and recommend in adjusting the carburetor, both at low, intermediate and high speed, you cut down the gasoline until the motor begins to back fire, and then increase the supply of fuel, a notch at a time, until the motor hits evenly on all cylinders. Do not increase the supply of gasoline by turning the needle valve adjusting screw more than a notch at a time, in your low-speed adjustment, and do not turn it any after your motor hits regularly on all cylinders. In making the adjustments on the intermediate and high speed dials, do not turn the pointers more than one-half way at a time between the graduated divisions or marks shown on the dials.

CHART NO. 84—The Model "L" Schebler Carburetor; Hand Controlled, Mechanically Operated Needle Valve. (See page 167 for adjustment of float.)

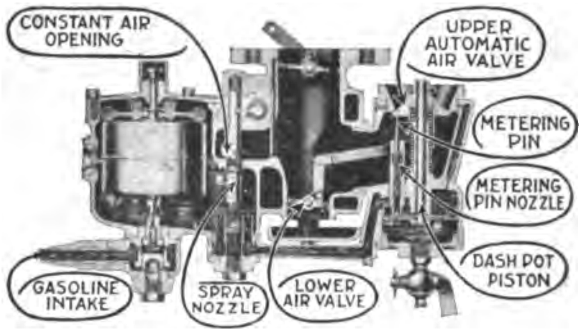
***Rayfield Principle.**

Rayfield carburetors are made in two types; model G and L, the difference being that model G has a water-jacket.

In both models the air valve adjustment has been eliminated, high and low-speed adjustments being made through the control of the fuel.

Both models are of the two-jet type, one jet feeding at low-speed and both at high-speed.

There are three air openings, one fixed and operating in conjunction with the low-speed nozzle and the other two having automatic valves linked together and operating simultaneously.



The high-speed nozzle is controlled by a metering pin actuated by the upper automatic air valve. The stem of the valve is connected to a piston working in the dash pot, from which a passage communicates with the float chamber; the dash-pot chamber has direct connection with the high-speed nozzle (see page 151).

When the throttle is opened, the tendency of the air valve to open suddenly and excessively, and to flutter, is checked by the dash-pot piston, which at the same time forces an extra supply of fuel into the nozzle and enriches the mixture for acceleration; the slow opening of the air valve increases acceleration by causing strong suction on the nozzles.

When adjusting a Rayfield carburetor, bear in mind that BOTH ADJUSTMENTS ARE TURNED TO THE RIGHT FOR A RICHER MIXTURE as indicated on adjustment screw heads.

A.—Stop arm screw. B.—Stop arm. Turn screw A to left to throttle engine lower.

The Rayfield dash control connects with carburetor by wire. When properly used, will render easy starting, furnish a richer mixture when engine is cold, and maintain a correct mixture under the extreme atmospheric changes.

When carburetor adjustments are once made, they should not be changed, as the dash control will take care of cold weather as well as cold engine conditions.

Raising the dash control lifts the spray needle and supplies a richer mixture. When it is raised full distance, a direct passage is opened permitting raw gasoline to be drawn from fuel chamber of the carburetor to engine. Control button (or lever) should be DOWN for running except when a richer mixture is desired.

The automatic air valve should be closed when engine is not running or when throttled down.

Remember that the low speed adjustment is to be used only when engine is running idle and positively must not be used in adjusting high speed. Never adjust a carburetor unless the engine is hot and the water jacket of carburetor warm.

Adjusting Rayfield.

Adjusting low speed: With throttle closed, and dash control down; close nozzle needle by turning LOW SPEED adjustment to the LEFT until block U (see cut), slightly leaves contact with the cam M. Then turn to the RIGHT about three complete turns. Start engine (see below) and allow it to run until warmed up. Then with retarded spark, close throttle until engine runs slowly without stopping. Now, with engine thoroughly warm, make final low speed adjustment by turning low speed screw to LEFT until engine slows down and then turn to the RIGHT a notch at a time until engine idles smoothly. If engine does not throttle low enough, turn stop arm screw A (see cut), to the LEFT until it runs at the lowest number of revolutions desired.

Adjusting high speed; advance spark about one-quarter. Open throttle rather quickly. Should engine back-fire, it indicates a lean mixture. Correct this by turning the HIGH SPEED adjusting screw to the RIGHT about one notch at a time, until the throttle can be opened quickly without back-firing. If "loading" or (choking) is experienced when running under heavy load with throttle wide open, it indicates too rich a mixture—this can be overcome by turning high speed adjustment to the left.

To start engine when cold: First: Close the throttle and pull dash control all the way up. Second: When engine starts, open throttle slightly and push dash control one-quarter of the way down. Third: As engine warms up, push control down gradually as required. When thoroughly warm, push control all the way down. When engine is warm it is necessary to pull dash control only part way up for starting.

Hot water connection—is connected with suction end of pump (between radiator and pump). The connection on other side connects with water jacket of engine or upper water pipe. A shut off cock is provided for hot weather. See that these connections are made in such a way that water will be drained out of carburetor jacket when system is drained.

Attach a hot air stove to the exhaust pipe and connect to constant air elbow of carburetor by a flexible tube. **Connections:** are 5/16 inch outside diameter tubing for gasoline and water connections.

CHART NO. 85—Adjustment of Model "G & L" Rayfield Carburetor.

See "Specifications of Leading Cars" for users. Findeisen & Kropf Mfg. Co., Chicago, manufacturers. This concern manufacturers another model called model "M," write for catalogue. *See also page 151, fig. 2.

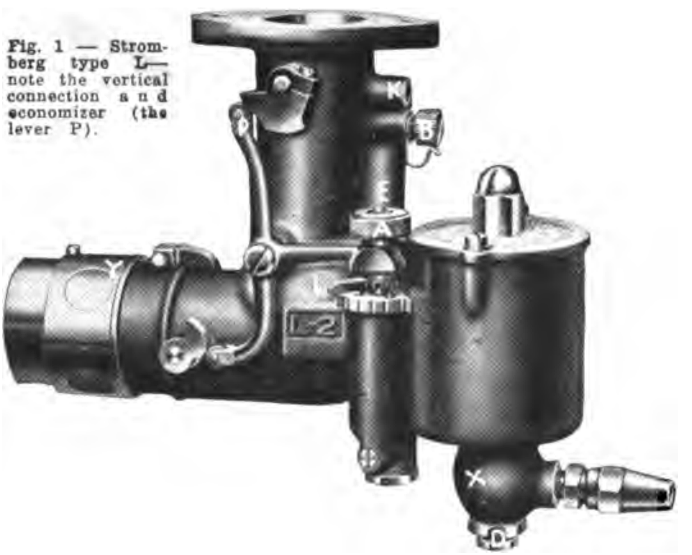


Fig. 1 — Stromberg type L—note the vertical connection and economizer (the lever P).

Stromberg Carburetor Models L and M.

The majority of Stromberg equipped cars are using models L, LB, M and MB, which are all called the "plain tube carburetor," principle of which is explained on page 177.

The L and M models are the same carburetor, except, model L has an "economizer" action. The L & M are made for **vertical** connections to intake manifold. See figs. 1 and 2.

The LB and MB models are of the same principle as L & M, except they are made for **horizontal** connections to intake manifold. The LB has the economizer action, same as L.

The economizer action is as follows (fig. 1): The high speed gasoline needle (A) is controlled by the nut (E), which rests on lever arm at closed and open throttle. With the throttle in ordinary driving positions—(15 to 40 miles per hour) the roller (P) drops into the cam notch, which permits the lever arm to drop free so that (A) descends to rest upon the economizer nut, thus lowering the needle into its orifice and partially cutting off the gasoline for these speeds. The amount of drop can be regulated by the pointer (L), which then acts as a special adjustment for the greatest possible economy.

The object of the economizer is to automatically graduate the gasoline adjustment, which is controlled by the throttle. As throttle is opened the needle (A) is raised; as throttle is closed it lowers. The amount this needle (A) can be raised is regulated by (L).

To adjust the economizer (see fig. 1) the spark should be fully retarded and the throttle opened to a position which turns the engine at a speed corresponding to about 20 miles per hour (m.p.h.). The lever L should then be set one notch less than for the mixture on which the engine will run steadily. Under ordinary conditions this would be the third or fourth notch of (L) fig. 1. See also page 927.

***Adjustment of L & LB.**

(1) Put economizer pointer in fourth notch.

(2) Open throttle to a position which will give about 20 miles per hour on a level road.

(3) Unscrew the high speed nut (A) to the left (counter-clockwise) until engine commences to fall away from too lean a mixture: then give richer mixture by turning the nut to the right, clockwise, notch by notch until a point is reached where the engine gives the best speed for that particular throttle opening.

(4) Then close throttle to idling position and adjust the idle screw (B), screwing inward. To the right, gives more gasoline; to the left, less.

(5) The dash control lever should be all the way down and the air horn cam plunger should clear the economizer lever so that this works freely as throttle is opened and closed.

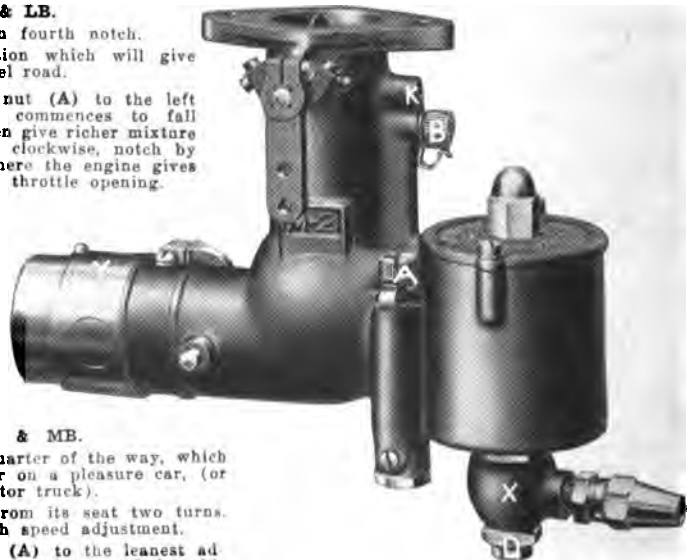

Fig. 2—Stromberg type M, without economiser. Used on small 4 cylinder engines for trucks, tractors, etc.

Adjustment of M & MB.

(1) Open throttle about one-quarter of the way, which will give about 20 miles per hour on a pleasure car, (or one-third governor speed on a motor truck).

(2) Open idling screw (B) from its seat two turns, so that this cannot effect the high speed adjustment.

(3) Adjust high speed needle (A) to the leanest adjustment which will give the best engine speed for this throttle position. Inward for less and out for more gasoline.

(4) Close the throttle gradually and screw idling screw (B) in as necessary to give adjustment for low speed and idle. Screwing inward, right hand, gives more gasoline; outward gives less.

This "plain tube" principle is also known as the "Pitot" principle and is further explained on pages 177, 149 and 800.

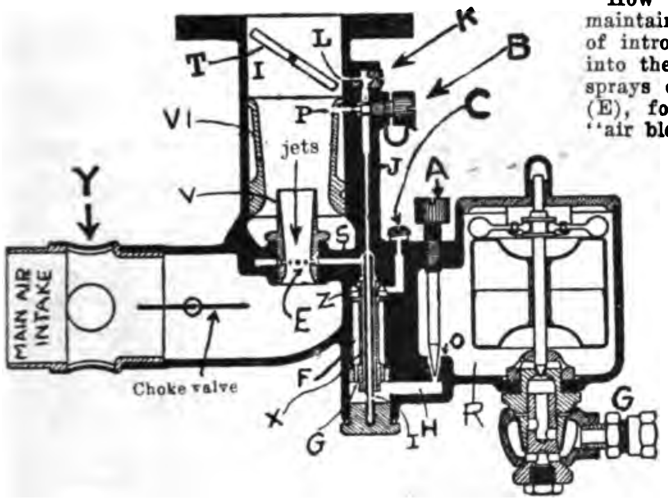
CHART NO. 86—The Stromberg "Plain Tube Carburetor" L & M. *Adjust only when engine is warm.

Note: all Stromberg carburetors are supplied with hot air attachments, similar to one described on page 159, fig. 1. Also a temperature regulator (Y) above, which principle is explained on page 159, fig. 2. See also page 927.

Principle of Stromberg "Plain Tube" Carburetor, (Model M).

This explanation also covers model L, LB and MB, except the economizer action, which is explained on page 176.

This carburetor is termed a "plain tube" type, because the whole air supply is taken through a single unobstructed channel of fixed size through the jet. Air valves, metering pins and dash pots have been dispensed with.



How the desired mixture can be maintained is answered in the principle of introducing a small amount of air into the gasoline jet at (C) before it sprays out into the main air passage (E), forming what is known as an **"air bled" jet.**

Action—the gasoline leaving float chamber (R) through (O and H), rises through a vertical channel (X) — not clearly shown, but around tube (J). Air taken in through (C), discharges into gasoline channel through small holes at bottom of passage (C), after breaking up into finely divided particles, the gasoline issues forth through a number of small holes or jets into the high velocity air stream of the small venturi (V). This gives a constant proportion of air to gasoline and atomizes the fuel completely.

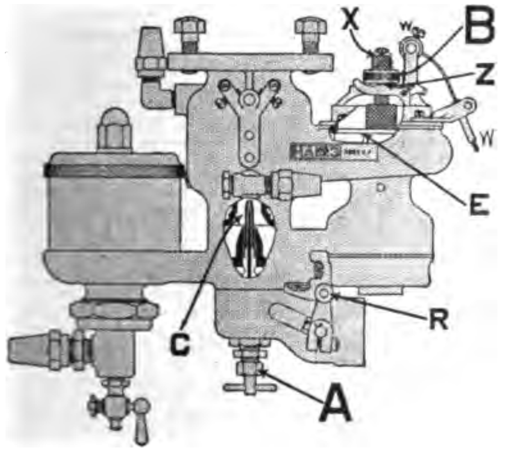
The accelerating well; to accelerate or speed up an engine, requires enrichment of the mixture. Dash pots, metering pins, etc., have hertofore been used for this purpose, but here they are dispensed with. Concentric and communicating with passage (X), which conducts the gasoline to the jet, is formed a reserve chamber, or "accelerating well" (F). With engine idling or slowing down, this well fills with gasoline, and whenever the venturi suction is increased, by opening the throttle, the level of gasoline in this well (F) goes down, and the gasoline thus displaced passes through small hole (G) at bottom of well and joins the flow from (H), on up (X), out (S) into jet, thus more than doubling the normal rate of feed.

Idling—This is where tube (J) action comes in. Note that (J) is not mentioned up to this time. When throttle is closed, gasoline is drawn in through hole (I) at bottom of tube (J), mixed with air taken in at (P) and discharged through idling jet (L) with highest degree of atomization, due to the fact that a vacuum of more than 8 pounds exists above the throttle (T) when engine is idling and throttle closed.

As the throttle is opened from idle, and the engine speed increases, more gasoline is drawn through (O and H), and it begins to discharge into the small venturi (V), as well as though the jet at the edge of the throttle. Thus the gasoline is given alternative paths, so that it can follow the one leading to the greater suction.

The difference to be noted, between slow speed and high speed, is that the flow for **high speed** is not up the tube (J), but through passage (X), out (S) into jet. **For idling,** it is through tube (J), out (L) and **when opening throttle from idling, out both.**

There are two venturi tubes; a small one (V), and a large one (V1), which produces a very high air velocity. (see page 147 for explanation of venturi.)



Stromberg Model H—with vertical connection.

Stromberg Model "H."

Is a different principle than L & M. It would be termed a compensating type carburetor.

For low speeds the gasoline is taken from spray nozzle (C), in venturi tube, through which bót air passes. Regulation of amount of gasoline is by needle valve (A).

For high speeds, the nozzle in center of air valve, which is automatically regulated by opening of the air valve, thus supplying the necessary volume of gasoline for high speed. Adjustment for high speed is by (B), which controls the amount of flow of gasoline on high speed by regulating the time when the needle valve begins to open. Needle valve opens only when (B) comes in contact with (X). (B) is raised by throttle opening at high speed. There is usually about 1/32" clearance between B and X.

Low speed adjustment is controlled by the needle valve "A." If too rich, as indicated by the engine "rolling" or "loading," turn "A" up, thus admitting less gasoline and making the mixture leaner. If mixture is too lean, turn "A" down, thus admitting more gasoline and richer mixture.

High speed adjustment: Advance the spark, open the throttle. If mixture is too lean on high speed, screw "B" up until desired results are obtained. If mixture is too rich, screw "B" down.

—continued on page 178.

CHART NO. 86A—Stromberg Carburetor. Explanation of the Model "L & M," "Plain Tube" o "Pitot" Principle of Carburetor and Model "H," Compensating Type.

—Stromberg model "H"—continued.

Nozzle: Before changing a nozzle, check up closely on the ignition system, examine all **manifold** and valve head connections, for **air leaks**, as it is absolutely impossible to make a carburetor operate properly if the ignition is not in good condition or there are air leaks in the engine.

If, however, with the engine in normal condition it is necessary to turn needle valve "A" down more than two and a half turns, and still **engine will not idle**, it indicates that the **primary nozzle is too small** and that a larger one should be used.

If it is impossible to get enough gas on high speed except when nut "B" is so high that there is no clearance at "X" on idle, a **higher number needle** should be used.

If too much gas on high speed when nut "B" is turned down as far as it will go, a **lower number needle** should be used.

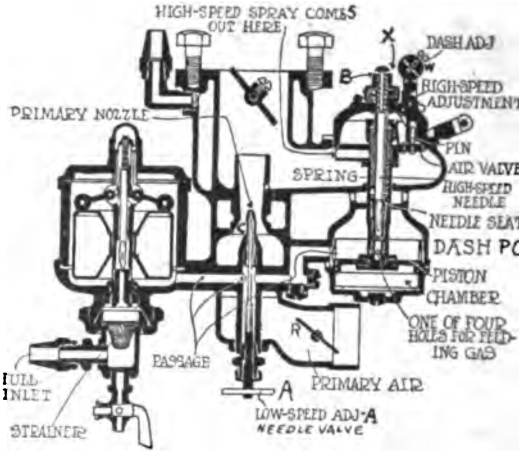
To change the primary nozzle, take out the needle valve "A" and remove nozzle with a regular screw driver. To remove taper valve on high speed, pull up steering post control, unscrew nut "B" all the way and lift valve out. This valve and nut "B" are assembled together and should be ordered in that way. Do not attempt to take these apart or to change the taper.

Never change nozzle more than one size at a time. The nozzle opening gets smaller as the number gets larger; thus—a No. 59 is smaller than a No. 58.

High speed needle valves deliver more gas as the number gets larger; thus—a number 7 will give more gas than number 6.

Always install carburetor with the float chamber towards the radiator.

This carburetor was used on 1917 Marmon.



Stromberg model HA—sectional view.

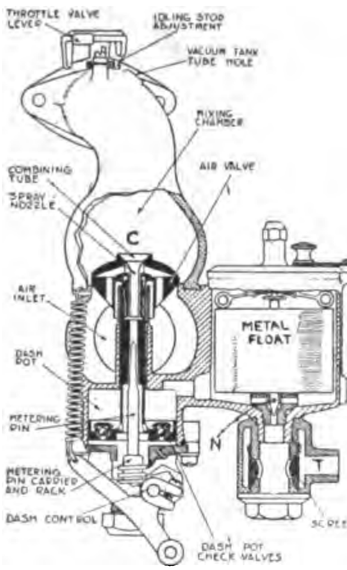


Fig. 4—There is only one adjustment and that is the metering pin, which is interconnected with the throttle. Ordinarily the metering pin should be two-thirds the way through.

*Stewart Carburetor (on the Dodge).

On the Dodge the carburetor (figs. 4, 3) is on left side of engine, and is fed from a Stewart vacuum tank. The carburetor is supplied with a hot air attachment which draws air from around exhaust manifold to air inlet.

Principle: (fig. 3). The automatic metering valve (A) rests on the valve seat (B) when the engine is not running. As the engine begins to rotate the suction of the pistons raises the valve (A) from the seat drawing in air around it (R to B) as indicated by arrows. The suction also draws gasoline up within the valve stem as indicated by arrow from (E) which mixes with the incoming air in the chamber (C).

The one adjustment of the Stewart is that of proportioning the volume of gasoline to the air admitted. The air being always a fixed factor it is only necessary to adjust or regulate the volume of gasoline admitted which is controlled by means of the tapered metering pin (D).

This adjustment is made when the engine is running at idling speed. By turning the adjusting screw (on "dash control," see lower part fig. 4), either to the right or left, raises or lowers the position of the tapered metering pin, thereby allowing an increased or decreased supply of gasoline to be drawn up into the mixing chamber. When the proper proportion has been determined at slow speed, it will be seen that as the speed of the engine increases, the automatic metering valve (A) will rise higher from the seat (B) and away from the tapered metering pin (D) which will allow a greater supply of both gasoline and air, in exactly the same proportion, be admitted to the cylinders.

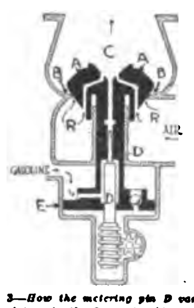

Fig. 3—How the metering pin D varies the mixture in the Stewart. Air passes through the passages R around the nozzle

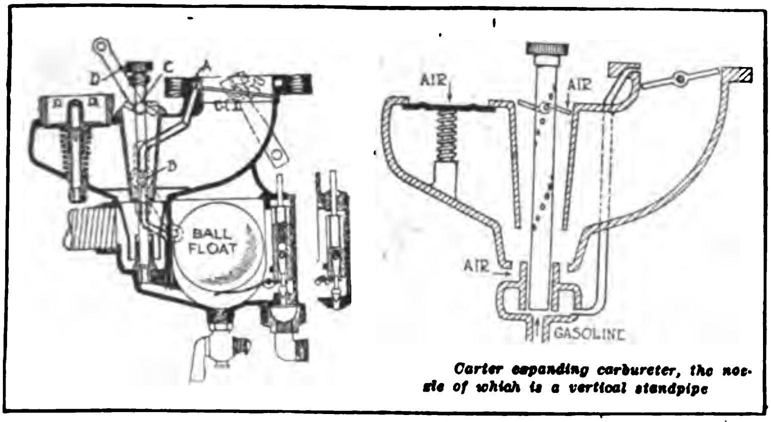
On the Dodge, fig. 4, the tapered metering pin is subject to control within fixed limits by means of the "dash control" ratchet, (see lower part of fig. 4 for connection), for the purpose of obtaining a rich mixture for starting. Should there be any reason for changing the fixed adjustment of the tapering metering pin (D), it can be done by turning the stop screw adjustment on the "dash control," (see lower part of fig. 4). Turning it to the right lowers the positon of metering pin and allows more gasoline to be admitted to the spray nozzle—enriching the mixture. Turning it to the left raises pin and decreases supply. The throttle valve is in top of carburetor, (see fig. 4.)

CHART NO. 87—Stromberg Model "H"—Continued. Stewart Carburetor on the Dodge Car. (see page 162, Address of Carburetor Manufacturers.) *See also page 783.



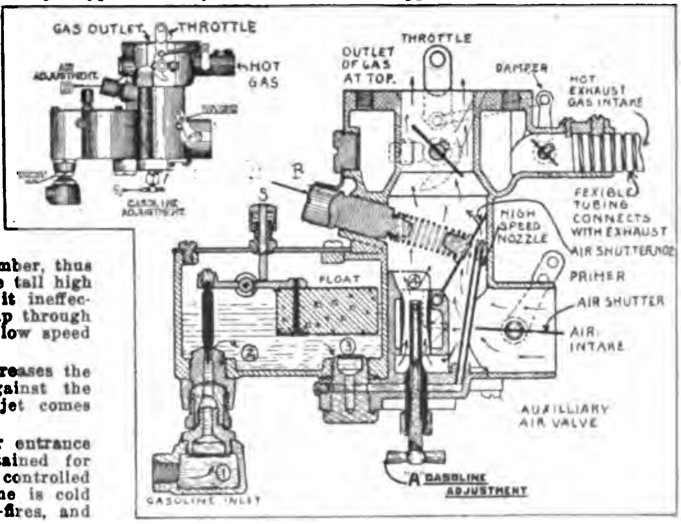
Carter expanding carbureter, the nozzle of which is a vertical standpipe

The Carter can scarcely be called a multiple-jet, yet it is a typical expanding design. The illustration shows why it is included in this classification in that its nozzle is a vertical standpipe in the walls of which are drilled various holes in the form of an ascending spiral and out of each hole the gasoline issues. At low speeds, when the gasoline is drawn to only a moderate height in this standpipe, the fuel issues from but few of the lower holes. As the gasoline rises higher in the standpipe at intermediate speeds it issues from more of the openings; and when it rises still higher at high speeds yet more of the openings are brought into operation. The main air opening is in a vertical tube surrounding this standpipe so that the inrushing air passes along the pipe excepting at the lower end. There is an auxiliary air valve. The pipe or multiple jet tube B can be unscrewed by the knurled head D. Heated air can be drawn in at the side.

At C—air enters; the amount is controlled by the little throttle shown. Still more air can pass into carburetor from the air valve on the left side, this supplementary supply passing upwards after mixing with the warm air.

The Marvel Carburetor—(used on Buick and Oakland 34B).

The Marvel model E is a double jet type whose special feature is the application of exhaust heat to a jacket surrounding the throttle chamber and venturi tube, amount of heat being automatically controlled by the throttle opening. Outside the float mechanism this carburetor has but one moving part, the auxiliary air valve.



Two jets are used, a primary low speed jet and a secondary high speed jet which is brought into action by the opening of the auxiliary air valve.

When the engine is idling the hinged auxiliary air valve rides on its seat against bore of mixing chamber, thus closing off the air passage past the tall high speed jet in this part, rendering it ineffective. At this time the air passes up through the small venturi surrounding the low speed jet.

As the suction of the engine increases the auxiliary air valve is opened against the spring pressure, and the second jet comes into action.

A choker valve in the main air entrance allows a rich mixture to be obtained for starting. This device may be controlled from the dash so that when engine is cold it may be closed to prevent back-fires, and gradually opened up as engine warms up.

The feature of this carburetor previously mentioned is the exhaust heated jacket. The heat is controlled by a damper connected to the throttle lever, which damper can be set to give any degree of heat desired. This is of particular importance as the quality of gasoline is yearly becoming heavier and heavier. This heat damper therefore can be set to admit sufficient heat to secure good vaporisation of such heavy fuel on low throttle, and then as throttle is opened the heat is automatically cut off, thus insuring maximum power at the higher speeds where heat is not necessary to good carburetion.

By such an application of heat the entering air is not preheated and this naturally results in greater thermal efficiency and power due to a maximum cylinder filling at each stroke of pistons.

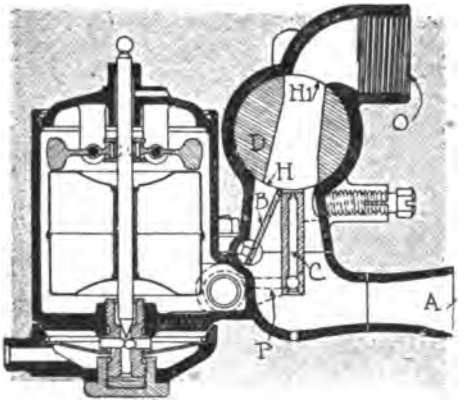
Adjustment; start by turning needle valve "A" to the right until it is completely closed. Then adjust the air adjustment "B" until the end of the screw is even with the end of the ratchet set spring above it.

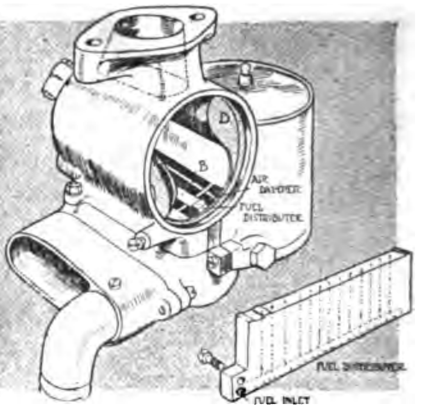
Next open "A" (gasoline needle) one turn, start the engine as usual, using the strangler button (S) to get a rich mixture at first. Allow engine to settle and warm up; then gradually cut down on "A," until engine runs smoothly.

Next turn air screw "B" to the left, a little at a time, until engine begins to slow down. This indicates that the air valve spring is too loose. Turn it back to the right just enough to make the engine run well.

To test the adjustment, advance the spark and open the throttle quickly, the engine should "take hold" instantly and speed up at once. If it misses or, "pops back" in the carburetor, open needle valve "A" slightly turning to the left. If this does not give results, the air screw "B" may be tightened a little by turning slightly to the right. It should be borne in mind, that the air valve should be carried as loosely as possible, and that the adjustment for "pick-up" may be obtained by carrying more gas with needle valve "A" rather than to tighten up the air valve too much.

The best possible adjustment is secured when air adjustment "B" is turned as far as possible to the left and needle valve "A" to the right, providing the engine runs smoothly and picks up quickly when the throttle is open. The speed of the engine is governed by the small set screw in the throttle stop. If the engine runs too fast, turn screw to the left, if too slow, turn screw to the right.





The Master Carbureter is a Concentric Float Type with a rotary throttle and horizontal fuel distributer extending across the air passage.

Referring to the Sectional View, the fuel distributer extending across the air passage is shown at C. This has a number of small holes drilled along its length, and the lower opening H in the rotary throttle D is so shaped as to uncover more and more of these holes as the throttle is opened . At the same time, due to a similar opening H in the upper surface of D, an increasing amount of gas is admitted through the intake O. Thus the fuel supply is mechanically apportioned in accordance with the throttle opening.

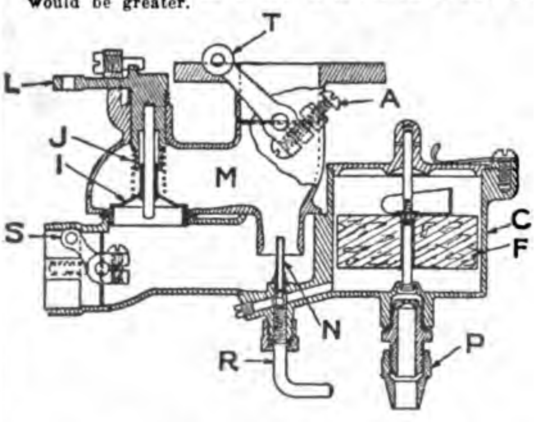
When the Throttle is Wide Open there are no restricted passages.

The Air Enters through the Intake A and mixes with the fuel issuing from the small holes, and passes on to the engine through the openings H and H'.

The Gasoline gets to the Distributer through the Passage P from the float chamber. A common supply tube running along the lower part of the distributer takes care of each individual distributer tube.

One Jet for Idling. When the throttle is closed, there is still one distributer hole uncovered which admits sufficient fuel for slow-speed or idling.

To Regulate the Air Supply and thus control the mixture, the air damper B is placed in the air passage. This is simply a flat piece of metal arranged to swing about its base so as to shut off any part of the air. As shown, it is set for a rich mixture, whereas, if partly open, the proportion of air would be greater.



THE MAYER CARBURETOR (Example of Model used on the Saxon.)

Carburetor Action: The float chamber maintains a constant level or supply of gasoline for the motor. Gasoline flows from the feed pipe through an intake plug (P), thence through the float valve and into the float chamber (C). A cork float (F) raises or lowers the float valve, thus regulating the incoming flow of gasoline in proportion to the supply in the float chamber.

After leaving the float chamber the gasoline passes through a nozzle (N) from which it is sprayed in a fine stream into the mixing chamber. The quantity of gasoline passing through the nozzle is regulated by the "needle valve" (R).

The suction created by the downward motion of the motor pistons draws air into the mixing chamber (M) through the primary and auxiliary air inlets. This air flows into the mixing chamber around the nozzle and picks up the gasoline which leaves the nozzle in the form of a spray. Thus the action of the mixing chamber is not unlike that of an ordinary atomizer in which the air, forced from the rubber bulb, picks up a certain amount of the liquid in the bottle and sprays it out in the form of a fine vapor.

At the front end of the carburetor is the auxiliary air inlet (I). At low speeds, when only a small amount of air is being drawn through the carburetor, the spring (J) holds this valve almost shut. As the speed increases and more air is needed, the suction draws the valve further open, admitting more air and automatically producing the correct mixture for all motor speeds.

When Adjustments are Necessary, observe the following instructions:

Adjust float (F), which is right when about 9/16 in. from top of float chamber, or when in about the third groove on float valve stem.

Slow Speed Idling: Throttle valve (T) should be adjusted at (A), to get proper speed for idling. The needle valve (R) is adjusted only to get proper mixture at low speed. The auxiliary air adjustment (L) takes care of high speed.

High Speed Adjustment: With the needle valve adjusted for proper mixture at low speed, the only adjustment required for high speed may be made from the dash, by means of dash adjustment, which operates cam lever (L). For less air, pull the dash adjustment out. It is advisable to use as much air as possible, as this gives best economy.

Easy Starting: To start the motor, close starting valve (S), which is operated by rod running to front of radiator, crank motor, and open starting valve immediately. In starting, during cold weather, with the motor cold, the air can be cut down to suit conditions, then, after motor is warmed up, the air may be readjusted.

If the weather is cold or extremely humid, turn the needle valve (R) at bottom of carburetor to the left for more gas, while the motor is running, until it fires evenly under load or while the car is in motion. Too rich a mixture will be distinguishable by black smoke from the exhaust. Too light a mixture will cause uneven firing of the motor.

If the weather is hot or extremely dry, readjust needle valve, turning to right for less gas.

CHART NO. 89—The Master Carburetor. The Mayer.
Master Carburetor Co., Detroit; Mayer Carburetor Co., Buffalo, N. Y.

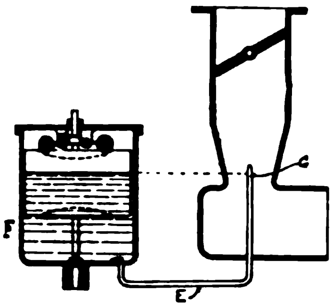


Fig. 1. A simple type of carburetor. Jet (G), fed from float chamber.

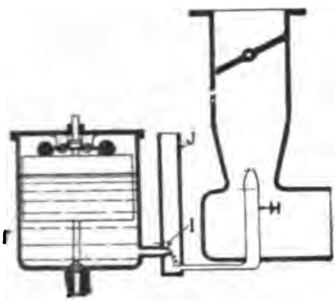

Fig. 2. Spray nozzle (H), receives gasoline from well (J), instead of float chamber.

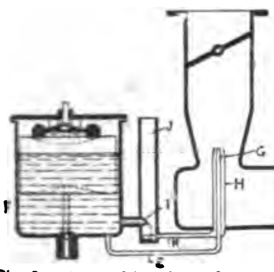

Fig. 3. A combination of 1 and 2.

Principle of the Zenith Carburetor.

We shall first consider a simple type of carburetor or mixing valve. This consists of a single jet (G), placed in the path of the incoming air, and fed from the usual float chamber (F), see fig. 1.

As the speed of the engine increases, the flow of the air increases, but the flow of gasoline from the jet increases faster, causing the mixture to become richer and richer. The mixture is practically constant only between narrow limits and at very high speed.

A second type of carburetor (fig. 2), is shown in which the spray nozzle receives its gasoline from the well (J).

The gasoline in the well is fed by gravity only through compensating jet (I), and is not affected by the suction, as the well is open to atmospheric pressure. The flow of gasoline is therefore constant at all engine speeds, while the flow of air increases with the engine speeds, the mixture also becomes poorer and poorer as the speed increases.

It will readily be seen that the second type produces the opposite effect from the first, while a combination of the two is shown in fig. 3, will result in a constant mixture, when jets are properly chosen.

This construction, further illustrated in fig. 4, admits of the addition of the priming tube (J) extending into the secondary well (P) and opening at the point (U) of the closing butterfly (T). With the butterfly partially open, the suction at this point (U) is powerful and draws the well full of gasoline into the cylinders, effectively priming the engine. Also by the introduction of this secondary well, which measures the gasoline used in running idle, a perfect mixture is obtained at very low engine speeds.

The level of the gasoline in the float chamber is set at the factory and need not be changed, but in case it does, the gasoline level is as shown on page 168.

Causes and Remedy of Troubles.

The matter in this page as well as the adjustments on page 182, refer to all types of Zenith Carburetors.

If engine does not slow down or idle: If engine "lopes," that is speeding up and slowing down as if fitted with governor; evidently too much gasoline—(1st) adjust air screw (O). (2nd) look for air leaks at manifold and other joints. See that jets are tight on seat. (3rd) water accumulation in the passages; remove plugs under carburetor and clean (I) and (G).

If engine does not pull properly going up hill: (1st) engine cold, insufficiently heated. (2nd) mixture too lean or too rich (irregular running results in latter case) try a larger and smaller compensating jet (I), using the one which gives best results. Also jet (G) and corresponding size of choke tube.

If the car does not attain its proper speed: (1st) mixture too lean; try adjusting slow speed (O). If chronic, try larger main jet (G). (2nd) mixture too rich, try regulating air intake at Z (figure 2, page 159). If chronic try a smaller size main jet (G).

When trying a new jet, the choke tube (X) must also be changed. Choke can be removed from upper part of barrel by removing screw (X1) and throttle valve. If stuck, remove cap and jet at lower part of carburetor and use a brass rod to drive it out.

T1—Lever operating throttle butterfly valve.

X—Choke tube.

X1—Screw holding choke tube in place.

Adjustments of the Zenith: There are but two adjustments on the Zenith. These adjustments are provided to properly "idle" the engine. With the average carburetor, if maximum speed is desired proper idling at slow speed is sacrificed or vice versa. By means of admitting more or less air, however, through the small slow speed adjusting screws (O) the Zenith carburetor will idle without "choking" and "loping" and yet, the maximum speed can be obtained—providing, of course, the main jet, compensator and choke tube are the proper size.

By referring to the illustration fig. 6 it will be observed that a small amount of air is admitted over and above the mixture through the plug (J) that is fed from the idling well. After the engine is speeded up the mixture is drawn through the main jet.

There are three parts which must be of the correct size. The choke tube (X), main jet (G), compensator (I). The size is determined by the manufacturer, according to the type of engine; four, six or eight cylinder, bore and stroke. After once being fitted to carburetor then there are no other adjustments except the slow speed valve (O) as mentioned above.

If the choke tube is too large the pick-up will be defective and can not be bettered by the use of a larger compensator. Slow speed running will not be very smooth.

If the choke tube is too small. The effect of a small choke is to prevent the engine from taking a full charge with the throttle opened fully. The pick-up will be very good, but it will not be possible to get all the speed of which the car is capable.

If the main jet is too large. At high speed on a level road it will give the usual indications of a rich mixture; irregular running, characteristic smell from the exhaust, firing in the muffler, sooting up at the spark plugs, low mileage. The influence of the main jet is mostly felt at high speeds.

If the main jet is too small. The mixture will be too lean at high speed and the car will not attain its maximum. There may be back firing at high speed, but this is not probable, especially if the choke and main jet are according to the factory setting. This back-firing is more often due to large air leaks in the intake or valves or to defect in the gasoline line.

The compensator (I): From the explanation of the Zenith principle given on page 181, it is readily noted that the influence of the compensator is most marked at low speeds. The compensator size is best tried out on a hill, as regular as possible and as long as possible, and of such a slope that the engine will labor rather hard to make it on high gear. A long, even, hard pull of this sort taxes the efficiency of the compensator to the utmost, and will indicate readily the correctness of its adjustment.

If the compensator is too large. Too rich a mixture on a hard pull. It will give the same indication as for rich mixture at high speed on the level.

If the compensator is too small. Too lean a mixture. Liable to miss and give a jerky action in the car, on a hard pull.

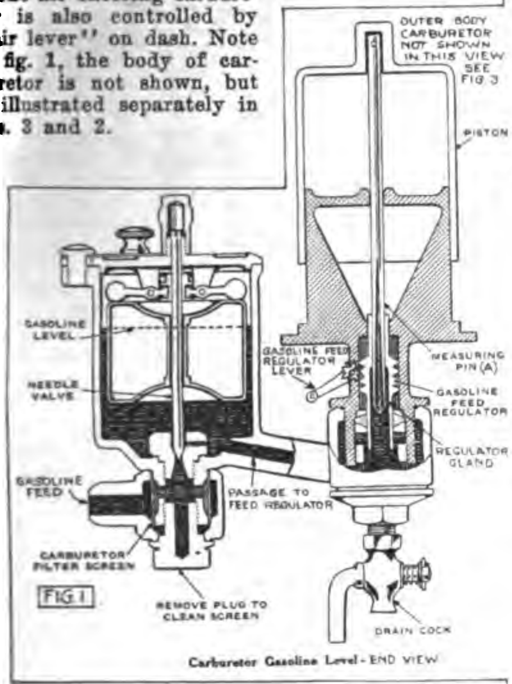
Remark: When trying out or fitting new jets, etc., tests should be made systematically, first starting the main jet, then the compensator, then the choke. Bear in mind that when the choke is increased the main jet should be increased. Water in gasoline will sometimes lodge in tube (J) and prevent proper idling. Remove and clean. This is a common trouble unless a strainer is used. **Temperature regulator type** used on the Zenith is shown on page 159, fig. 2.

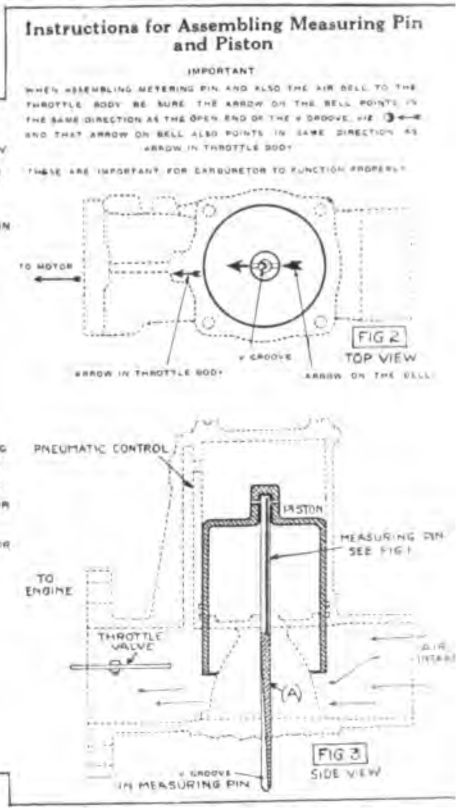
CHART NO. 91—The Zenith "Duplex" Carburetor (vertical type) as used on V-type Automobile and Airplane Engines.

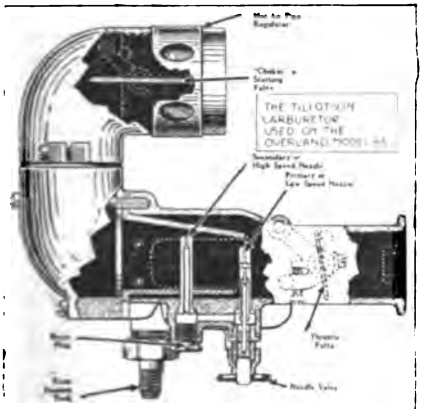
The Hudson Carburetor

Is illustrated below. The carburetor is of the "metering pin" type, also called "meas uring" pin. A, fig. 1, is the measuring pin, which is controlled by a small lever connecte with the "gasoline feed regulator lever." This lever is connected with a lever on the das which "measures out" the gasoline to be fed. A study of fig. 1, will make this clear.

The air entering carburetor is also controlled by "air lever" on dash. Note in fig. 1, the body of carburetor is not shown, but is illustrated separately in figs. 3 and 2.







Tillotson Carburetor

Used on the Overland engine is illustrated. may be termed a double jet, variable venturi c buretor.

A uniform partial vacuum is maintained at t fuel nozzle by two flexible reeds, which are mount in a cage, so designed that the maximum openi gives the required volume for maximum speed.

When the reeds (fig. 2) are closed they cause t highest possible vacuum at slower engine spee The reeds open and close according to the speed of engine. These reeds are so placed that as they move they form a virtual variable venturi. A secondary nozzle comes into operation at higher speeds and is not in use at the lower speeds.

Adjustment; there is but one, which is the needle valve.

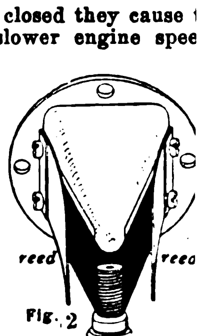


Fig. 2

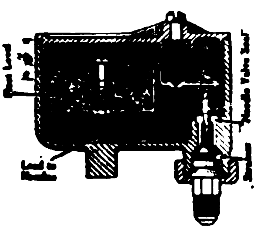
Position of reeds wide open thrott High engine spee



Float mechanism of the Tillotson carburetor, used on the Overland: Note level of gasoline.

CHART NO. 91B—The Hudson Carburetor—metering pin type. **The Overland Carb'uretor lotson).**

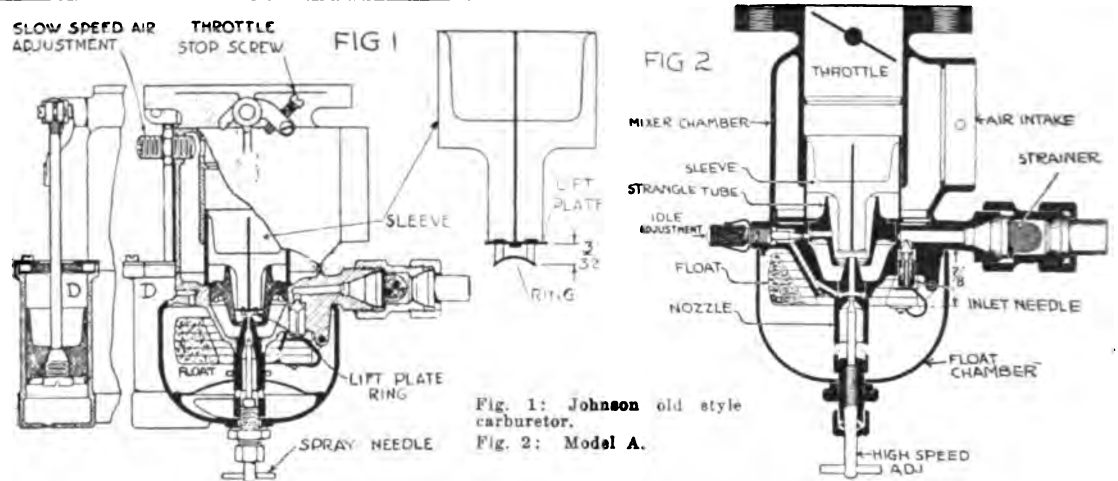


Fig. 1: **Johnson** old style carburetor.
Fig. 2: **Model A.**

Adjusting Johnson Carburetor (old style).

Indications of adjustment: (A)—lean mixture; **(B)**—engine difficult to start; **(C)**—"popping-back" on quickly opening throttle; **(D)**—engine knocks when throttle is opened quickly; **(E)**—engine will not idle.

Many mechanics can adjust this carburetor for high speeds but sometimes find difficulty in adjusting for low speeds or idling.

The correct procedure of adjustment is as follows:

(1)—retard spark.

(2)—close the slow speed air adjustment screw (fig. 1).

(3)—warm engine.

(4)—see that the intake pipe manifold where it connects to carburetor flange does not leak air. Sometimes a water jacketed intake manifold will become "air-locked" and water will not circulate, depriving it of heat. Open "plug," as per fig. 1A, page 157.

(5)—accelerate engine by opening and closing throttle rapidly. If mixture is too rich, acceleration will be sluggish; if too lean, it will "pop-back" considerably. The spray needle adjustment should be set between these two points.

(6)—retard the spark and close the hand throttle. Adjust the throttle stop screw until the engine runs very slowly regardless of whether it operates evenly or not.

(7)—open the slow speed air adjustment until the engine idles evenly if possible. If it runs too fast close down the throttle stop screw. The adjustments on the stop screw and the low speed screw should be made simultaneously.

(8)—it may be found that the low speed air adjustment cannot be opened at all. In this case the low speed mixture is too lean. Possibly the low speed air adjustment can be opened more than 3½ turns, when the mixture is too rich. Do not touch the spray needle setting, but proceed as follows:

(9)—disassemble the carburetor. A small ring, shown (fig. 1) is attached by two lugs to what is known as the lift plate. This ring is somewhat curved, and if the slow speed air adjustment can be opened more than 3½ turns without obtaining good idling, the curve is excessive and the ring should be slightly flattened.

(10)—if on the other hand the air adjustment cannot be opened, the ring is too flat and should be slightly curved. The standard setting is 3/32 in. from the edge of the ring to the lift plate to which it is attached.

Adjusting (Model A).

(1)—turn both idle screw and high speed needle (fig. 2), to their seats, and set the throttle stop approximately the correct position for closed throttle.

(2)—open the high speed needle 1½ turns. This permits the engine to be started. Warm the engine up by running a few minutes.

(3)—place spark lever in full retard position, and open the throttle until the engine turns at a speed equivalent to about 20 to 25 miles per hour.

(4)—turn high speed spray needle to the right until the engine speed decreases.

(5)—then turn the spray needle to the left until the engine speed increases and then decreases from a rich mixture.

(6)—turn again to the right to a point midway between the extremes. This is the correct mixture and will give the best results for all throttle positions.

(7)—Adjust the throttle stop screw to the desired idling position.

(8)—**if uneven firing occurs** correct either by unscrewing the idling jet to enrich the mixture or screwing up the idling jet to give a leaner mixture. The average setting is ½ turn from the seat. This adjustment must be made with the spark and throttle levers fully retarded.

The float should set evenly all around, the bottom being ⅞ in. from the float chamber seat as shown in fig. 2.

Principle of Johnson Carburetor.

The Johnson is a **"gravity air valve type,"** with a single concentric jet, in which air valve is made up of a sleeve rising and falling by suction and gravity in cylindrical passage above jet.

There are three stages of vacuum; one is the space between the throttle and strangle tube, the second, in the strangle tube itself, and the third, in the space below the plate on the bottom of the air valve sleeve. By removing the location of the idling adjustment (in fig. 1) the flow of gasoline for this purpose has been brought into a zone of greater vacuum and hence better idling.

CHART NO. 92—Johnson Carburetor. See "Specifications of Leading Cars" for users, page 543.

INSTRUCTION No. 14.

*COOLING: Water Cooling. Circulating Pumps. Radiators. Fan. Water Thermostat. Radiator Damper. Air Cooling. Cause of Trouble in the Circulating System. Cleaning Radiator. Stopping Leaks. Non-Freezing Solution. Heating a Car.

Water Cooling.

If no provision is made for cooling the cylinder of a gasoline engine, the intense heat of the explosions would heat it to a point that would cause the lubricating oil to burn, and become useless. At the same time, the cylinder must not be kept too cool, for that would prevent development of full power; the cylinder must therefore be permitted to get as hot as is possible without burning the lubricating oil. About 170 degrees Fahr. or below the boiling point, appears to give the best results—see page 188, fig. 9.

The cylinder may be cooled either by water or air, and while the greater number of engines are water cooled, air cooling, however, has been developed to a point where successful results are attained.

The water cooling system consists of jackets (see fig. 6, page 188), around the part of the cylinder that is to be cooled, through which water may flow; a radiator or cooler for cooling the heated water; and some method of keeping the water in circulation, together with the necessary connections (see charts 94 and 95). **The jackets are usually cast in one piece with the cylinder,** although in some cases they were formerly made by forming sheet copper around the cylinder to form passages through which the water would circulate. When heated, the water passes to the radiator, where the rush of air to which it is exposed absorbs the heat, cooling the water.

To maintain the cylinders at a workable temperature, a quantity of water is carried in a supply tank or radiator, from which it is caused to circulate continuously through the jacket of the engine cylinder by a small pump driven direct from one of the cam shafts or by the thermo-syphon principle. The heated water from the cylinder returns back to the tank on radiator and then passes through a series of thin copper tubes. The object is to dissipate as much as possible, the heat absorbed by the water by exposing it to a large cooling surface of metal.

The radiator system is always fixed in the forward part of the car, to obtain the full benefit of the draught of air. The same water is used over and over again so that it is only necessary to replace the loss caused by evaporation and leakage.

It is usual with radiator systems to have a rotary fan to assist in inducing a draught of cold air through the radiators and accelerating the cooling when the car is moving slowly, as in hill-climbing or slow running in traffic. The fan is driven from the engine shaft by a belt or gear and fixed back of the radiator. (Fig. 6, chart 95.) The alternative method, which avoids the use of a separate fan, is provided by fan-vaned arms in the fly wheel. (See fig. 3, chart 94.)

The two systems of circulation are the "thermo-syphon" system and the "force" system.**

Thermo-Syphon Water Circulation System.

The thermo-syphon circulates the water, because when water is heated, it rises. The connections are the same as for the force system, except there is no pump, and the connection from the water jacket outlet to the top of the radiator slants upward. It is more necessary to have clear passages for the thermo-syphon system than for the force system, because the pump, in the force system, will force the water past an obstruction that would stop the flow of water that moves only because of its heat.

Height of radiator—Thermo-Syphon system—must be higher and lower than the extreme top and bottom of the water jacket. (See fig. 6, chart 95.)

Height of water—Thermo-Syphon system—to properly circulate, water should be kept at level above top inlet of radiator. Below this point circulation ceases and water boils.

Force Water Circulation System.

In the force system, the engine drives a pump which keeps the water in constant circulation, as shown in fig. 4, chart 94 and fig. 7, chart 95. The pump forces the water from bottom of radiator to the inlet at the bottom of the water jacket, through which it flows to the outlet at the top, whence it goes to the top of the radiator, flows through the radiator to the bottom. As it passes through the radiator tubes it is cooled. After passing through in this manner it is again drawn through the pump.

*By referring to page 543, "Specifications of Leading Cars" the cooling systems of leading cars, is given.

**Lower priced cars show a tendency to use the thermo-syphon system whereas higher priced cars the pump or forced circulation.

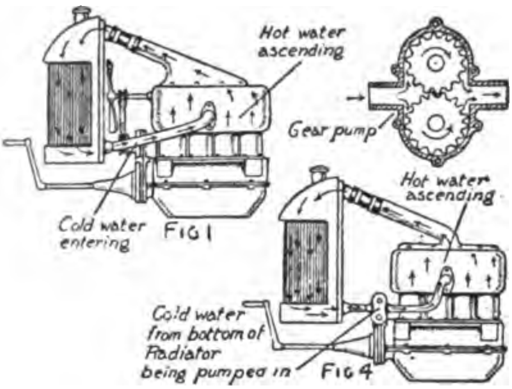

Fig. 1—Thermo-Syphon principle of water circulation.

Fig. 4—Forced or Pump principle of water circulation.

The gear type pump is shown at the top, right hand corner.

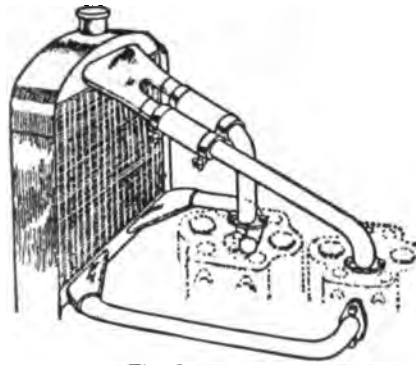

Fig. 2.

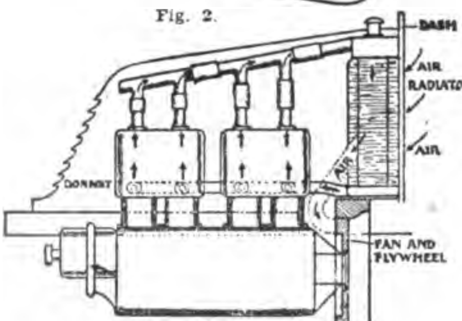

Fig. 3.

Water Cooling Systems.

Fig. 1—Thermo-Syphon Circulating Water Cooling System. This system does not require a force pump to circulate the water. The water enters the cylinder jacket at bottom. Upon becoming heated by the explosions going on within the engine the water rises to the top, entering the pipe and passing into the radiator at top where it is brought into contact with a large cooling surface, in the shape of the radiator. On being cooled and thereby becoming heavier, the water sinks again to the bottom of the cooling system, to enter the cylinders once more and to repeat its circulation. The cooling action is further increased by a belt-driven fan which draws air through the radiator spaces.

Fig. 2—A Thermo-Syphon system in which independent pipes are taken from each pair of cylinders, the outlet pipes joining at the upper or tank part of the radiator. Cylinders in this instance are cast in pairs.

Where cylinders are cast en-bloc, one water inlet and one water outlet pipe will suffice, as in Fig. 1.

Fig. 3—Simple Thermo-Syphon Circulation. (Renault system.) **Pump dispensed with. The arms of the fly wheel are designed to act as fan blades;** a separate fan is unnecessary, but the underpart of the engine must be carefully screened in.

Fig. 4—Forced Circulation Water Cooling System. A water circulating pump is used with this system to force the circulation of water through the water jacket and radiator. A fan is also used, but not shown, which is driven by a gear from a cam shaft. The fan draws air through the radiator tubes. Fresh air passing through the tubes tends to keep the water cool. At the point "G" fig. 7, chart 95, gaskets are used to make water tight joints with the water pipes.

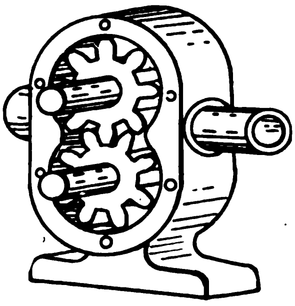

Fig. 5—A gear type of circulating pump consists of two small gears with large teeth, the two being in mesh, and placed in a casing that fits as snugly as possible. The water enters at one side where the teeth separate and is carried around to the opposite side in the spaces between the teeth where it escapes through an outlet. This is the type in general use.

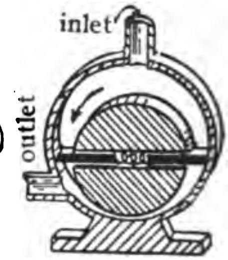

Fig. 7—The rotary type of circulating pump consists of a ring-shaped casing, within which a disc revolves, the disc being "eccentric," or to one side of the center of the casing. Through a slot across the disc are two arms their ends being pressed against the casing by a spring. As the disc revolves, the water is forced from the inlet to the outlet by the arms.

Fig. 9—This illustration shows how the fan (see fig. 6, chart 95) draws air in through the cores in the radiator to keep the water cooled. This demonstrates clearly the function of the fan, and shows how futile is its attempt to cool the radiator when the winter cover is fully closed. There is no cooling action to the fan unless the front of the radiator is at least partially exposed.

Fig. 6.—The centrifugal pump acts on the principle of an air blower, and has blades projecting from a hub, which revolves at high speed inside of a casing. The water enters at the hub, and is thrown outward by the blades to outlet in casing.

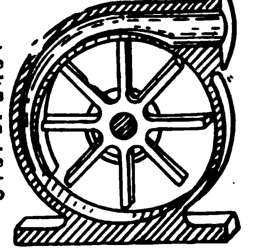

Fig. 6.—Centrifugal type.

CHART NO. 94—The Two Water Cooling Systems; the Thermo-Syphon and the Force **System. Water Circulating Pumps. Purpose of a Radiator.**

Note—There is no chart 93—(error in numbering).

**Circulating Pumps.

Practically all water circulating pumps are driven by a gear on the crank shaft or cam shaft, so that the motion is positive, and without slipping. All **forced** circulating systems must use a circulating pump.

There are three types of circulating pumps, in general use, the "gear type," the "centrifugal type" and the "rotary type" (see page 186.)

Radiators.

Purpose of a radiator is to keep the water, which circulates around the water jacket of cylinders, below the boiling point.

The location of radiator **is usually in front** of the engine where it will come in contact with the air. The air passes between the tubes or fins on a tubular type of radiator and through the cells of a cellular type (see page 190). **A fan** is usually placed directly behind the radiator, which is operated from a pulley on crankshaft of engine, for the purpose of drawing a large quantity of air through the radiator, thus increasing the cooling capacity.

Construction of a radiator. There is a reservoir or tank placed at the top and one at the bottom, as shown in fig. 7, page 188. Between these two tanks, the tubes or cells are connected*. A pipe connection is made with top and bottom tank from engine, as shown in fig. 7, page 188. When engine is running, the hot water passes to top tank, thence downword through the radiator tubes (if a tubular type), or around the cells, (if a cellular type), and is thus cooled. The cooled water then passes into lower part of engine from lower tank of radiator—see fig. 7, page 188.

Radiators must be used with either the "forced-circulating" system, using a pump or with the "thermo-syphon" system, which does not use a pump—see page 185.

Types of radiators: There are two types in general use, the "tubular" and the "cellular or honey-comb."

The tubular type consists of vertical tubes placed between upper and lower radiator tank. The water passes downward **through** all of the tubes. If one tube becomes clogged, then all of the water must pass through the other tubes. Each tube is a seperate path through the radiator. See page 190.

The cellular radiator consists of tubes or cells placed horizontally, through which the air passes and the water flows downward **around** these cells or tubes. See page 190.

The honey-comb type radiator was a term originally applied to a cellular type of radiator, due to its likeness to a honey-comb, but now that tubular type radiators can be constructed to have the appearance of a cellular radiator, the term could also be applied to the tubular type.

Early Type of Radiator.

The early type of radiator fig. 8, consisted of a corrugated copper tank, with horizontal tubes running lengthwise of tank. A tank was placed on each side of body connected with water jacket of engine. A circulating pump was used to circulate the water. Modern constructions are shown on page 190.

FIG. 8

Cooling Fans.

In order to cool the water sufficiently, a fan, driven by a belt, attached to a special bracket on engine, is shown in figs. 6 and 7, page 188.

Fan adjustment: the belt can be tightened by raising the fan by an **eccentric** adjustment, or by bodily lifting the fan and its bearing and tightening a bolt holding it.

The belt should be kept tight. Slack fan belt often causes **overheating.** Ball bearings are usually provided and they should be kept **well oiled**—(this is quite often overlooked).

The fan draws a current of air through the passages in the radiator (see fig. 9, chart 94), in addition to that driven through it due to the forward motion of the car. There are two types of fans in general use; the 4 blade and 2 blade —see chart 97.

Water Temperature Regulation.

The temperature of the water circulating around the water jackets should be about 170° to 180°, at which temperature gasoline engines operate at maximum efficiency. If over this temperature or as high as 212°, the water will boil and steam. If the temperature of the water is low, then the cold engine condenses a portion of the gasoline, which leaks past the piston rings, dilutes and thins the lubricating oil, with result that engine is not properly lubricated and furthermore raw, unvaporized gasoline produces carbon deposit in cylinders. See also, page 205 and 155.

†There are three methods employed to heat **a cold engine:** (1) to close the front of radiator, to prevent cold air being drawn through. Such an arrangement is shown in fig. 10, page 188, and is termed a **radiator shutter;** (2) by restricting the water circulation. Such a device is known as a **water thermostat or syphon** and is explained on page 130, fig. 2 and page 860; (3) by **heating the intake manifold,** as explained on pages 155 and 157.

Temperature indicator—see fig. 9, page 188.

A condenser, to prevent loss of alcohol when used as a non-freezing liquid, see page 730.

*Called the "Core", see page 715 and 789 for meaning of "core".
**See footnote bottom page 185. †A new principal developed by the Packard Co., is explained on page 855.

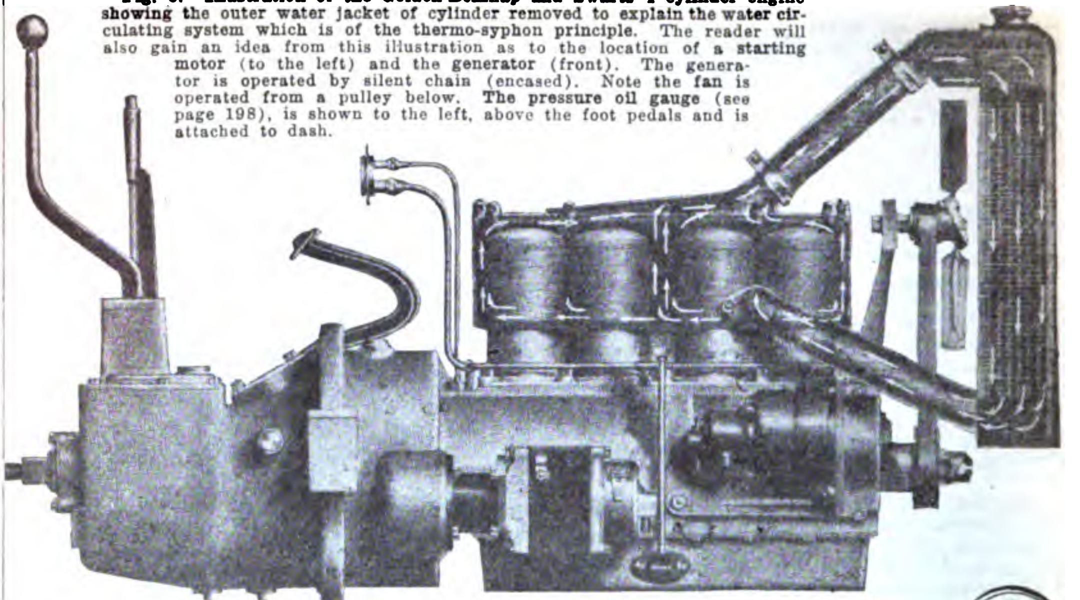

Fig. 6. Illustration of the Golden-Belknap and Swarts 4 cylinder engine showing the outer water jacket of cylinder removed to explain the water circulating system which is of the thermo-syphon principle. The reader will also gain an idea from this illustration as to the location of a starting motor (to the left) and the generator (front). The generator is operated by silent chain (encased). Note the fan is operated from a pulley below. **The pressure oil gauge** (see page 198), is shown to the left, above the foot pedals and is attached to dash.

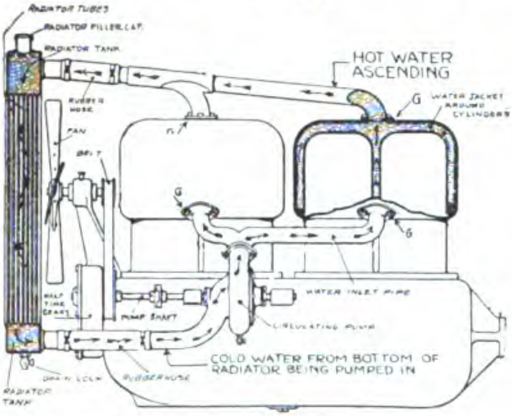

Fig. 7. This illustration shows how the pump shaft on the forced water circulating system is usually driven, also the fan. "G" are gasket connections which must be kept tight—usually made of an asbestos composition. Also, shows the path of the water circulation.

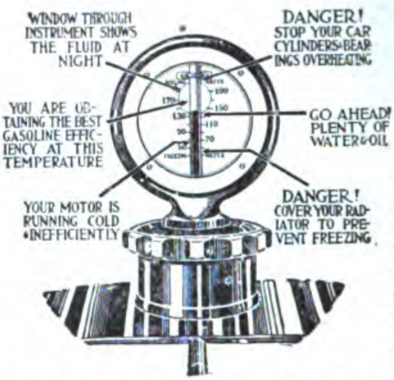

The thermometer bulb (B) does not extend to the water (W). The temperature of the vapor above the water is indicated.

Fig. 9. A temperature indicator—the Boyce motometer: A very useful device for warning the driver when his engine is overheating, is called a "motometer." This device is placed on the radiator cap. The fluid in the tube reaches different levels according to the *temperature. These figures can be seen from the drivers seat. If the level of the fluid reaches too high a point the driver is warned to stop and locate the trouble before serious trouble develops. In this instance, first determine the different causes of overheating and try first one, then the other until the trouble is found. If you think the trouble is in the lack of lubrication, lack of water or too much gasoline feeding at carburetor; examine each and remedy the trouble and watch the results. ***A distance type moto-meter is also made,** which can be placed separate from radiator and is adapted for use on aeroplanes, motor boats, tractors, etc. (Boyce Moto-Meter Co., Long Island City, N. Y.)

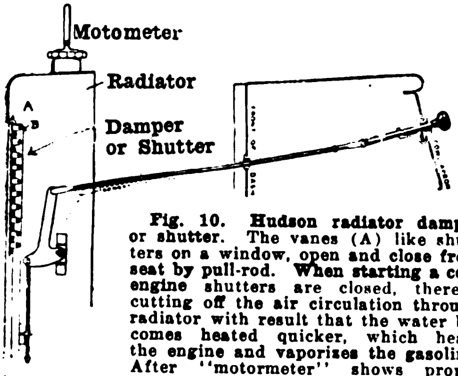

Fig. 10. Hudson radiator damper or shutter. The vanes (A) like shutters on a window, open and close from seat by pull-rod. **When starting a cold engine** shutters are closed, thereby cutting off the air circulation through radiator with result that the water becomes heated quicker, which heats the engine and vaporizes the gasoline. After "motormeter" shows proper temperature, shutters are opened, air circulation begins and temperature remains normal.

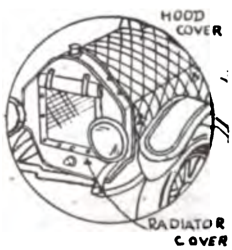

Fig. 8. Radiator cover over the cooling surface of the radiator during cold weather is advisable. The roll in front on the radiator cover can be lowered or raised during cold weather, until engine warms up. **Some merely tie a piece of card board over the lower front of radiator and keep it there during extreme cold weather.**

Hood cover: During cold weather the hood cover is advisable, as it tends to retain the heat under the hood.

CHART NO. 95—Example of a Thermo Syphon Water Circulating System. Location of Pump on a Force System. The Temperature Indicator (Motometer). The Radiator Damper or Shutter.

***High altitudes, say 10,000 ft. above sea level, boiling point of water is reached about ⅛" below point indicated at top of instrument.** *See page 921.

Air Cooling.

The object of cooling is to remove the excess heat from the cylinders. There are only a few cars on the market in which this is accomplished by the air direct, without the use of water.

Air cooling, however, is confined principally to small engines, as motorcycle and cycle-car engines. Air cooling is not successful with large cylinders. It is necessary to give the cylinder a large surface on which the air may act, and the usual method is to make it with deep flanges projecting from the walls and head (as well as the valve chambers), which become heated, as they are part of the cylinder. (See fig. 6, chart 96.)

When in motion, the current of air blowing against the flanges drives the heat away.

Air cooled engines have small cylinders, and must run at a high speed to develop their full power.

**The Franklin air cooled engine is about the only successful engine for automobile pleasure cars employing the air cooled method. The six cylinders are 3¼ bore and 4 in. stroke, giving a formula horsepower of 25.3.

Fig. 1—Direct air cooling of the Franklin. The fly wheel is the only moving part of cooling system.

Vertical steel fins are made integral with the individual cylinder casting, by having the iron poured around the strips of steel. Very light aluminum jackets guide the air draught downward from the heads of the cylinders.

By referring to the illustration the path of the air is shown, first through hood, thence over and down through the air jackets. The air is then deflected downwards and out through the fly wheel blades.

Note the vanes in fly wheel which create a suction equal to 2,200 cubic feet every 60 seconds; a continuous flow of air literally wiping the heat away. It is stated that the heat on a Franklin engine is about 350° Fahr., see fig. 4, page 157 for Franklin exhaust heated inlet manifold. This heat is shut off after engine is warmed up.

The Franklin at one time employed auxiliary exhaust valves to assist in dispelling the heat of explosion from the cylinder as rapidly as possible. This method, however, has been discontinued.

A forced draught air cooling system (fig. 7, chart 96), formerly used years ago on a prominent make of car. With this system the circulation of air was forced through jackets, placed around each cylinder, open at the bottom and top, being connected to a pipe from a centrifugal air blower or fan. The forced air passed the radiator flanges, and out at the bottom. In some respects, this principle is similar to the Franklin.

The different methods of air cooling are summed up as follows:

(1) By having a large radiating surface by means of cast flanges or gills, inserted pins or tubes. (2) By using extra large exhaust valves, so as to cool the combustion space between power strokes. (3) By combining large radiating surfaces with low speeds in multiple-cylinder engines. (4) By the use of auxiliary exhaust ports, combined with surface radiation. ((5) By forced draught of air circulating through an air jacket around the cylinder.

Water Cooling Troubles.

***Overheating:** Assuming that the design and the construction of the engine, including all features of the cooling system, are correct, then, **outside of leaks, insufficient water and bursting of the water jackets from freezing, overheating is the final result of all troubles from the cooling system,** and overheating is due to either or all of these **secondary** troubles which may in turn originate from a number of **primary** causes.

Secondary causes: First, the circulation of the water through the system; **second,** the conductivity of the heat through the walls of the cylinders or radiator tubes; **third,** the passage of air through the radiator and around the cylinders.

Primary causes of overheating in both thermo and forced circulation: (1) Insufficient water supply in radiator; (2) constricted holes in gasket where pipe connects to cylinders and on pump; (3) frayed hose connection; (4) incrustations or lime deposits on walls of cylinders or radiator tubes; (5) mud between fins or cells of radiator; (6) water frozen at bottom part of radiator.

Overheating causes in forced circulation: (1) Broken fan belt; (2) fan belt too loose; (3) tight fan belt bearing; (4) improperly bent fan blades; (5) broken pump shaft; (6) lost pin from pump shaft coupling; (7) lost pin from pump shaft gear; (8) lost pin from internal pump mechanism; (9) pin holding pump shaft sheared off, but shaft continues to revolve.

Other causes for engine heating: A shortage of lubricating oil or a poor grade; too rich a mixture with a retarded spark will cause overheating; the spark bears a fixed relation to the mixture, which is best learned by experience. The valves being set wrong will also cause heating; for instance, if the exhaust valve does not open and close at the right time the heat or burnt gas will not be discharged properly. Pre-ignition, want of compression, old oil being used too long; (cheap oils are false economy and only the best grade should be used). Improper driving will produce heating, particularly in hilly districts, by hanging on to the third or fourth speeds when ascending inclines and so causing the engine to labor, and running on retarded spark.

In some engines an inclination to overheat gradually develops as the car gets older, and appears to defy all efforts to remedy by means of carburetion or ignition.

This may be due to the clogging of the cooling system with incrustation or deposit in the walls of cylinder jackets and water system generally.

*Also see index for "spark control and overheating and page 788." **See index for "Franklin engine."

**The Holmes Automobile Co., Canton, O., are also manufacturers of an air cooled car with many distinctive features.

Tubular Radiators.

Purpose of a radiator, see page 187 and fig. 7, page 188, showing how the water circulates.

There are two types of radiator cores in general use, the "tubular" and the "cellular".

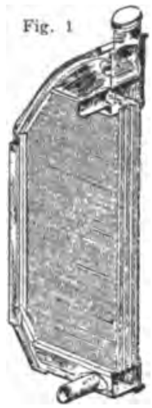

Fig. 1

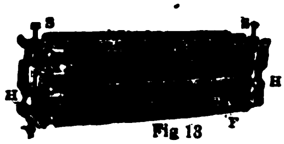

Fig 13

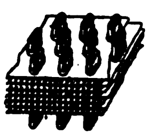

Fig. 5-A

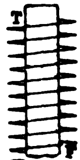

Fig. 5

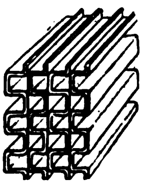
The tubular type of radiator used in 1900 and 1901, is shown in fig. 13. The tubes were placed horizontally in heads (H). Crimped fins (F) were placed on the tubes. The radiator was suspended under front of car by studs (S). A pump circulated the water.

The vertical tubular type with "spiral" fins (F), fig. 5, was the next type introduced. These tubes were placed between an upper and lower tank, per fig. 7, page 188. This type is still in use, principally on trucks.

The vertical tubular type with "flat" fins, fig. 5A, was the next type introduced, the idea being to have it resemble the cellular radiator which at that time was introduced on the Mercedes car. A tubular radiator made up with flat fins is shown in fig. 1.



F g. 5-B

Fig. 5-C

Fig. 5-D

Variations of construction of the tubular type radiator are shown in figs. 5B, 5C, 5D. Note the appearance is similar to the cellular type, but the water flows through the tubes, whereas with a cellular radiator the water flows around the tubes.

*Cellular Type Radiators.

The original cellular type was the Mercedes (fig. 4). It consisted of four or five thousand ¼" square copper tubes 4" long nested horizontally together, being seperated from each other by wires arranged to run between the rows of tubes in both directions. The blocks so made were clamped together, and dipped in a bath of solder, both front and back, by which means a space $\frac{1}{32}$" thick was left on each side of every tube. The blocks (divided into sections similar to fig. 12) when made, were assembled with top and bottom tank of radiator, and water was forced to pass in between the tubes, the air being allowed to travel through the inside of the tubes. A very large radiating surface was thus obtained, and it would be hard to conceive of any arrangement offering a larger radiating capacity for any given size radiator.

The cellular radiator is a very expensive type to construct, therefore, in this country where large quantities are required this construction was quickly modified to make the production cheaper.

The FIAT true cellular type radiator is similar to the Mercedes. It is formed in four divisions indicated by horizontal lines. Where these lines cross there are open horizontal passages through which the water may flow from one side to the other. Thus a section can be removed and repaired seperately.

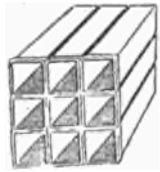


Fig. 4

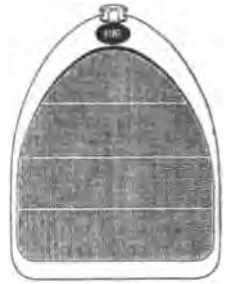

Fig. 12

Some of the modifications employed are shown in figs. 4A, 4B. Note in 4A, the tubes are expanded at the ends thus eliminating the wires. The Mayo

Fig. 4-A

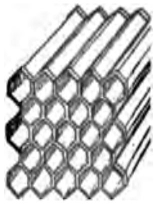

Fig. 4-B

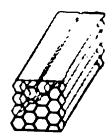

HARRISON

is constructed in a similar manner with the water passage to the sides of tubes. The Fedders, fig. 4B, the hexagon tubes can be removed and replaced. The Harrison hexagon cellular is shown to the right. Between every other row of cells there is a water passage .08" thick.

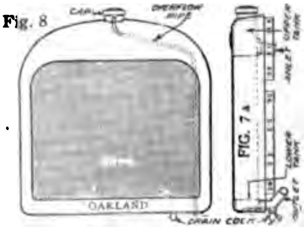

Fig. 8

Fig. 9. Extension or syphon tank (S), used on many thermo-syphon systems to give greater body of water and to absorb steam and to maintain a constant level. A desirable feature on all radiators.

Air Cooling Methods.

Fig. 6. An air cooled cylinder, with radiating flanges. While in motion the air current carries off heat deflected from flanges.

Fig. 7. A forced draught air cooling method. See page 189 for a similar method.

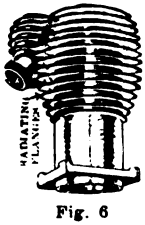

Fig. 6

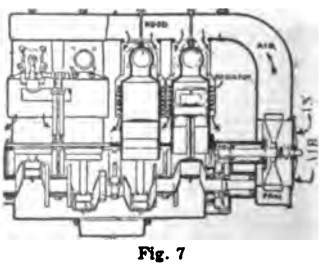

Fig. 7

CHART NO. 96—Types of Radiators. Air Cooling Methods. See page 188 for radiator damper or shutter.

*Also called a honey-comb type, but these are tubular constructions which resemble the cellular, for instance fig. 5D.

To determine if the boiling is due to stoppage of circulation, feel of radiator; it should be slightly hotter at the top than at the bottom, but if clogged there will be a pronounced difference in temperature.

‡Water Boiling.

Water boils at 212 degrees Fahrenheit at atmospheric pressure. For this reason the cooling system of an automobile is so designed that the water is at the temperature of about 170 to 200 degrees under average running conditions.

This leaves quite a margin before the boiling point is reached. **When climbing a hill with a retarded spark the engine naturally becomes warmer** and for this reason the margin is left although as a matter of fact the engine would run at a higher efficiency if the temperature of the cooling water could run higher. If the cylinders are kept too cool, it means that too much heat is being withdrawn from the explosions. On the other hand, if permitted to become too hot, power is lost through:—(a) the entering gases being unduly rarified or prematurely expanded, and thereby containing less combustible material per volume; (b) friction due to the thinning of the oil, and probable binding or seizing of the piston or bearings. **Therefore the best water temperature to maintain** is about 170 degrees. (see fig. 9, page 188.)

Radiator Damper.

Improvements in water circulation are shutters, as per fig. 10, page 188. A very efficient heat conserving device. Engineers saw the futility of putting gasoline into an engine to get heat and at the same time permitting great drafts of cold air to be drawn through the radiator to drive away the heat. Therefore the shutter was devised to retain the heat, especially on starting during cold weather.

††Water Thermostat.

In addition to the radiator shutters, we have the heat "**thermostatically**" controlled, which is another great advance to conserve engine heat. See fig. 2, page 130. In addition to these devices, warming devices have been invented to deflect the heat from the exhaust manifold into the air chambers of the carburetion, as per pages 157 and 159.

Miscellaneous Cooling Troubles.

Water: In localities where pure water is not easily obtained it is well to strain the water through muslin. Soft water is better than hard water, because the latter is apt to deposit a scale on the walls of the radiator. The best water to use is rain water.

It is very hard to tell whether water is hard or soft, but the following may be used with success: Take a quantity of water in the hands and go through the motion of washing. If it is difficult to rub the hands together the water is hard. Ordinary city water is generally hard to some extent, but is not as bad as that which is found in streams. Rain water is very soft and for that reason is desirable for automobile use.

Many automobilists have a rain catcher on the roofs of their garages, while others depend on the old-fashioned rain-barrel. The water should be filtered first, however, if it is taken from the roof, as it is apt to contain impurities. But even with fairly soft water the monthly use of a soda solution will prevent harm (this applies only in districts where the water is unusually hard).

The pump requires no attention, other than to see that it does not become choked by using dirty water. There is a "packing nut" on the shaft, which, if the pump should ever leak around the shaft entrance, should be repacked. This can very easily be done by turning off the packing nut, removing the old packing and rewinding the shaft with a few inches of "well graphited packing" and tightening up the packing nut. The packing should be wound on in the same direction as you turn the nut to tighten it.

The fan requires no particular attention, except oiling. Sometimes the **belt gets loose** and causes the fan to slip and not to turn as rapidly as it should, causing overheating of engine. If this happens, loosen the nut which holds the eccentric arm of the fan, raise the arm slightly and retighten the nut. This will tighten the belt. **Note**—This nut frequently has a left hand thread. Don't tighten too tight as you are liable to crack the fan support. (see page 788.)

†Cleaning radiator: A good way is to dissolve a half pound of lye in about five gallons of water. Strain through a cloth and put in the radiator. Run the engine for five minutes, then draw off the cleaning mixture. Fill with clean water and run the engine again; remove the liquid once more, and finally refill the cleaned cooling system. Avoid the use of more powerful chemicals. Ordinary baking soda can also be used, by mixing ½ lb. to 4 gallons of water. It is best to dissolve the soda in warm water before pouring it into the radiator, otherwise the crystals drop to the bottom. If the cooling system seems to be very dirty as far as scale goes, it would be very wise to run the soda solution through it several times in order that all of the scale will be removed.

It is a good plan to drain the water from the radiator about once a month and refill with clean pure water (soft water, if possible), opening the drain cock and continuing to pour water in after the system fills in order to flush it out thoroughly letting all accumulated dirt, etc., run out. An effective way to do this is to keep on filling the radiator while the water continues to run out below; when the water begins to look clear, stop. Close the drain cock after you are satisfied that the system is thoroughly clean. **Oil must not be allowed to get into the cooling system,** for it interferes with radiation.

Cleaning a muddy radiator: If the air spaces of the radiator become clogged with mud, after driving over dirty roads, do not attempt to remove the mud with a screwdriver, wire, or other metal instrument. Instead, soften the mud with water. The best way is to wash the radiator by flushing a stream of water from a hose through it from the rear. In doing this, take care not to let water get into the magneto, which is apt to be short-circuited in that way.

**Leaky Radiators.

Leaks in the radiator are often hard to reach. They are detected by the steam arising from the water that flows through the leak and down the outside of the radiator. The great facility with which the cooling water will boil after the radiator has been refilled is another clue which, although it is common to all leaks in the system, will lead the operator to the point at which it occurs.

Testing for leaks: see pages 194 and 715.

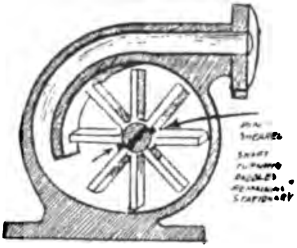
The act of scouring out the circulation system with a strong alkali, such as soda, will sometimes tend to seal up any small leaks, and it might also be effective for a slight crack in a water jacket as the soda, coming in contact with the iron, would form an insoluble filling and prove even better than rusting up the crack.

The standard honeycomb radiator is somewhat prone to these leaks; the metal is so thin and the joints so numerous, and it is not always possible to have a leak soldered up at the required time. In this case recourse can be had to a small useful accessory known as a "**leak preventer.**" It consists of a couple of small plates or washers with a piece of sheet rubber fixed on; these plates have hooks so that a spiral spring can be fixed on to draw them together. The spring is threaded through the aperture at the leaky cell, the plates hooked on, and thus held firmly up against it. Most accessory houses keep them, and if the car has a honeycomb radiator it pays to carry several of these devices. The construction of this type of radiator lends itself to a repair of this kind, but leaks in other forms of radiators, when they occur on the road, are rather troublesome. Even soldering them is by no means an easy job, there being such a large mass of metal that the solder cools as soon as it touches it.

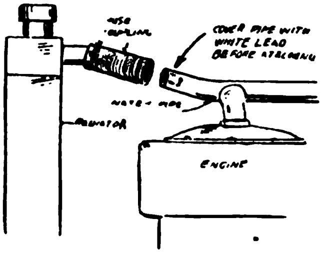
†See page 789. ††See also page 860. ‡Water heats quicker at high altitudes, see page 582.

Many small leaks or drips about the cooling system can be traced to loose rubber hose.

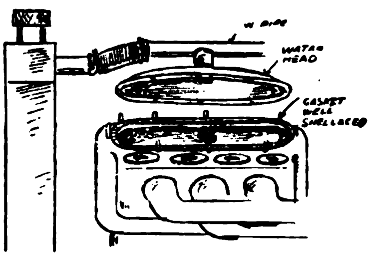
****Small water leaks in the water circulating system** can be stopped by the use of pr[illegible] made for the purpose—see foot note page 715. One manufacturer states that ordinary [illegible] 'th the water will stop a slight leak. The writer has never tried this.



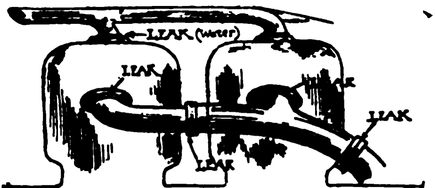
Examine circulating pump shaft and see if pin is sheared; if engine overheats.



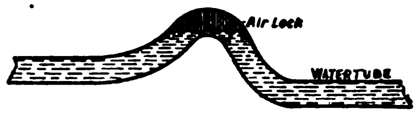
When placing water hose back, put white lead on the end of pipe.



When placing water head casting back on top of cylinder use shellac or white lead on the gasket.

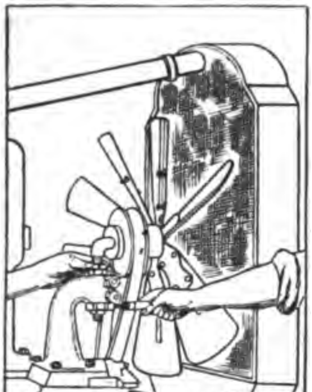


Where the leaks are often found

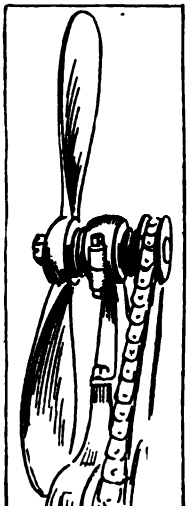


***An air lock** often occurs in the top of an inverted U bend in the water tubing of an engine, which means that almost the whole flow of water has been stopped at that point. No amount of pressure from the water, can dislodge the air, because its only effect will be to compress the air in the top of the bend. The remedy, is either to release the air at the top, by putting in a pet cock, or else to empty the water and carefully refill.

If there are water pipes instead of a casting; use shellac or white lead on the gaskets. Screw up gaskets tight, but not too tight and strip the threads of cap screw.

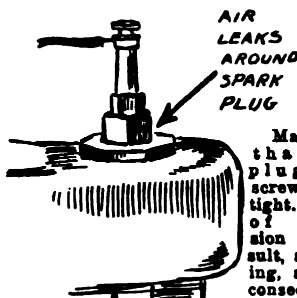


If engine heats, or water boils over, examine the fan belt, see that it is tight and fan runs up to speed. There is usually an adjustment for taking up slack belts. A little Fullers earth on a greasy belt, will make it grip if it slips.



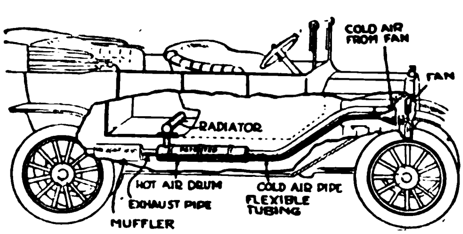
A two-blade fan —called the propeller type.

Use rain water for the radiator, if there is a lot of lime in the water and it is constantly clogging up. See page 191, "cleaning radiator."



Make sure that spark-plugs are screwed in tight. Loss of compression will result, and missing, a natural consequence.

Heating the Car. There are Three Heating Principles:



(1) hot water; (2) exhaust gas; (3) hot air. The two former mentioned are explained in chart 98.

The Brickley hot air heater takes the air from the fan through a funnel opening, and a flexible metal hose; drives it through a metal jacket 24 to 30 inches long, which covers the "piping hot" exhaust pipe, and warms it thoroughly. Then drives it through a 1½-inch opening in the floor of the car, into a tubular register, along the back edge of the front seat; sending a continuous stream of heated air into the car. (Exhaust gases not used.)

CHART NO. 97—Cooling Troubles and Remedies Illustrated: Fans. Heating a Car.

*When filling radiator which is empty, open pet cock on water pump for a moment to prevent air pocket.

Another plan is to carry a small box of white lead of a suitable consistency. If the water is not coming through quickly, a temporary repair can be made with this, especially if a piece of tape can by any means be bound over the repair. It is often possible to hammer up or plug a leakage in a tank or radiator.

Watch for rotten appearance

††The rubber hose and its connections are often a source of leaking. When the hose is worn it will become ragged-looking on the outside. The rubber which surrounds the fabric will commence to have a torn appearance and the water will seep through the fabric. There are two ways of remedying this; one is renew the hose and the other is to repair old hose. The first is the better and more permanent repair. In doing this a piece of hose of the same thickness and length as that now in place is secured. The clamps which hold the hose in place are removed. The new hose is slipped in place and the clamps put over it and screwed up tightly, if they are of such a type that they are secured by a small bolt. If not, the operator will do very well to obtain same. The cost will be small and they are easily removed, being far better for this work than wire or any similar contrivance. Paint all threads of water pipes with white or red lead.

Cylinder leaks: A slight leakage of water from the jacket into the cylinder may be caused by a crack, but more usually will be found to be simply a defect in the seating of pipe plug fitted in the heads of many engines.

***A crack in cylinder**—when on the inside, is difficult to locate. Its action may be of such a nature as to be only operative when the engine is at full working heat; due of course to the expansion. It is generally accompanied by misfiring and boiling. The former owing to leakage of water into the cylinder and the latter owing to the exploding gases (at a very high temperature), being forced into the water jacket.

The best means of detection, is to fill radiator entirely to top of cap, run the engine till hot, then stop it and turn it over by hand against the compression in each cylinder, if there is a crack: bubbles will appear at the cap. So by noting the compression of each cylinder, the defective one can be located.

Slight leaks inside of cylinder have been remedied by rusting if the hole is very small. See page 718, "rusting a hole in cylinder."

Gasoline leaks: A temporary repair for a slight leak in a gasoline tank can be made by applying ordinary soap. Such a repair may last till the defective part can be soldered. Leaks at gasoline taps can generally be cured by screwing up the nut securing the tap plug, or by grinding in the tap with crocus and oil.

Cold Weather Precautions.

In winter, a water cooled engine must be carefully guarded against freezing, for if the water freezes in any part of the system it will cause the breakage of piping or radiator, or crack a water jacket. When the engine is running, the water is kept warm, therefore no danger; it is when engine is stopped that care must be taken.

When leaving the car for several days, during cold weather, the safest plan is to drain the water out of all parts of the system, cocks being provided for the purpose at the lowest point of the system, usually at the bottom of radiator. The engine should be run for a few minutes to make sure all the water has been removed.

†Non-Freezing Solutions.‡

To prevent the water from freezing when it is not desirable to drain it out, either wood alcohol, denatured alcohol or glycerine may be mixed with the water. The alcohol mixture is as follows:

Wood Alcohol and Water.

10° above zero; 80% water, 20% alcohol.

Zero; 75% water, 25% alcohol; sp. gr. .969.

7° below zero; 70% water, 30% alcohol; sp. gr. .963.

22° below zero; 60% water, 40% alcohol; sp. gr. .951.

If denatured alcohol is used, increase percentage in above table by approximately 15.

For evaporation—use 75% alcohol to 25% water—as the alcohol evaporates quicker. This does not apply to loss by leaks or boiling over.

A hydrometer can be used for mixing and maintaining correct solution, by first testing the original and keeping it up to a standard. Denatured alcohol is recommended in preference to wood alcohol as the boiling point is 10° higher.

Glycerine and Alcohol.

30 to 15 above zero:	
Alcohol	10%
Glycerine	10%
Water	80%
Not lower than 5 below:	
Alcohol	15%
Glycerine	15%
Water	70%
Not lower than 15 below:	
Alcohol	17%
Glycerine	17%
Water	66%

Where glycerine is used only alcohol need be used for evaporation, which should be added occasionally. The glycerine does not evaporate with the water. A simple solution of alcohol, while it is not injurious in any way, lowers the boiling point of the water. Consequently on warm days, with the car standing and the engine running, the solution will tend to boil easily and evaporate. The boiling point of denatured alcohol is about 10 degrees higher than that of wood alcohol.

**The use of glycerine raises the boiling point of the solution. It is more expensive than alcohol, (a pound of glycerine costs 88½c. There are 8 lbs. to a gallon) and is slightly injurious to rubber. A combination solution of alcohol and glycerine in water is most satisfactory but expensive.

There are three grades of alcohol; denatured which is a disguised grain alcohol of first still, (not suitable as a beverage). It sells for $1.05 per gallon and has a higher boiling point than wood alcohol. Wood alcohol sells for $1.60 per gallon and has a lower boiling point. The high proof or double still grain alcohol used as a beverage is too expensive. Therefore, denatured alcohol is cheaper and the proper thing to use. **††Alcohol boils at 172°.** Therefore don't overheat engine.

Calcium chloride or any alkaline solution, is injurious to metal parts.

If calcium chloride is used, then the proportions are: 3¼ pounds to a gallon of water for zero weather, and 4 lbs. for 17° below. In using calcium chloride it is the acid in it which attacks the metal. This can be neutralized by adding ammonia or soda ash until blue litmus paper no longer turns red when dipped into solution.

If the cooling water should freeze; the usual indication of a frozen radiator is steaming excessively. It would appear that the steam or heat would thaw it out and start the circulation again, but such is not the case. When the water freezes don't run engine to try and start circulation. Find the nearest warm garage and, if possible, turn hot water onto the bottom of radiator until steaming ceases, as a radiator in this instance usually freezes at the bottom first. (See bottom of page 788.)

In addition to non-freezing solution, it is always well, when making a stop, to cover hood and radiator.

Also draw in a full charge of gas by speeding up engine and opening throttle before stopping.

In carbide gas lighting generators using the water drip, a suitable non-freezing solution is alcohol and water, same proportion (no glycerine).

*See pages 713, 715. ††See page 585 "freezing point of gasoline, alchohol," etc. **Prices not now correct.
†**Anti-freezing powder** is used extensively. Sold by all supply houses. **Kerosene is not suitable for non-freezing** for reasons given on page 585. ††On airplane engines, where hose connection is made to the pipe it is not only connected with a connector, but connection is taped and shellaced. ‡**Be sure that the radiator does not leak** and that hose connections are tight before putting in non-freezing solution.

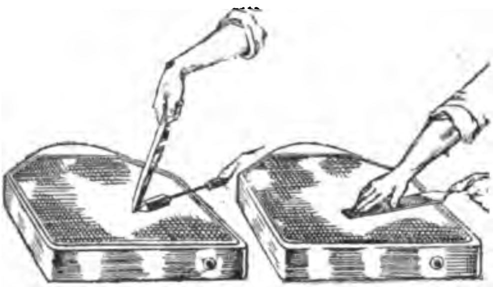
Radiator Leaks.

Testing for leaks. It is hard at times to detect the exact spot at which a leak occurs in a radiator. The best plan is to remove the radiator from the car and plug up all but one opening, then run the tube of a tire pump through a cork and then place the cork in this last opening.

Place radiator in a tub or box which will hold water and submerge the radiator as per illustration. Then pump air into radiator. Bubbles will issue from the point of leakage. The leaks should be marked and radiator removed from the water.

The next procedure is to determine if the radiator is a tubular or cellular type, by studying page 190. Then read pages 714, 715 and 789 and proceed with the repair.

Remember, when soldering parts of the radiator that the metal must be scrupiously clean before the flux is applied or else the solder will not hold.



After completing the soldering, file smoothly and then place radiator in the water and again test it with air pressure in order to see if the leak is properly repaired.

Small leaks are dealt with on pages 191, 193 and 715.

Painting a Radiator.

It is very difficult to paint a radiator quickly and thoroughly with a paint brush, and the usual plan, where a great deal of the work is done, is to dip the radiator in a paint solution. A very satisfactory job can, however, be quickly done with a spraying outfit. A very simple and home-made device is here illustrated.

It consists simply of a construction such as is shown in fig. 4, in two sizes and designs, which comprises a can (D) for the paint, consisting of a mixture of lampblack and turpentine, a hollow cylindrical tin handle (B) attached to the can, an air pipe (A) passing through the handle and through can, as indicated by the dotted lines; and another similar pipe or tube extending downward at right angles from the one end of the horizon-

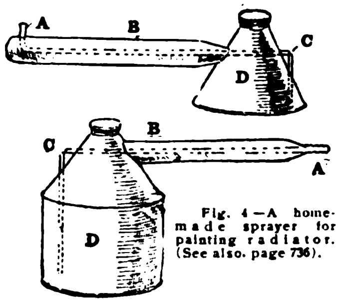


Fig. 4—A home-made sprayer for painting radiator. (See also, page 736).

tal tube into and near to the bottom of the can, as is also indicated by dotted lines. This is merely an adaption of the principle employed in most atomizers.

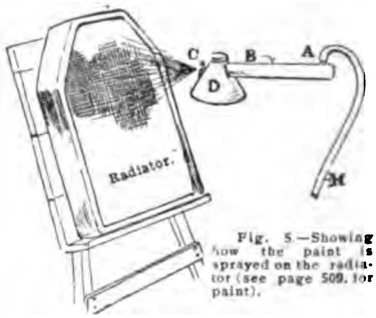

Fig. 5—Showing how the paint is sprayed on the radiator (see page 509, for paint).

When a stream of air is forced through the air tube (M and A) passing through the handle and directed across the opening (C), at top of the vertical tube the fluid from the inside of the can is drawn up and sprayed onto the radiator. It is best to tilt radiator when spraying, so solution will drain off.

Heating a Car.

There are three methods of heating a car as explained on page 192.

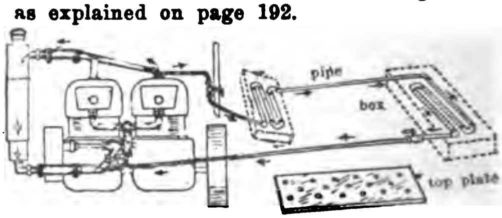

Illustration shows the hot water method which can only be used where there is a forced or pump circulation system. Connections are made with the circulating system at the top of rear cylinder and circulated through the heater, whence it returns to the bottom of the radiator.

The heater is made of regular water pipe and the housing of aluminum or light cast iron. The floor is cut away, allowing the surface of the heater to be flush with the floor. The top plate, made of aluminum is then placed over the heater box.

The exhaust method for heating is to utilize the exhaust gases instead of water. In this instance the pipes would be connected with exhaust pipe instead of the water pipe. Only one side, the inlet would be connected and an outlet is provided for the emission of the gas.

The hot air method is shown on page 192.

CHART NO. 98—Testing a Leaky Radiator (see also, pages 714, 715, 789). **Painting a Radiator** (see also, pages 194, 509, 736, 584). **Hot Water Heating of Car.**

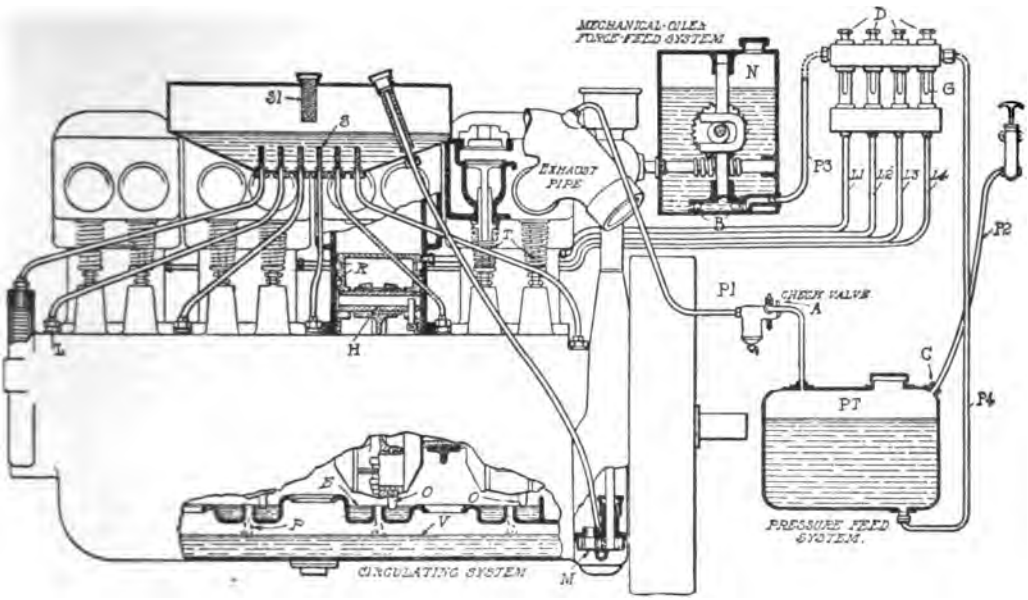

Fig. 1. Some of the early methods of engine lubrication. There are four different systems shown on this engine in order to clearly explain each system. The systems are enumerated and described below.

Explanation of the Four Engine Lubrication Systems—Above.

First: We will follow out the splash system; we will assume oil is placed in crank case **through** breather pipe. The scoops (O) on end of connecting rods pick up the oil from troughs (E), and splash it to the various parts.

Second: Force feed, splash and gravity. We will assume the splash system just described is a part of this system. The overflow passes to reservoir (V), it is then forced by pump (M) to a gravity feed reservoir placed on top of engine. The passage is then through the different pipes (S to L) to the bearings, thence back to the troughs (E) and reservoir (V). This system would also be termed a circulating system, as the oil is in continual circulation.

Third; Separate forced feed and splash. The mechanically operated pump is driven by belt, chain or bevel gears. There are several small pumps under the oil reservoir box (N), in fact a pump for each feed; each separate feed is piped to the different parts to be lubricated. The oil passes through a sight glass (G). The oil then passes to bearings and falls to bottom of crank case. The oil reaches a level or height in the crank case so that the connecting rods give an additional lubrication by splash. The amount of oil fed is regulated by drops, through the sight glasses, by the regulation of the screws (D), and depends upon the size of engine and speed. (Note—pipe (P4) is not connected with this system.) This would be termed a non-circulating system.

Fourth: The exhaust pressure feed and splash. This system consists of an air tight oil tank or reservoir (PT). A small pipe (PI) connects the tank with the exhaust pipe. A check valve permits the gas pressure to pass into tank but not to flow back.

The initial pressure is given to the tank by a small hand pump through pipe (P2). After engine is started, the pressure from exhaust is sufficient to force the oil through pipe (P4) to sight feed glasses, thence to the various parts to be lubricated—thence to crank case.

This system, like the third system, requires oil to be fed by drops as it is not pumped over and used again and would be termed a non-circulating system.

CHART NO. 99—Engine Lubrication Systems. The above explains some of the original systems of oiling. The modern systems are explained farther on.

INSTRUCTION No. 15.

LUBRICATION: Different Engine Lubricating Systems. General Lubrication. Lubrication Troubles. Carbonization. Oil Pumps. Oil Pressure.

Purpose of lubrication: When two parts of a mechanism rub together, it is necessary to use some means of preventing excessive friction, and this is usually done by applying lubricating oil between them. Without a lubricant the friction would cause heating, and the result would be cuts or scratches on the surfaces of the two parts.

Two parts intended to rub together, like a shaft in its bearing, should be made as smooth as possible, for roughness would cause friction that lubrication could not prevent. The more rapid the movement of the parts against each other and greater the pressure the more they must be lubricated.

A bearing in which a shaft is turning at a constant speed requires a constant supply of oil which must be fed to it regularly as required. Too much oil would be wasteful, and too little would permit the bearing to become heated. All the moving parts of an automobile must be lubricated, but as some parts move much more than others and are subjected to greater strain and pressure, the kind of lubrication must be varied to suit these conditions.

Engine Lubrication Systems.

The principal parts of an engine to be lubricated are: **main shaft, cam shaft, crank pin and wrist pin bearings; cylinder walls; piston** and **piston rings; valves; push rods,** etc.

Methods of engine lubrication may be divided into two general classes; the "circulating" and the "non-circulating" systems.

The circulating systems would be represented by systems having a continuous circulation of oil and is frequently termed the "pump over" system. For instance, a system using a force pump for pumping the oil from the lower part of the crank case to the upper part, with a drain back to the lower part again, would be termed a "circulating system."

A non-circulating system, such as a drip or gravity system, or a mechanical feed; so many drops per minute, depending upon the speed and size of the engine, with no provision for circulating the oil again, would be termed a "non-circulating system."

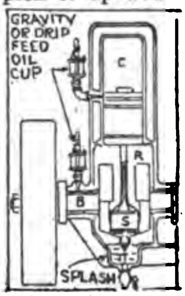
These systems may be combined, which is frequently done. For instance, the combination of a "force feed" and "splash" system.

But speaking generally, the systems can be grouped under: (1) splash and (2) force feed lubrication.

Drip (or Gravity Feed) and Splash.

This non circulating system consists of a drip or gravity feed oil cup placed over the bearings and also on side of cylinder. Special oil cups are required for the cylinder which will prevent the compression, interfering with oil entering side of the cylinder wall.

The oil drips by gravity and the surplus flows to the oil trough from where it is picked up by the connecting rod and splashed to parts above. C is the cylinder and B the bearings. S is the crank pin. The oil in the lower part of crank-case is kept at a sufficient level for the connecting rod to pick it up and splash. The filling is done once in a while as required, by pouring the oil in by hand.



The oil cups feed by drops and usually the manufacturer determines how many drops per minute are required.

The oil flow is not controlled by the engine, and each cup is therefore provided with an adjustment, whereby the feed may be regulated when the engine is running, and turned off when it is stopped. This would be classed as a "non-circulating system."

This system is used extensively on two cycle marine engines, and stationary engines. Two cycle engines are also lubricated by mixing the oil with the gasoline through the mixing valve, the mixture being about one pint of oil to five gallons of gasoline.

The Splash System—non-circulating.

The true splash system alone is non-circulating.

The crank case is made oil tight, and oil is placed in it to such a depth that the bottom end of the connecting rod dips into the oil, and splatters it to all parts of the crank case, the bearings, and the lower part of the piston. An oil groove is some-

*See "Specifications of Leading Cars" for the type of lubricating system used on leading cars.

times cut around the lower part of the piston, and the oil splashing into this is carried upward and distributed on the cylinder wall and rings. There are no oil troughs in this system.

As the oil is used, more must be added to the crank case to keep the necessary level. This is done either by means of (1) a hand pump connecting the crank case to an oil tank or (2) by an oil cup that drips a certain amount of oil into the crank case every minute, or (3) by filling through a breather pipe.*

With the hand pump, the driver gives it a stroke or two every few miles, experience being his guide as to how often and how much. This latter system, however, is not much used on automobiles, but is extensively used on motorcycles. This system would be termed a non-circulating system.

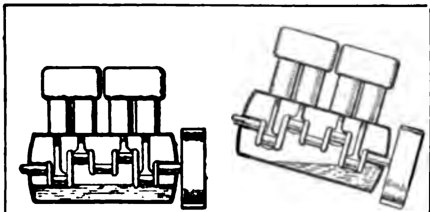


Fig. 1. Fig. 2.

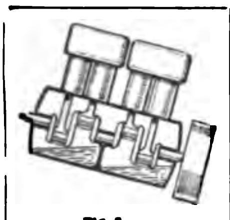

Fig. 3.

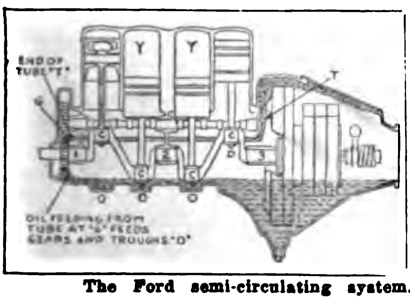
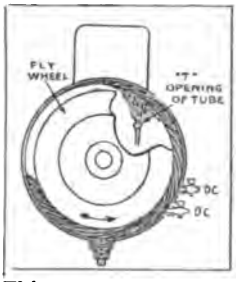
The objections to the splash system are as follows; refer to fig. 1—note the engine is in a level position. As long as the engine remains level the splash system gives fairly good satisfaction, so long as the level of the oil is kept up to the lowest point of the connecting rod where it can be picked up and thrown to the upper part. If, however, the car is in such a position the engine will be tilted, as shown in fig. 2, then the oil goes to the rear cylinder. The rear cylinder is **over** lubricated and the others are **under** lubricated. Even though a "baffle" plate is placed as shown in fig. 3, still there is one cylinder minus oil. Therefore some other means must be employed so that all cylinders will receive their proper share of oil.



The Ford semi-circulating system.

Splash System—semi-circulating.

One method of overcoming this latter mentioned objection is to provide **troughs** (O) under each connecting rod, which is shown in the cut of Ford engine. The troughs retain the oil, even though engine is at an incline. The next method is to keep the oil at a **constant** level in the troughs. This is accomplished by some means of **circulating the oil.** In this instance the constant level of oil is maintained by the action of the fly wheel.



The fly wheel throws the oil to the top of the transmission case where part of the oil is caught by tube "T" and fed by gravity to the cam gears. The overflow coming back tends to keep the troughs (O) filled with oil. This system would be termed a semi-circulating system (used on the Ford engine).

****Splash System**—circulating.

This system could be termed a "circulating splash system" also a "pump over" system and is the true **constant level, circulating splash system** because the oil troughs are kept at a constant level by a pump. Could also be termed a "force feed and splash" system.

The operation of a "circulating" or "pump over" oiling system is shown in fig. 6; the main oil supply is contained in the reservoir (R), from which it is drawn by the pump (M) and forced through the pipes or leads (L) to the main crank shaft bearings (G).

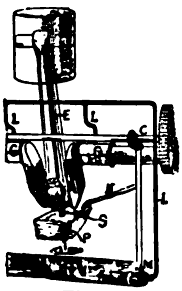


Fig. 6.

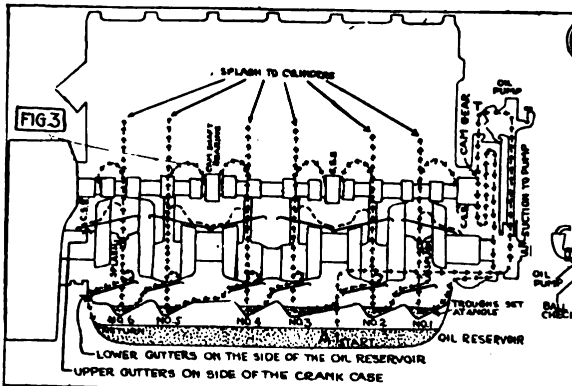
The overflow from these bearings is thrown by centrifugal force against the walls of the crank case and cylinders and, as it runs down, is collected by inclined channels (N) which conduct it to troughs.

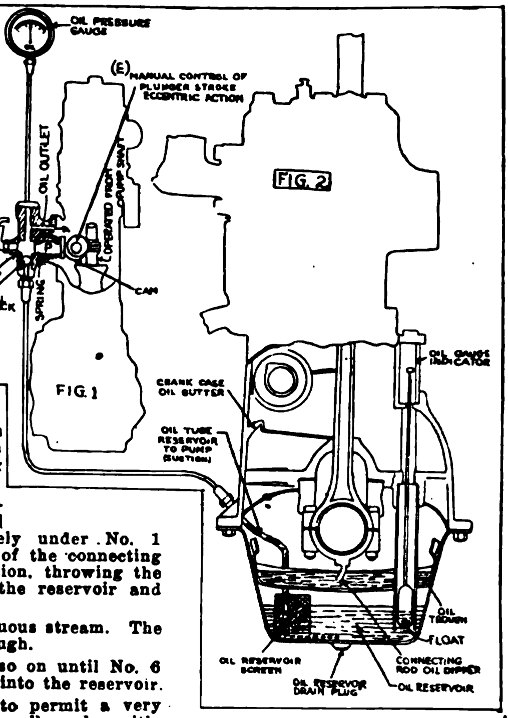
For lubrication of the connecting rod bearings, scoops (S) are fitted to the lower ends of the connecting rods, which dip into the oil contained in the troughs and scoop it up into the crank pin bearings at the lower ends, and through tubes (E) running up the rods to the piston-pin bearings.

Overflow pipes (P) are provided in the trough so that the excess oil can return to the reservoir (R).

The pump (M) is usually a gear type of pump, operated by bevel or spiral gears and vertical shaft from the cam shaft C. On many engines the pump is a plunger type operated by a cam from the cam shaft.

*A breather for an engine (see Studebaker, page 71), is a pipe opening connected with crank case, where oil is poured into crank case. The opening is closed by a cap which does not fit tight, but allows the air to enter, and at the same time prevents oil from working out. **The depth of oil in oil-pan of an engine using the splash system should be just enough so that the splash will distribute the oil.





Figs. 3, 1, 2: Method of circulation of the Hudson Super six "circulating-splash system:" The oil is taken from the pressed steel reservoir at (A), straining all of it through a filter or metal screen of fine mesh.

The oil is fed directly into the front compartment containing the timing gears at (T) and their bearings and flows from this into the first oil trough immediately under No. 1 cylinder (see fig. 3). The large splasher on the end of the connecting rod practically empties the oil trough at every revolution, throwing the oil into suitable channels or gutters on the side of the reservoir and crank case.

The upper gutters feed the main bearings in a continuous stream. The lower gutter feeds the oil directly into No. 2 oil trough.

The splash from No. 2 oil trough feeds No. 3, and so on until No. 6 oil trough is reached, at which time the oil flows back into the reservoir.

The connecting rod dipper is sufficiently effective to permit a very high level being maintained, thus insuring lubrication on all grades without excessive oil consumption. The two center bearings are fed by two troughs each.

The front bearing is fed from the timing gears and one trough, and the rear bearings is fed by two large troughs. It is apparent that all oil which enters at the front end must circulate through the various troughs to the reservoir again (see page 200).

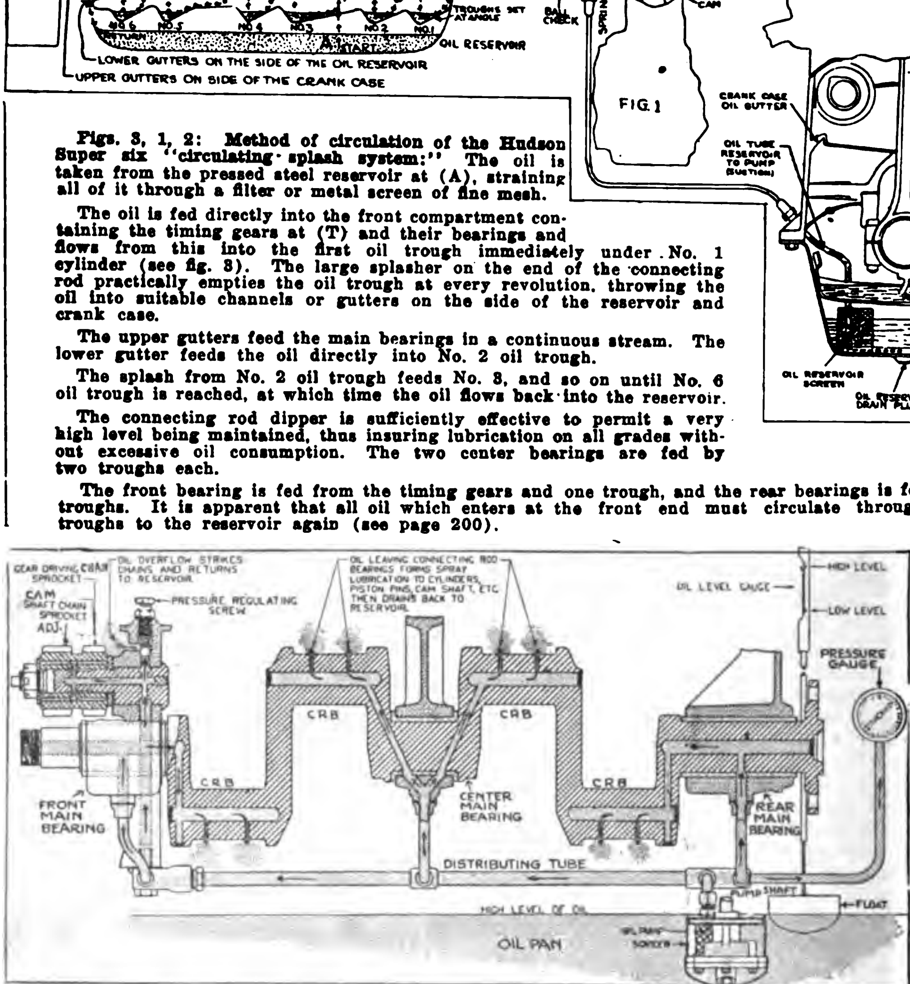


Fig. 4: Method of circulation of the King "Force Feed System:" There are no troughs or splash with this system.

Oil poured into the filler tube, flows down into the oil pan, filling it up to a height indicated by the oil level gauge on right-hand side in center of engine. From the pan or reservoir the oil is drawn up through the oil pump, which is driven by a vertical shaft from spiral gears on the camshaft. The oil pump itself is surrounded by fine screen so that all oil entering the system is thoroughly strained to remove the dirt or lint that might stop up the oil ducts and cause damage. The illustration shows the principle of the system, and by following the arrows the oil can be traced from the reservoir to the various parts of the engine.

The gear pump at the extreme bottom of reservoir draws the oil through the screen which surrounds it and forces it into a **distributing** pipe running the entire length of the crankcase. From this pipe the lubricant is forced to each of the three crankshaft main bearings.

From the main bearings the oil is forced through holes in the crankshaft to the connecting-rod bearings. Since, at every revolution of the crankshaft, these holes register with the leads from the distributing pipe, an excess of oil is forced to the connecting rods. where it is drawn off in fine drops or mist onto cylinder walls. A part of this spray, is also utilized for lubricating camshaft, valves, tappets.

Principle of adjustment of the "spring and ball" valve; the ball is placed in the path of oil line with a spring tension behind it. When pressure of oil circulation is reached, to which spring tension is adjusted, the ball is forced open and oil overflows past hole; in this instance, to the chain sprocket. In other words it is merely a "relief-valve." (see page 200.)

CHART NO. 99A—Example of Two Modern Engine Lubrication Systems: The "Circulating Splash" (Hudson as example) and the "Force Feed" System (King).

*Note the "eccentric" movement of cam for adjusting the pressure on the Hudson, and the "ball and spring valve" on the King. Also see page 694, for Adjusting Hudson Oiling System.

Force Feed System.

Oil is forced by pressure from oil-pan by a pump, to crank-shaft bearings, then through drilled holes in crank-pins, per King system, page 198. **Oil is not forced to piston-pin, piston and cylinder,** but these and other parts are supplied by oil thrown from the crank-pin bearings. The connecting rods do not dip.

Full Force Feed System.

Oil is forced by pressure from oil-pan by a pump, to crank-shaft bearings, then through drilled holes in crank-pins, per fig. 4, this page. **Oil is also forced to connecting rod upper part, or piston-pin** through channels or pipes, thence out piston-pin to wall of cylinder. **Thus the difference between the "force" and "full force" system.** The connecting rods do not dip.

Note the dotted lines showing the path of the oil. (A) is the oil reservoir. (B), piston or gear type of pump, (C), eccentric or gear for operating pump. (G), gauge placed on dash to indicate the pressure, (F), check valve, (D) is a strainer.

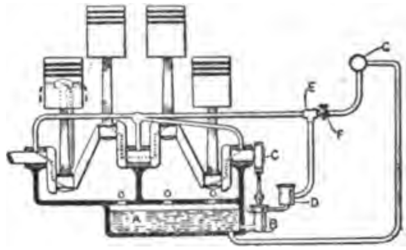

Fig. 4—Diagram of a "full force feed" system.

This would be termed a true "full force feed" engine lubrication system.

Oil Pump and Oil Pressure Gauge.

The Oil Pump.

There are two types of oil circulating pumps in general use. The gear type, fig. 1 and the plunger or piston type, fig. 2.

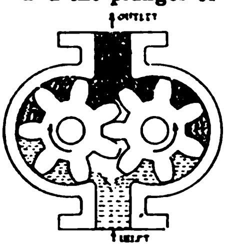

Fig. 1.

The gear type (fig. 1) can be operated by chain, but is usually operated by a shaft, through bevel or spiral gears, as per fig. 6, page 197.

The plunger type (fig. 2) is usually driven from the cam shaft, by an eccentric, and on marine engines instead of utilizing the cam shaft, the pump is sometimes driven from the crank shaft, fig. 4.

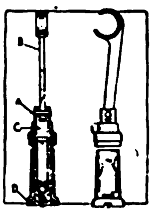

Fig. 2.

The adjustment of this type pump is made by screwing the plunger-rod (O) **in**—(this shortens **the stroke**); or **out**—which lengthens the stroke). This lengthening or shortening of the stroke, has the effect of regulating the flow of oil. The longer the stroke, the more oil flows and vice versa.

A modification of this type is shown in fig. 1, page 198 — note the plunger is shorter and is operated by a cam or eccentric movement. The cam forces the plunger in and a spring forces it out again, thus creating a suction effect which draws the oil from the lower reservoir.

Oil Pressure and Gauge.

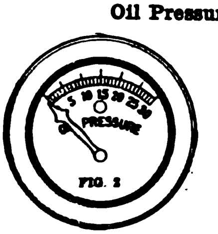

Fig. 2. Oil Pressure Gauge

This is a gauge placed on the dash board (see page 188), which shows the oil pressure. The normal on the Packard is 20 to 30 lbs. at 1000 r. p. m., engine hot. On the King, 15 to 20, on the Pierce-Arrow, 3 to 4 lbs. at lowest speed — to 35 lbs. at highest speed (50 m. p. h.); Cadillac, 5 to 7 lbs. when idling.

If the indicator needle on gauge drops to zero, it indicates oil level is low or for some reason oil is not circulating. In cold weather it may be an indication, that the cold test of the oil you are using is not sufficiently low and that the oil has congealed to a point where the pump cannot draw it from the oil pan. Do not under any consideration continue to run the engine if the hand on the cowl board vibrates or returns to zero or if it remains at zero after starting the engine.

The amount of pressure varies with the speed, temperature and viscosity or thickness of oil.

When the engine is cold, the pressure will be higher until the oil thins down. An excessive pressure on the gauge may also indicate the clogging of the system.

In other words, maximum pressures will be indicated at given speeds when the engine is cold and the oil is fresh; minimum pressures, when the engine is hot and the oil becomes thin.

Practically all engine lubricating oils become less viscous from use even under normal conditions. Running the engine too long with the "choker" control lever pulled back will cause the oil to be thinned more rapidly, due to the condensation of gasoline from the rich mixture. See page 205.

Too high a pressure will cause abnormal oil consumption. This should be adjusted according to the pressure recommended by the manufacturers (see page 542). **Always adjust when engine is hot.**

Regulation of Oil Pressure.

There are two general methods; (1) by an "eccentric" movement as per fig. 1, chart 99A, and by the adjustment of a "spring and ball" valve as per fig. 4, chart 99A.

If gauge does not show pressure: Make sure that the oil pan contains plenty of oil, as shown by oil level indicator. Should this show "full," remove priming plug on top of the pump and start engine. If oil flows from this, the pump is working and the trouble is with the gauge.

Priming the pump: In case you think that the pump is clogged it is a good plan before taking it down to try priming it with the same kind of oil that you put in the crank case. To prime the pump, remove the plug, pour in oil until it fills, replace the plug and start engine. If priming does no good then it will be necessary to clean the pipes in order to find the obstruction. It is also advisable to occasionally clean the oil strainer.

When the pump is taken down it must be primed with oil, after replacing.

†Should at any time the oil gauge show full pressure when running at a slow speed, foreign matter has become lodged in your distributor pipe, and you will have to proceed as follows:

Take off oil pan, remove oil pump by removing cap screws which are usually accessible through the holes in the clutch cone and flywheel. The distributor pipe may then be drawn back through the opening left by the pump, and it should then be blown out with air pressure.

If the system is a splash system as well as a forced circulating system, it is possible to drive in, but be sure there is plenty of oil in pan.

†Sometimes high gauge pressure is due to cold weather and heavy congealed oil. If after engine is warmed up the pressure is excessive and the regulation does not vary it, then it can be attributed to clogged pipes.

Example of Modern "Circulating Splash" System—See chart 99A.

A modern engine lubrication system combining the splash and pump circulating system is shown in illustration figs. 1, 2, 3—used on the **Hudson super six.**

Oil pump; plunger type, mounted at front of engine and driven by a vertical shaft from crankshaft.

Regulation of oil pressure is governed by the speed of engine. An "**eccentric**" (E) is connected with the carburetor throttle. This keeps the cam from operating on the plunger: should the regulation be set so oil gauge registers 1 to 1½ degrees of pressure when engine is running slowly. By this we mean at speeds from 10 to 20 miles an hour. (see also page 694.)

As the throttle is opened, the eccentric is turned away from the plunger so as to allow it a greater amount of travel from the cam action. When the throttle is wide open, the eccentric should be in such a position as to permit a full travel of the pump plunger. By this adjustment, the oil pressure shown on the gauge will gradually increase as the car speed increases. It should register 3 to 4 degrees at 30 miles, per hour.

If gauge does not show this amount as above, the pump mechanism should be investigated. Upon indication of a pump being inoperative or gauge needle shows no movement, make sure there is plenty of oil in reservoir and engine is getting lubrication by splash, and run irrespective of the pump, then you can drive in carefully and have the system examined.

The oil reservoir on the Hudson contains over 8 gallons of oil in the troughs and in the reservoir itself. It is fitted with a float indicator which shows the level of the oil by means of a red button working in a glass tube. This is on the left-hand side of the engine. See fig. 2, chart 99A.

Example of a Modern "Force Feed" System—See chart 99A.

The principle of operation, is explained in lower illustration in chart 99A and the text pertaining thereto refers to the King car.

The pressure regulation which differs from the Hudson is explained below.

Oil pressure regulation: The pressure of the oil in this force feed system is controlled by a "**spring and ball**" valve located on the front right-hand side of the crankcase. The valve is provided with an adjustment which should not be tampered with unless the pressure drops below 5 lbs. or raises above 20 pounds, when the engine is speeding up.

To regulate, loosen lock nut and turn pressure regulating screw to the **right to increase the pressure,** and to the **left to decrease** it—see page 198.

Over lubrication: If the oil pan at any time contains more than *seven quarts of oil, the connecting rods will dip and thus create a splash which will over oil the pistons and cylinders, more on the right-hand block than the left, causing smoke to issue from the muffler pipe.

If the engine smokes, drain oil pan and measure its contents, as the oil level gauge may be stuck. If the oil pan does not contain more than the right amount, the oil is probably pumping past the pistons, due to worn or stuck piston rings. If this is the cause, new rings should be fitted at once.

Also remember that the use of too light a grade of cylinder oil is apt to cause engine to smoke. (The King Co. recommend "Mobiloil Gargoyle A.") Always clean screen and oil pan, washing with kerosene after draining dirty oil. (See "cleaning crank case," page 201.)

**The Kind of Lubricating Oil to Use.

At the present time most lubricating oils are straight **mineral** oils made from different distillates of petroleum.

A good high grade gas engine oil is necessary because the heat inside of an internal combustion type of engine will burn the oil, leaving nothing for lubrication—hence wear. Therefore nothing but a high grade oil will answer, one which will stand up under high †temperature of the cylinders without thinning down.

Another point to consider; if rings are tight and compression is good, then it is possible to use a light weight oil so it will splash readily. A light weight oil, under heat, can hold its body and will lubricate

**The chart of automobile recommendations, issued annually by the Vacuum Oil Co., Rochester, N. Y., specifies the correct grade of oil for each car and model for the last five years. It is free.

*Amount varies on different cars. This is for King, model E. †Studebaker instructions.

†Maximum temperature in cylinders, at top of explosion stroke is approximately 2700° F.; the minimum temperature during suction stroke, about 250° F.; average temperature during the four strokes, about 950° F. These are temperatures in the cylinders to which the outer side of oil film is exposed to.

just the same as good heavy oil, if proper quality.

Some engines require a light bodied oil, others a heavy oil: Sometimes the heavy bodied oil may appear to hold its body or consistency but under heat it will thin down considerably whereas a light bodied oil will hold its consistency equally as well.

Note—any oil, no matter how thick or heavy, will thin down to a certain extent when heated.

Where multiple disk clutches are used which run in oil it is very important that a light bodied oil be used, else the plates will have a tendency to drag by sticking together.

If piston rings leak, which naturally lowers compression, then too light an oil will pass into the combustion chamber where the fire and flame will rapidly turn it to carbon, causing this carbon to stick to the valves, combustion chamber and spark plug. Consequent result is loss of oil, fouled spark plugs and carbon deposit.

The proper oil to use is generally recommended by the maker of a car. The object has been to secure an oil that leaves no carbon deposit and that at the same time gives uniform complete lubrication. It must hold its body and form a **lasting film** on the wearing surfaces. If it thins down too much, it will leave the bearing without lubrication (see also, page 205, bottom).

****A difference in oils is shown by their "flash points" and "burning points."** When a lubricating oil is heated to a certain point, it will give off a thin smoke, if a lighted match is touched to it, the smoke will take fire with a quick flash. This is called the "**flash point.**" On heating the oil still more, the oil itself will finally take fire and burn, and the temperature that will permit this is called the "**burning point.**" The flash and burning points are much higher in some oils than in others.

If oil with a low burning point is used in the cylinder of a gasoline engine, the intense heat will burn it before it can lubricate the cylinder walls and piston. If oil of a **sufficiently high burning point is used**, the temperature of the cylinder will not be high enough to burn it, and the cylinder walls and piston will be properly lubricated.

One simple method of testing—drain oil which has been used in engine, into a long narrow tube—let it stand 24 hours. If good oil it will show a small amount of black sediment at bottom; but floating above it, the sediment is red in color (by transmitted light).

Let a poor oil be tested, which is used under same conditions. At the end of a few minutes it will turn to a dense black. After standing 24 hours it will show a voluminous black sediment several times greater than that of good oil.

Black sediment indicates sulphur compounds in the oil. Sulphur is injurious to bearings due to lack of lubricating qualities; also pits the valves causing leakage of compression.

Using Oil Over Again, Adding Fresh Oil, Cleaning Crank Case, Etc.

Using cylinder oil over again. The cylinder oil which is drained from the crank case of an engine having a circulating system, after every 1000 miles of use, may be used for the gear set if it is strained through a filter, and is good oil to begin with.

It is then mixed with grease. The oil is merely charred and is slightly stringy from the wax which has been formed in it. This wax-like consistency is the very qualification necessary for a gear lubricant in that it holds the oil to the gear. The oil should be drained in a pan, mixed with grease until the mass assumes the consistency of the regular transmission lubricant familiar to all automobilists, being neither liquid nor solid.

Adding Fresh Oil.

It is important to note that fresh oil of another make should not be added to the oil pan before thoroughly washing out the old oil. Clean, good oil put into a dirty engine with gummed-up bearings has simply no chance of asserting its superiority under the unfavorable circumstances. It has first of all to get rid of the gumming round the bearings before its lubricating qualities will be manifested.

*Cleaning Crank Case.

The system should be drained every thousand miles by removing the plug in the bottom of the oil pan. After the dirty oil is drained off, the plug should be replaced and about one gallon of kerosene poured into the oil pan through the filler tube. With ignition switch "off" so the engine will not start, press in on the starter button and allow the starting motor to crank the engine for about one minute.

Also step on the running board and rock the car back and forth. This will allow the kerosene to wash the interior of the engine thoroughly. Remove the drain plug again and drain off all the kerosene. Clean strainer.

It is very important that the kerosene be entirely drained, for if left in engine it will thin the fresh oil and cause it to lose its lubricating qualities.

The engine will probably smoke more or less and there may be missing, due to the kerosene, but after running engine for a while the smoke ought to pass away and the spark plug can then be cleaned and properly set.

Do not start engine under its own power even after new oil has been put in, until first turning it over several times with starter, this is done to eliminate all kerosene from engine distributor pipe and bearings. This action pumps the engine oil in its proper channels before it is run on its own power.

A "scored" cylinder, means there are scratches or cuts in the cylinder caused by lack of oil. "**Burnt" bearings on a crankshaft or elsewhere,** means the bearing is cut, caused by friction from lack of oil.

Engine Lubrication Troubles.

Cause—too much oil: Oil pan too full; oil pressure adjustment too high. Piston pumping oil or rings leak oil.

Effect—too much oil: Smoking at exhaust; carbon in cylinders; pre-ignition and knocking; carbon on valves necessitating grinding; spark plugs become fouled.

Cause—not enough oil: Oil level in oil pan too low; oil pressure improperly adjusted; oil pipes clogged; pump not operating.

Effect—not enough oil: Overheating; seized bearings or pistons; scored or cut cylinders; knocking.

***Manufacturers advise that oil pan be cleaned frequently**, especially during cold weather—due to more raw gasoline being drawn into cylinder and not being combusted—see page 205, bottom.

†**Cooling the lubricating oil**; on some racing cars and high speed marine and aeronautical engines of high compression and speed, the oil is cooled by leading the oil out of the engine base, where temperature can be lowered, before pumping it back into engine. Castor oil is also used, page 918.

****Another test is the cold test**—not to be over 25° F.

Results of Not Using Enough Oil or Too Much.

If the engine is not getting enough oil, the cylinder will become so hot that any oil that may have splashed on its outside will be burned—the smell being an indication of the condition. Further running without oil will produce a hard metallic knock, and the heat will finally cause the piston to stick in the cylinder.

An engine that is run without oil will be ruined, for the piston rings and the walls will be cut and scratched lengthwise, (called "scored") so that the compression will not hold.

If the piston sticks or "seizes" and pounds from lack of oil, stop—wait until it cools and then fill the crank case to pet cock level—also fill radiator with water **after engine has cooled sufficiently.**

The engine should then be thoroughly inspected before driving, to see if any damage has been done. If no obvious damage has been done, a thorough examination should be carried on to determine whether or not the running without oil has burned the bearings or caused other trouble. This can be ascertained by starting the engine, and if it pounds or knocks it is a certain indication of bearings burned or cylinders scored.

A new bearing, or any other new part that has not worn smooth, requires more oil than one that has been run. It is always better to give a bearing too much oil than too little, but the exact amount of oil required for each part of the car should be learned as quickly as possible, in order to prevent waste.

Results of Using Too Much Oil.

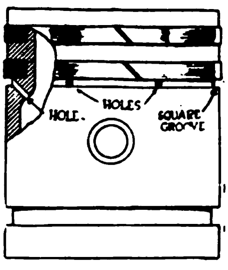
The only place where too much oil is harmful in an engine is in the cylinders, where it is burnt with an excessive precipitation of carbon that adheres to the piston and cylinder heads, lodges on the valve-seats causing pre-ignition, overheating and knocking, loss of compression, and passes off into the muffler, clogging it, giving off much objectionable smoke, and ultimately reducing the efficiency of the muffler to such an extent that the back-pressure causes a noticeable loss of power.

The local remedy for these is to scrape and cleanse the cylinders, grind the valves, clean the muffler, and then find the cause of the excessive oil supply and cut it down.

Too much oil in a circulating system in which the oil is simply drawn from the reservoir and forced into the splash compartments of the crank chamber, is caused only from an excessive supply in the reservoir, of improper design.

The oil pressure to be maintained on various cars shown under "Standard Adjustments of Leading Cars"—chart 228.

****Prevention of over-oiling:** Carbonization, sooty spark plugs and a smoky exhaust are due to the fact that the oil works up past the piston into the combustion chamber. The illustration shows a simple but effective method of supplying a return for this excess oil to the crank case. The piston is removed, chucked in a lathe, and a groove 1/16 in. square cut in the outside edge of the ring groove just above the wrist pin. †Six 1/16-in. holes are then drilled through the piston at regular intervals and are inclined toward the wrist pin at an angle of about 45 deg. The oil is caught in the groove and thrown downward onto the wrist pin, not only removing the excess oil from the cylinder but also effectively lubricating the wrist pin.



If the piston rings leak, the oil passes around the rings, out the exhaust, causing considerable smoke. Another indication of leaking rings is the constant oil soaked spark plugs. Therefore it would appear if **the rings are not in the best condition** it would then be a wise thing to use heavier oil or fit new rings.

*Carbon.

The cause of carbon deposit is due to; (1) amount and grade of oil (2) the carburetion mixture.

If too much gasoline is used it will cause carbon deposit just the same as a poor grade of oil.

Excessive heat will also cause carbon, as oil vaporizes.

Because oil becomes more fluid when it is heated, the oil feeds should be adjusted after the engine has been running, for if adjustments are made for cold oils the flow will be much more rapid when it is warmed, and the bearings will be flooded, and the excess oil will pass by the rings causing carbon deposits.

**Smoky Exhaust—Cause of

If the vapor is black and foul smelling it is caused by too "rich a mixture" (too much gasoline); this can be remedied in carburetor adjustment.

If the smoke is white or blue, the engine is supplied with an excess of oil.

If the smoke is grey, there is too much fuel as well as lubricating oil.

The reason an engine excessively supplied with oil smokes is that there is too much in the crank case; the entire lower portion

*See page 623: "Relation of Carbon to Lubricating Oil," and page 735. †Oldsmobile advise 5/32" holes **See also pages 652 and 793.

of connecting rod will dip into it and the lubricant will be forced into the cylinder to work by the rings on the piston, then into the combustion chamber, thence out the exhaust.

Depending upon smoke issuing from the exhaust pipe of a car as a means of testing whether or not the cylinder lubrication is sufficient or over-sufficient is by no means conclusive. The fact that the exhaust is smoky does not indicate that lubrication is complete, or excessive in all cylinders. If it issues in a steady and continuous stream probably there is sufficient oil in the engine and probably, too much, but if it comes in intermittent puffs, it may be inferred that one compartment only of the crank case is flooded.

Leaky piston rings are quite frequently the cause of excessive smoke—see repair subject, "leaky piston rings."

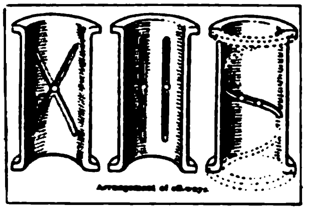
Oil Drips.

The average oil drips come from the cap screws being loose on crankcase. Other drips come from bearings and quite frequently from the plungers or tappets above the cam shaft.

On some cars the fan often picks up the oil oozing from bearings and throws it over the inside of hood.

**Oil Grooves in Bearings.

The old-fashioned arrangement of two simple **holes on the upper side** leading into oil-way either straight, starred, or spiral, appears to be as good as any. But, be it noted, the oil-ways should not be cut to the extreme edge of the bush, or their action as reservoirs is apt to be interfered with.



Similarly the bevelling of the edges of the bush should likewise be discontinued before reaching the outside. The arrangements of oil-ways is shown in illustration. (see also page 644.)

***"Running-in" a New Engine.

Fine grooves (not visible to the eye) are left **on piston** by the cutting point of the lathe tool when originally made. Also **pear shaped pits** are left by grinding machine on **cylinder walls.** When engine is new the projections are in the fine line stage.

At ordinary temperature, say, .0035 piston clearance, will permit the projections to pass one another. When temperature of engine is raised the projections will touch from expansion and if speed is excessive the temperature is raised which increases expansion and friction takes place and the projections imbed themselves in the recesses opposite them, which will cause a stuck or "seized" piston (see page 639) with the attendant condition of a "scored" or cut cylinder wall (see pages 201, 653).

Care is necessary to use plenty of oil and run at normal rates of speed until the projections gradually change shape, and are bent over in such a way that the high points fill the recesses.

After engine has been run a 1000 miles with care the piston and cylinder surfaces become very smooth and polished. (see also pages 489 and 651, why "piston clearance" is necessary.)

†Pointers on General Lubrication of the Car.

It is a difficult matter to advise just what lubricants to use on all cars, as different manufacturers advise what to use and their advice ought to be followed. However, as an example, the average is given on page 204, Studebaker and Hudson.

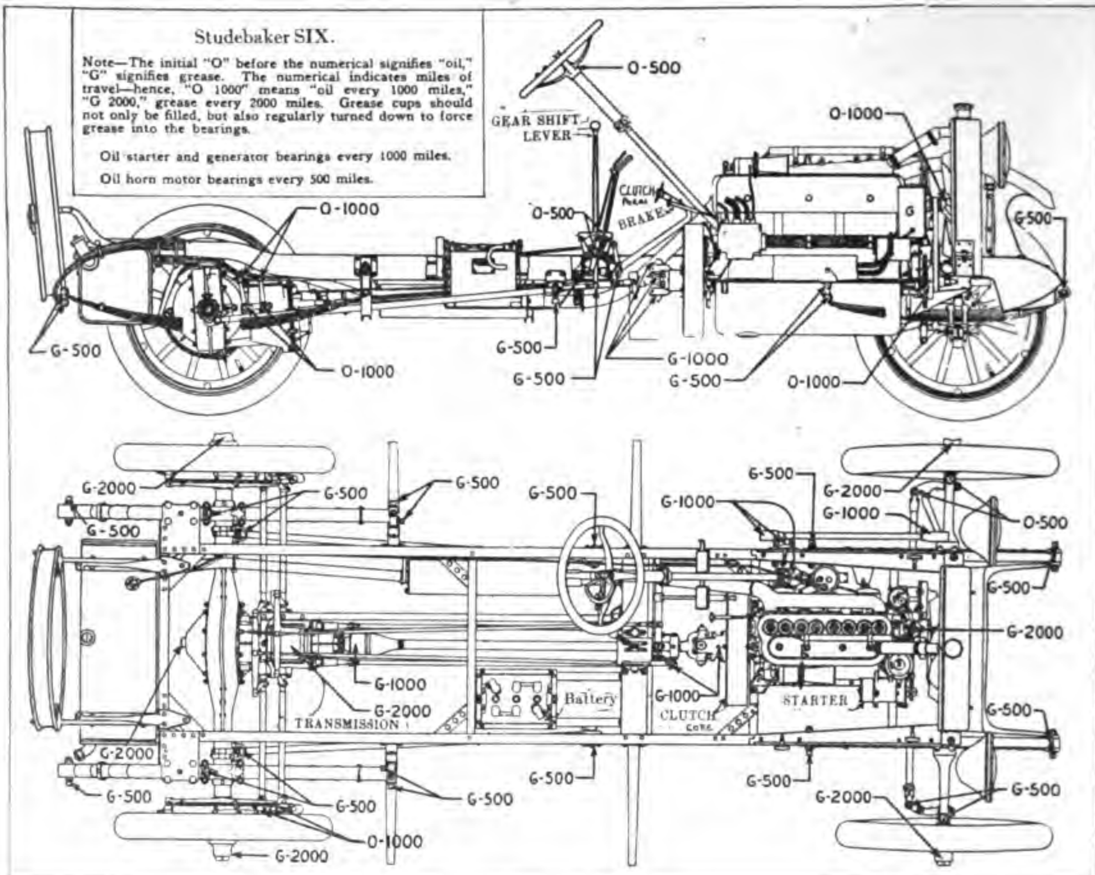
A few pointers on lubricating the different parts will be given in the lines following:

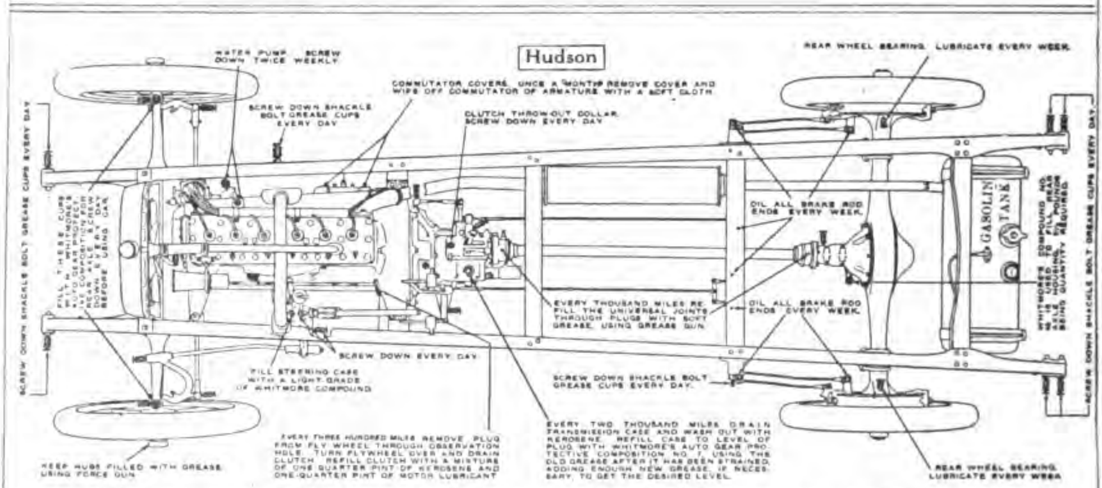
Disk clutch: There is much misinformation about the caring for and lubrication of a disk clutch. Heavy oil often is put into such a mechanism with rather disastrous results. At the end of a reasonable distance, say 500 miles, the old oil in a disk clutch should be removed. There is usually a drain plug fitted to the clutch housing and this should be removed to let the oil out, after which the clutch should be rinsed with kerosene, and again allowed to drain completely. Thus cleaned, a supply of a light clutch oil should be put in until the level is about even with the bottom of the clutch shaft. This allows the plates to pass through a bath of oil, and is the desirable condition. Some recommend a mixture of a **light oil with kerosene,** but as the proportion varies, it is best to purchase a regular light clutch oil. The foregoing does not apply to dry disk clutches.

The transmission: It is important in lubricating the gear set that the oil or grease should not be too heavy, for in that case it will stick to the gears and be thrown from them by centrifugal force against the sides of the gearcase. This happens for the first few minutes, but after the mechanism has been in operation for some time, all of such solid lubricant has been picked up by the rapidly rotating parts and thrown from them. Very soon, they are free of the very lubricant they have been acting upon and soon run hot. The best lubricant is a **heavy oil that will run, or a grease of such consistency that it will flow.** Thus, when the gears and shafts pass through it, it does not adhere to them, and there is not the tendency to throw it out of contact with the bearing surfaces. There are many special forms of gearset and differential semi-fluid greases and heavy oils on the market and the makers have studied these facts so that the products perform their function of be-

**See page 644. †See pages 621, 622. ***See also pages 489 and 507.

***When engine stands over night, don't immediately race engine to warm it up, because the oil has drained from bearings, cylinder walls, etc. Consequently it's going to take a few minutes to lubricate these parts properly. Therefore first let it run slowly for a minute or so





NOTE.—Every fifteen hundred miles, drain all oil from the motor by removing the plug at the bottom of the oil reservoir. Pour kerosene into the crank case through the filler on left side of motor, and turn the motor over with electric starter for a minute. Stop motor. Drain out kerosene and add fresh motor oil until the oil indicator on the left side of motor shows "FULL." This should require approximately 3 gallons. Once a week when the car is laid up for the night, and while the motor is still hot, pour in each priming cock about three teaspoonfuls of kerosene, close them and let stand all night. In the morning start the motor in the usual manner.

Studebaker Four and Six: Engine lubrication is the "circulating splash" system with a gear pump. To drain and clean oil reservoir of engine: At the bottom of the oil pan is a large plug which can be taken out for cleaning purposes. After all old oil has run from this plug, pour one gallon of kerosene oil through the breather pipe, which will flood out all dirt and sediment which may have collected at the bottom of pan. The reservoir should then be filled with clean oil. When properly filled, the FOUR holds one and one-half gallons of oil and the SIX holds two and one-half gallons. Parts to lubricate are explained above. Note the transmission is at the rear of drive shaft attached to the axle housing.

Hudson super-six: Engine lubrication is the "circulation splash" system as described on page 198. Parts to lubricate are explained above. Note the transmission and clutch are a unit with the engine.

CHART NO. 100—Parts to Lubricate on a Modern Car: Studebaker Six and Hudson Super Six.

The above Studebaker is the 1917 "six." The 1918-19 model has transmission set forward, instead of rear as shown above.

ing just light enough to prevent sticking to the revolving parts. It is obviously wrong, therefore, to put any common grease into a gearset, for it not only acts as above, but has not the ability to get into bearings like a fluid material.

In filling the gearset, put in the lubricant to a depth about half the height of the gearbox. That is, have it come about even with the center of the main shaft, this will completely submerge the counter-shaft in the average gearset design and will bring the under face of the main shaft gears into the lubricant. It is important in this connection to see that the packing rings are tight and prevent leakage where the drive shaft emerges from the gearcase and where the shaft from the clutch enters it. If there is leakage here, it not only will act as a collector of dirt and dust, but the gears will be robbed of their proper lubrication.

The differential housing should hold the lubricant in the rear axle gears, so that attention is needed only as stated above but sometimes a disagreeable looking rear axle is noticed where the oil or grease oozes out through cracks or leaks in the rear cover plate or through the axle tubes onto the wheels. This is not so common a fault as it used to be when axles were not designed so well to trap the oil and keep it where it belongs. However, an occasional careless driver will let his axle get in this condition by not having a proper gasket between the differential housing cover plate and the housing itself. It is not much trouble to cut a gasket if the old one gets worn or out of shape, and it saves the brake bands which often become oil soaked and slip.

†**The axle:** In some cases, a heavy transmission oil is recommended for the axle but in most instances it is best to use either a sem-fluid grease or even a heavy grease. There is less chance for the gears to throw these, and the space is smaller so that it is next to impossible for the grease to get away from the lubricating points. It is next to impossible to give any fixed rule for rear axle lubrication. There are so many designs, and where a heavy oil or a grease will work satisfactorily in one instance, some other form is better in another.

Dodge for instance uses 600W—steam cylinder oil two parts, and one part medium grease.

*The Use of Graphite in the Automobile Engine.

The use of flake motor graphite mixed with cylinder lubricating oil when properly used will improve compression, decrease the amount of oil required, fill up scores in the cylinder walls, prevent valves and rings sticking and thereby cure smoky exhaust.

A great deal of prejudice has existed against graphite lubrication due to ignorance. When automobiles first came on the market, chauffeurs would go to a hardware store to buy graphite to mix with their grease and would get Dixon's Flake Graphite No. 1 which is intended for lubrication of steam cylinders and other heavy work. Then they would use about five times too much of it and trouble would result. Of course, graphite was blamed. However, anyone who has ever taken the trouble to investigate Dixon graphite automobile lubricants has seen the sense of their claims and would use no other kind of lubrication. It stands to reason that when bearings and gear teeth are polished with fine flake graphite that there are actually no metallic surfaces in contact and hence there can be no wear, no heating and practically no friction.

However, assuming that graphite is an ideal lubricant certain requirements are necessary, for instance:

For splash oiling system, the Dixon Co. recommend adding a scant teaspoonful of motor graphite to each quart of oil in the crank case and then add another teaspoonful at the end of each one thousand miles. The graphite may be mixed with a little oil and poured down the breather. You will notice that this is a very small amount of graphite but it is all that is required.

For force feed system it is not advisable to mix the graphite with the oil on account of the possibility of clogging some of the small passages.

A small amount of dry graphite may be placed on the hand and permitted to be inhaled through the air intake of the carburetor directly to the cylinders. This should be done about once a week when your car is in ordinary service.

More graphite can be used when it is introduced in the dry form because part of it is immediately blown out through the exhaust.

On account of the location of the magneto on Ford cars and the possibility of short circuiting it we do not recommend the use of graphite in the crank case or transmission case of these cars. This is merely a precaution that we take, although we know of many Ford owners who use graphite in their engines with entire satisfaction.

How Unvaporized Gasoline Thins The Oil.

Gasoline vapor that is not completely consumed in the engine does one of three things; it either passes out into the exhaust in an unburned state and is wasted, is deposited in the form of carbon within the cylinder, or condenses and runs down past pistons into the crankcase.

The first of these is the most direct loss, but the other two are equally important in the long run. A carbonized engine is of itself inefficient. **Carbon makes the engine miss, makes it overheat and pre-ignite. All of these things are sure to shorten the life of the engine. When the unburned fuel runs down past the piston it destroys the seal between piston rings and cylinder, removes the oil which is to protect the surface of the cylinder and piston from friction and wear and, lastly dilutes the lubricating oil in the crankcase to such an extent that in time it becomes worthless.

Manufacturers are advising now that the crankcase be drained even more frequently than ever before for this very reason. As cold weather approaches, the necessity for frequently refilling completely with new oil will become more imperative. Either the motorist is forced to drain out his oil and refill with fresh at an increased outlay or he must suffer the consequences of an engine damaged by insufficient lubrication.

**See page 623. †Grease working out axle ends on brake bands—cause brakes to slip.

*A free booklet, advising just where graphite as a lubricant can be used on a motor car and the kind to use, can be obtained by writing the Joseph Dixon Crucible Co., Jersey City, N. J. The writer knowing the importance of good lubricant, recommends the use of graphite.

INSTRUCTION No. 16.

IGNITION: LOW TENSION COIL. Purpose. Brief Explanation of Electricity. How Electricity is Produced. Methods of Generating Electricity. Low Tension "Make and Break" Ignition—using a Low Tension Coil.

Principle of Ignition.

There are three things required before a gasoline engine will run. These three things are absolutely essential. **First**, it is necessary to have a mixture of gasoline and air in the engine cylinders. **Second**, this mixture must be compressed, and third, there must be a spark to set fire to the compressed mixture. The **third** thing required to make the engine run is the one which is most difficult to understand, if the reader is not familiar with electricity. The system of ignition, as it is called, is usually made up of certain electrical devices which probably give more trouble to the motorist than all the other mechanisms on the machine.

In order that you may thoroughly understand the principles upon which the various ignition systems are built up, and how these systems are operated and maintained, it is well to start at the beginning.

The original and first method for igniting the gas in a gasoline engine was by the means of a "hot tube" or flame, but this method now being obsolete, we will deal only with the electric ignition.

The ignition systems used on automobile engines at the present time are all electrical systems giving an electric spark which passes in the cylinder of the engine and sets fire to the compressed mixture, and as you will be dealing with electricity and electrical apparatus in these systems, the first thing to know is how electricity acts and how you can make it do work for you.

What is Electricity?

No one can tell you just what electricity is; we know how it acts and how it moves in the same way that we know how the force of gravity acts.

If you throw a stone into the air it will come down again, but you cannot explain why, beyond saying that the force of gravity makes it come down. You cannot say just what "gravity" is—so it is with electricity.

Electricity is in everything—in your body, in your clothes, in the magazine you are reading, in the chair upon which you are sitting—and the only reason you do not feel a shock is because the electricity is not in "motion."

If you put a water wheel in the middle of a pond, the wheel will not revolve, no matter how deep or how large the pond may be.

To make the wheel revolve to get any work out of it, you must place the wheel in position that the water may flow from a high level to a low level, and in flowing, move or push the wheel around.

There must be a current of water before the wheel will move—so in electricity—there must be a "current or a flowing of electricity" before you can get any work out of it.

If you want water to flow, you provide a path for it downhill, or, in other words, you allow it to take a natural course from a high level to a low level.

You can pump water to a high level and then get it to flow through pipes or along a stream.

When water is pumped into a tank that is, say, 100 feet high, you know that there will be a certain pressure in the pipes leading from the tank, and if you want to know how much pressure there is, you will measure it in so many pounds pressure.

At the same time you can measure the quantity of water flowing out of the pipes, and you can say that so many gallons will flow in a minute.

You are no doubt perfectly familiar with the measurements called a pound, gallon and minute, and if you were told that 200 gallons of water were flowing out of a certain pipe in a minute at a pressure of 50 pounds, you would have a pretty good idea of the current of water referred to.

Now, when you come to work with electricity, you should be able to understand the current in the same way, but you will find that the measurements of electric currents are not stated in gallons and pounds, but in other terms, as, **amperes**, meaning the **quantity** of current flowing; **volts**, meaning the **pressure**, causing it to flow; and **ohms**, meaning the **resistance** offered to the flow of current.

How Electricity is Transmitted.

Electricity produced in one place may be transmitted to another place, provided a path is arranged so that it may **return** to where it started. It will not flow if there is no circuit; that is, a continuous path.

If the circuit is broken, the flow will immediately stop, and will not start again until the circuit is once more completed.

Copper wire is usually used to take the electric current from where it is produced to the place where it is to be used, and another wire may be used to bring it back again, the first wire being called the "**lead**," and the second the "**return**."

If there is any way in which the current may leak from the *lead wire and return to the starting point without going through the entire circuit, it will do so, and this leakage is called a **short circuit** or **ground.**

****A conductor**: Anything that will permit a current of electricity to pass through it is called a **conductor**; all metals are conductors.

Insulators: Substances such as rubber, china, porcelain, glass, wood fibre and mica are called **non-conductors** or **insulators.**

A wire is insulated to prevent leakage of current into any metallic substance it may touch by wrapping it with cotton or silk, which is soaked with rubber to prevent dampness from getting in.

When dry, cotton and silk are insulators, but as water is a conductor, damp cotton and silk cease to be insulators.

While all metals are conductors, some are better conductors than others; a copper wire, for instance, will pass a larger current than an iron wire of the same size. Due to the fact that copper has a lower resistance.

If a wire has more electricity passed through it than it can easily conduct, heat will be generated, and it may get so hot that it will melt.

The larger a wire is, the greater is the current that it can pass without heating. (voltage being the same.)

Copper is in most general use as a conductor of electricity, because of its low resistance; silver is a better conductor, as it has a still lower resistance, but is not used because of the expense.

Explanation of Voltage and Amperage. Also "Series," "Parallel" and "Multiple" Connections.

A current of electricity flowing in a wire may be measured just as a current of water flowing in a pipe may be measured.

The amount of water that flows through a pipe depends on the pressure, or head, and the friction in the pipe. The volume of electricity that flows through a wire depends on the pressure or voltage at which it flows and the ohmic resistance of the wire.

Volts (pressure). The quantity of water flowing through a pipe depends largely on the pressure. The amount of electricity flowing, or the strength of current in amperes depends in part on the pressure in volts. Thus the amount of current flowing is measured in amperes and the pressure causing it to flow is measured in **volts.** The **volt** is the practical unit of electromotive force.

The electro-motive force, usually written E. M. F., is the total force required to cause the current to flow through the entire circuit.

The unit of electromotive force is the volt.

Ampere (current) a current of water flowing in a pipe is measured in gallons per second or cubic feet per second. An electric current is measured in **amperes.** Thus we say the strength of one ampere flows for 60 seconds, then the total quantity is 60 ampere-seconds, or 60 coulombs of electricity.

The coulomb is the unit of quantity which equals the rate of flow X time, as ampere seconds. One **ampere hour** would equal 3600 coulombs. **The ampere,** therefore is the current strength, intensity of current or rate of flow, but in this instruction we have referred to the ampere as the **volume** or **quantity** of current flowing.

The velocity of electricity through a copper wire is said to be 288,000 miles per second.

An ohm is the unit of electric resistance. Such a resistance as would limit the flow of electricity under an electromotive force of one volt to a current of one ampere. For instance, we speak of a certain size of copper wire, a certain length having so many ohms resistance. Iron wire offers 6½ times more resistance to the flow of current, than the same length and size of copper wire, therefore if it is not of sufficient size to permit the free passage of current, the wire will heat.

The watt is the unit of electric power. 746 watts equal one horse power. **Multiplying** the amperes by the volts gives watts.

In order to explain the meaning of voltage and amperage more clearly, we will use a hydraulic analogy, which gives the explanation as follows:

Usually the ignition coil is so made it will work with a pressure of 6 volts. The resistance (see page 209 for meaning of this word) that the electricity meets in the wiring of the ignition system is so great that if we only had a pressure of 1 volt, this would not be sufficient to force **enough** current through the wires.† As the pressure increases the quantity of current that flows becomes greater. It has been found that a pressure of 6 volts is sufficient for most ignition systems which require from 1 to 5 amperes.

Series connection. The way we build the pressure up to 6 volts, with dry cells as an example, which give only 1¼ or 1½ volts each, is by connecting them in "series" as it is called.††

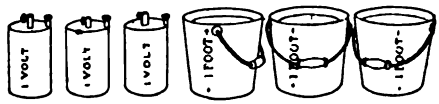


Fig. 1.—Comparing dry cells or storage battery cells with pails of water.

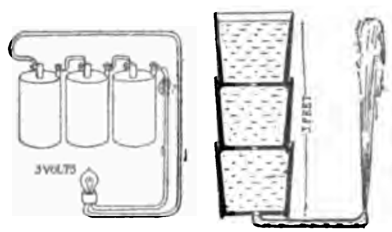

Fig. 2.—Dry cells connected in "series" similar to pails of water placed as shown.

*Pronounced leed, not lead. ****The best conductor** is silver, next best, copper, then aluminum, zinc, brass, platinum, iron, nickel, tin, lead, German silver, antimony, mercury, bismuth, carbon, water. Thus it will be seen that iron offers more resistance than copper, and carbon and water more resistance than iron. **Non-conductors** are slate, marble (if no metallic veins), oils, porcelain, glass, rubber, dry paper, silk, gutta percha, shellac, ebonite, etc. †See page 427, size wire to use.

††**Storage battery cells** give 2 volts, large or small. The pressure is built up by adding more cells in same manner.

This can be explained by referring to our hydraulic analogy, as follows: **Suppose we had three pails of water**, each of them 1 foot high, as shown in fig. 1, and suppose we had three dry cells, each of them giving a pressure of 1 volt, we will say for the sake of simplicity. If we would take these three pails and set them one on top of the other, and make an opening in the bottom of the three pails, connecting the opening in the bottom one with a pipe, the pressure in the pipe would be three times as great as if we had only one pail. That is, we would have a head of 3 feet of water in the pipe and the water would squirt up approximately 3 feet in the air, as in fig. 2.

When the cells are connected so that the pressures in them are added, it is called a "series" **connection** because it corresponds to putting the pails of water in a series one above the other. To make this connection, which is shown in fig. 2, we connect the positive terminal of one cell with the negative terminal of the next, the positive terminal of that one with the negative of the next, and so on. Finally, running one of the wires of the outside circuit, from a lamp in this case, to the negative terminal of one end cell and the other outside wire to the positive terminal of the other end cell. Since there is a pressure of 1 volt, we will say, between the positive and negative terminals of each cell, we have simply added the voltage of all the other cells to it, just as we added the pressure in the other pails of water to the first one when we set the others on top of it.

Series connection means that the carbon (positive pole) of one cell is connected to the zinc (negative pole) of the second; the carbon of the second to the zinc of the third and so on. This leaves the carbon of the last cell free to be connected with the outside circuit, likewise the zinc of the first cell. So, when the entire battery of cells flows from the outside carbon through the lamp or ignition coil, or whatever is in the outside circuit, and back to the battery through the zinc of the first cell.

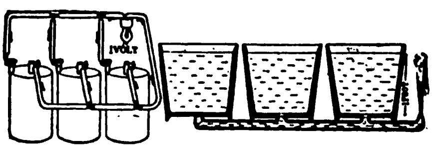

Fig. 3.—Dry cells connected in "parallel" or "multiple," similar to pails of water connected one with the other.

Parallel connection: There is another way in which we can attach the three pails of water to the pipe, and that is the arrangement shown in fig. 3. Instead of setting one pail on top of the other we have them all on the same level and if we connect the bottom of each one to the pipe the water will flow through the pipe, but **we will have only one foot of head** and the water will squirt only as high as the level of that in any one of the three pails, that is, the pressure would be no greater with the three pails connected this way than it is if there was only one pail connected with the pipe, but the water will flow three times as long.

We can do almost the same thing with the electricity in the three dry cells (or storage battery cells) as we did with the water in the pails, that is, we can connect them up so that the pressure of each of them is added to that of the rest, or we can connect them up so that the pressure of all three is equal only to that of one, and like the water, the current will flow 3 times as long.

This arrangement in fig. 3, is called the "parallel," or "multiple" arrangement, and corresponds to connecting the pails of water to a pipe when all of them are at the same level. When we connected the pails of water in this way we simply added to the capacity of one pail without increasing the head or pressure.

When we connected the three pails set on a level it was just as though we multiplied the size or capacity (amperage) of one pail by three.

In the multiple or parallel arrangement of a dry cell (or storage battery cells) we simply connect all the positive terminals, or plates, and all the negative terminals, or plates, together, and the effect is merely that of adding to the size of the plate or capacity of the cell. When we connect the three cells in multiple or parallel, as in fig. 3, we have multiplied the capacity (amperage) of the cell by three, but we did not increase the pressure.

If we increase the size of the plates in a cell we lengthen the time during which it will give a current of electricity.

If one dry cell will give 1 volt for one day, three dry cells would give 1 volt for three days if connected in multiple, but if connected in series, as shown in fig. 2, we would get 3 volts pressure, but the three cells would last only one day. This can be explained by considering the water pails again, with the pails one on top of the other, giving a 3-foot head, the water would run out in one-third the time that it would if the pails were connected together as at the right of fig. 3, where they get only 1-foot head. It will be seen that in series connecting we increase the voltage but leave the volume or amperage the same, and in parallel connection we increase the volume or amperage, but leave the pressure or voltage the same, and in both cases the watts will be equal.

In order, then, to get a pressure of 6 volts, with dry cells giving 1½ volts each, we simply need to connect four cells in series, for then we have four times 1½ or 6 volts, which is pressure enough for the ordinary ignition system.

As the voltage has a tendency to drop when in use, 6 cells are usually placed in series.

It is not well, however, to use more cells in series than are needed, for good working, because the excess of pressure would force the electricity through the circuit at too great a rate or amperage and this high current would damage the vibrators of the spark coils as will be explained later on.

With the four cells connected in series and the total giving 6 volts pressure, we have the life of only one cell, that is, the four cells connected this way will not last any longer approximately than if we had only one cell.

Multiple-series connection: We can double the life of the battery, thus obtained by connecting the four cells in series, simply by connecting up four more cells in series and then connecting the two sets of four cells each in "parallel or multiple." The arrangement is illustrated in fig. 4, in which case we have three of the 1-volt cells we speak of, connected in series and three more in series, with the free negative terminals of each set tied together and the free positive terminals of each set tied together.

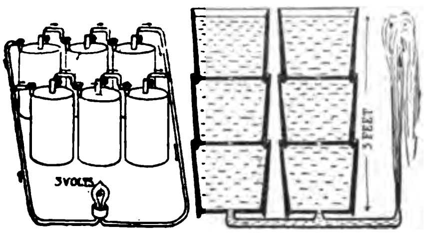

Fig. 4.—Two sets of cells connected in "parallel." Each set connected in "series;" called "multiple series." Note the comparison.

Here we have obtained a pressure of 3 volts by connecting three cells in series and have doubled the life or capacity (amperage) by connecting in parallel another three which have been connected with each other in series. The effect is just the same as if we had taken three cells of double the capacity (amperage) and connected them in series. We would accomplish the same result with water pails by making two piles of three each and connecting both to the same pipe, as indicated in fig. 4. Here we have obtained a head of 3 feet and doubled the capacity (amperage) of our source by doubling the amount of water.

In the cell parallel arrangement, illustrated in fig. 3, the current flows from the carbon of one end cell through the circuit and back to the battery through the zinc of the same cell, so that the current from the first cell does not have to flow through the second and third cells in order to go through the circuit and back to where it started, but is able to flow past them. The current from each of the three cells flows into the wire connecting their carbons and on its return flows back into the cell from the wire connecting their zincs. If you have a current of four amperes in the circuit, each cell will be giving one-third of the current, and only one-third of it will be flowing through any one cell. With two sets in multiple only half this amount of current will be flowing through each cell.

Separate sets if used for ignition: In a motor car where dry cells and vibrator coils are used for ignition it will be found necessary to use two sets of cells which are not connected to each other, but either one of which can be switched into the circuit if desired. In fact, it will be found almost necessary to change from one set to the other every 25 to 50 miles. Otherwise the engine will begin to miss and finally will stop. This is because the current flows through the cells so rapidly too much gas forms for the depolarizer to take care of and the cells polarize. After resting a while the cells will be restored or will recuperate, at least in part, to their former condition and can be switched on again.

But if there are eight cells connected in two sets of four in series and these two sets connected in parallel arrangement explained, the quantity or amperage of current required from each cell is lessened and they last very much longer—see foot note bottom of page 211, also index.

†Meaning of Resistance.

Electricity will flow more easily through some conductors than through others because there is a difference in their **resistance** to the flow of current.

Everything presents more or less resistance to the flow of current, and the **less resistance that** a substance presents, the better conductor it is. The **greater the resistance,** the less total current can pass; the pressure or voltage will drop‡ and the volume (amperage) will be reduced. In forcing a current through such resistance, **heat is produced, and the greater the resistance the greater will be the heat** (see ohms page 207, also index).

Positive and Negative Terminals.

Generator terminals: Every generator of electricity has two terminals; a positive (+) and a negative(—), that being the names given to the points from, one of which the current leaves (positive) and to the other of which it returns (negative).*

*The current always flows in the same direction, from the positive pole to the negative pole; it leaves the generator by the positive pole and returns by the negative.

Connections can be grounded either from the negative or positive pole—it makes no material difference. Manufacturers as a rule ground the positive terminal of a storage battery to the frame.

†Resistance is that property of an electrical conductor by which it opposes the flow of an electrical current, for instance, carbon, iron wire, German silver and water will permit current to flow through, but it opposes or offers resistance to the flow—see ohm, page 207. A rheostat is a device for the purpose of varying the resistance of an electrical current, see pages 474 and 460. ‡Termed a potential difference or energy lost. For instance, "two volts lost on a line," means this much pressure is lost in sending the current through the line.

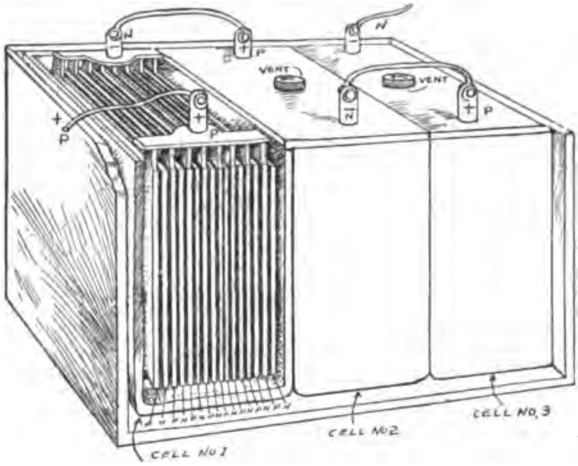

Fig. 2—The Ignition Storage Battery; a Chemical Generator of "Direct" Flow of Electric Current. Contained in a battery box. Sometimes called an accumulator.

The Storage Battery will also supply electricity to operate a Jump Spark or High Tension System of Ignition or a Low Tension "Make and Break" system. The Storage Battery for ignition consists of three cells placed in an acid-proof box. (See instruction on storage batteries.)

These cells are covered over with a nard rubber or coal tar composition, leaving the lead lugs projecting. These lugs connect one cell to the other and two ends are left "open," one a "Positive" or North, and the other a "Negative" or South. They are called "Positive" or "Negative" Terminals. Wires are connected to these terminals and the current is conducted over the wires to the ignition system.

When the Storage Battery is "run down" it is "recharged" by attaching wires from electric wires to the battery. (Will be explained later.)

The cells contain lead plates (N) negative and (P) positive, and are immersed in an acid solution.

Each cell gives two volts and are usually placed in a box and connected together, making a total of six volts this being the usual pressure required to operate a coil,

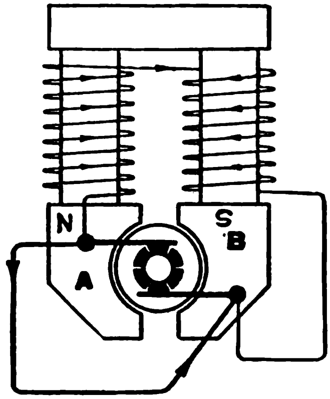

Fig. 3—The Dynamo; a Low Tension, Mechanically Generated, Direct Flow of Electric Current. The Dynamo will supply electricity to operate the coil of a Jump Spark or High Tension System of ignition or a low tens:on "Make and Break" System (not in use on automobiles to any great extent).

The Dynamo is more adapted for generating current to recharge the storage battery; the storage battery then supplies light and ignition.

Small "direct" current generators are also used on stationary and marine engines for ignition, where "make and break" or "wipe" spark ignition system is used.

The Dynamo has an "Electro-Magnetic" Field, meaning that the "pole pieces" are magnetized electrically.

The Magneto has "Permanently" magnetized "pole pieces" (will be described later).

The Dynamo generates a "Direct" or continuous flow of electricity, meaning the current flows continuously, whereas the current in a magneto is reversed and flows "alternately" and is not a direct flow.

The magneto is used in a different manner and is a separate and distinct system of ignition and will be described later.

The Dry Cell Battery (a Primary Cell); a Chemical Generator of a Direct Flow of Electric Current will also supply electricity for ignition, but is not reliable. Continuous use of dry cells will exhaust them or run them down rapidly and the pressure drops accordingly and thereby causes a "weak" spark. This battery will recuperate, however, if left standing for a while unused.

The dry cell battery is better adapted for ringing door bells or telephone work where the work required is not continuous.

The dry cell contains no liquid, but merely moisture, hence its name—Dry Cell Battery.

A is the filling or electrolyte, usually consisting of chloride of zinc, sal ammoniac, sulphate of lime and powdered charcoal (don't confuse this electrolyte with that used on a storage battery).

Six cells connected in a series connection is usually the combination for a set for ignition.

The positive pole of the dry cell is the carbon. The zinc being the negative.

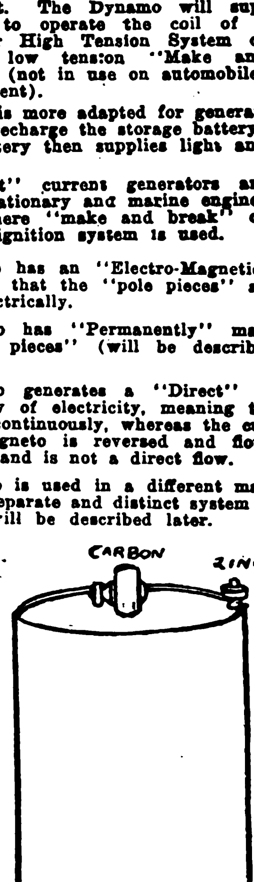

Fig. 4A.
Complete View of a Dry Cell.

CHART NO. 101—Chemical and Mechanical Generators of a "Direct" Flow of Electricity. No reference is made here to Magnetos; this will be treated later, under a separate heading.

How Electricity is Made to Do Work.

Flow of current: The current only flows when the two terminals, or poles, are connected by a conductor.

A current will flow if any opportunity is presented; if there is no regular conductor, moisture will often make the connection. Because of this desire to flow, the current may be made to perform work.

If the circuit includes a coil or lamp, the current in flowing through the circuit from the positive pole to the negative pole is made to light the lamp or pass current through the coil.

The circuit, with the lamp or coil, presents a resistance to the flow of the current, and **if there is a short circuit that presents less resistance,** the current will return by it instead of going through the coil or lamp. Therefore, the circuit must be so arranged that the current cannot return to the generator without doing the work set for it.

A switch is provided to close this circuit when work is desired and to open the circuit when work is not desired. Therefore, **for ignition,** instead of a switch a **timer or commutator** is made to open and close the circuit at the time the spark is required.

Parts Necessary to Produce the Ignition Spark.

While there are several methods of producing the spark in the cylinder at the proper instant, they consist in general of the same parts.

In the first place, there must be a **generator** to supply the current of electricity; **spark plugs** or sparkers, also called igniters, in the cylinder, at which the spark is produced; a **timer** or cam arrangement, by which the exact instant of the spark may be controlled, and the **circuit,** consisting of the necessary wires or conductors.

Whatever the system may be, the current is produced by some kind of generator, and therefore a description of generators will be given before describing the systems.

Methods of Generating "Direct" Electric Current.

A current of electricity may be generated by **chemical** means, by cells; or **mechanically,** by a magneto or dynamo. (The magneto will be described further on as it generates an "alternating" current and the dynamo "direct" current.)

Chemical Generators.

Cells are of two kinds, "primary" and "secondary;" primary cells actually **making** the current, and secondary cells **storing** the current and giving it out as needed.

A dry cell or storage battery cell produces a "direct" flow of current and would be termed a "chemical" source of electricity.

The* primary cells used for automobile work are called **"dry cells,"** and consist of zinc cups, in which are placed sticks of carbon (see chart 101).

The cups are lined with some substance like blotting paper, and the space between the carbon stick and the cup is packed with bits of carbon and the necessary chemicals. The blotting paper and carbon bits are moistened with the proper solution, and the top of the cup sealed with tar, so that it is watertight. The zinc cup and the carbon stick each have a thumb nut at the top, called a "binding post," to which the wires are attached.

When the circuit is closed, the current of electricity flows from the carbon binding post over the circuit and back to the cell by the zinc binding post, the "carbon" being the "positive pole," and the "zinc" the "negative pole," in this type of cell.

Dry cells have a pressure or voltage, of about 1½ or 1¼ volts, and the volume of the current they produce, called the "amperage," depends on the size of the cell. The ordinary dry cell used in automobile work gives a current of 20 to 30 amperes.

When in use, a primary cell becomes exhausted, and the voltage drops gradually. When it has reached a point where it does not give sufficient current, it must be discarded, and replaced with a new one.

It should be remembered that dry cells are intended for "intermittent" *service, as for ignition starting where a magneto is used, but for continuous service, the dry cell is not a suitable source of current. After the engine has started dry cells for ignition are not very satisfactory for they become exhausted in a short time.

For continuous current service the most efficient means of obtaining current is by means of a storage battery consisting of a battery of "secondary cells," or as it is sometimes called an "accumulator." This chemical type of electric generator is in more common use for ignition than the dry cells in connection with a dynamo—which will be explained further on.

****Secondary cells, also called "storage cells,"** or "accumulators," are usually charged with current from a lighting circuit, and may be recharged again when exhausted.

*The less continuously current is used from a dry cell the longer it will last or the more efficient it will be.

**Storage batteries will be treated under a separate instruction.

A storage battery consists of two or more storage cells. Each cell gives about 2 volts, therefore, a storage battery with three cells would give 6 volts, and is termed a "chemical generator," that is, it will generate electricity by a chemical action when discharging after first being charged —see page 447.

A storage cell is made of prepared lead plates, placed in jars made of hard rubber or celluloid and filled with a solution of sulphuric acid and water, called the "electrolyte." The jar is filled with electrolyte until the plates are covered, a cover preventing it from spilling. A hole in the cover, closed with a plug, is used for examining the condition of the cell, and refilling it when necessary. Through evaporation, leakage or spilling, the level of the electrolyte may get below the top of the plates, in which case the jar should be refilled, enough electrolyte being added to bring it to the correct level.

Electrolyte is made by adding one part of chemically pure sulphuric acid to—from three to nine parts of pure water—preferably distilled water.

An instrument called a **hydrometer** is used to determine the correct solution, and when floated in the solution its scale should read about 1290 sp. gr.

†The terminals of a storage cell are usually marked with signs to indicate the poles; a "plus sign," the same that is used in arithmetic, being the "positive pole," and a "minus sign" being the "negative pole."

The poles are often painted, as well, red being the positive and black the negative.

A storage cell has a voltage of a little over 2 volts, and this will drop slowly to 1.8 volts, when it requires recharging. In this it is like water running out of a tank, when the tank is empty it is necessary to refill it.

Cell Connections.

On pages 207-9 the "principle" of cell connections was explained in order to exemplify the meaning of volts and amperes. Cell connections will now be explained. Bear in mind the same principles apply to storage battery cells.

One cell in a storage battery or dry battery will not give enough current to produce the spark required to ignite the mixture, and therefore, three, four or more are used, connected together.

The most usual form of connection is in **series**; the negative pole of one cell is connected to the positive pole of the next, so that the current from one cell must pass through all of the others in order to return to where it started. (See chart 102, fig. 1.)

This method of connecting increases the voltage as many times as there are cells; for instance, if there are four cells of 1½ volts each, the voltage of the battery of cells will be six volts. The volume or amperage does not change, being the same that it is for one cell. (See fig. 2, page 207.)

Another method of connecting is in **parallel**; all of the positive poles are connected to one wire, and all of the negative to another. (See chart 102, fig. 2.) This gives the same voltage (pressure) as one cell, but increases the amperage (quantity) as many times as there are cells.

A third method is to connect the cells in **multiple series**. (See chart 102, fig. 3.) In this the cells are divided into two equal groups, each group being connected in series, and the two groups being connected with the circuit in parallel with each other. This gives a voltage of one-half what it would be if all were connected in series, and an amperage of one cell multiplied by the number of groups.

Mechanical Generators.

A mechanical generator, which is driven by the engine, produces a current of electricity, and its action depends on "magnetism," which is the property sometimes possessed by iron or steel, by which they attract other pieces of iron or steel.

A generator consists of two parts; the "poles," between which the magnetic field flows and the "armature," which revolves in this magnetic field, and produces the current of electricity. (See fig. 4, chart 102.)

The field is made in two ways; it is either a "permanent magnet," that is, steel that is magnetized so that its magnetism does not change, or an "electro-magnet;" that is, a coil of wire wound around a soft piece of iron, which is a strong magnet only while electricity is flowing through the coil.

*When the field is a permanent magnet (fig. 5, chart 102), the generator is called a "magneto;" when the field is an electromagnet (fig. 4), the generator is called a "dynamo." (See chart 101 and 102.)

The armature has a core, consisting of soft iron, with insulated wire wound around it endways. There are two types; a "drum" type and a "shuttle" type. The drum type could be revolved in either the "electro" or "permanent" magnetic field and would generate "direct" current. The "shuttle" type is used only on generators in which the magnetic field is produced by permanent magnets and always generates "alternating" current. (Will be explained under magnetos further on.)

The voltage of a magneto or dynamo depends on the size and quantity of wire wound on the armature and field coils, and on the speed.

Terminals: Mechanical generators usually have but one terminal, the other being "grounded," which will be explained. Where there are two terminals and "direct"

†When the poles of a storage battery are not marked the polarity can be determined by their natural color; the positive is darker, usually a brown color, whereas the negative is gray. *If armature is of the "shuttle" type.

current generators, they are marked as the terminals on a storage cell are marked. (+positive,—negative.)

When using "chemical" generators, such as a storage battery; the circuit is also (quite often) grounded on one side.

*Grounding the Circuit.

When the current of electricity is required to do work, as, for instance the producing of a spark in the cylinder, using a "make and break" ignition system for example, it must be taken to the igniter through a coil, by means of a wire but may be returned to the generator by means of a ground." Which is usually abbreviated as "G" or GRND and designated by a sign as shown in chart 109. See chart No. 102, fig. 7; and fig. 3, chart 103; dotted lines show path of current through metal of engine.

The frame and engine of an automobile are made of metal, and therefore will conduct electricity.

If the negative pole of the direct current generator is attached to the metal frame or engine, and a wire attached to the positive pole, the current will flow in the circuit when the positive wire is touched to any other metal part of the frame or engine, for the metal acts as a conductor and permits the current to return to the generator.

This method saves wire, for wire is used only to take the current to where it is needed, the metal of the frame or engine bringing it back again.

**Switches.

When the current for the ignition is supplied by battery, it is usual to have two sets (fig. 1, chart 103), and is used to start the engine; after engine is started, the dynamo or magneto supplies the current. The reason for this is due to the fact that a battery supplies a constant source of electric supply, whereas a mechanical generator generates current only when running.

A switch is placed in the circuit, so that either may be used. They are made in many forms, but a simple form is a flat piece of spring brass, pivoted at one end, so that it may swing from side to side. The free end may touch either of two knobs of brass, one on each side, or be between them without touching them. Each of the knobs are connected to one of the sets of batteries, or one to the battery and the other to the dynamo, and the flat piece of brass is connected to the ignition circuit.

Thus when the free end of the switch is swung to one side, or the other, it rests on one of the knobs, and the corresponding battery is thrown in circuit, furnishing the current for the ignition.

When the switch is between the knobs, it is out or "off" of contact, and the circuit is broken. Thus a switch serves not only to connect either of the two sources of current, but also to break the circuit, which, of course, stops the engine.

The switch lever can be detached from some makes of switches; when it is withdrawn, it breaks the circuit regardless of which side the switch is on. Thus only the holder of the lever may run the car.

Ignition Systems.

There are two systems of ignition used for automobile engines; "**low tension system**" and the "**high tension system**;" the source of electric supply being either by chemical means as: dry cells, or a storage battery, or mechanical means as: a magneto or dynamo (also called generator). (The magneto is explained further on.)

The word "tension" means pressure or voltage; high tension being high voltage, and low tension low voltage.

The low tension system of ignition is used on only a few makes of automobiles. The low tension system was formerly used to a great extent on boat engines and is still used to a great extent on stationary engines.

The low tension system uses a low tension single wound primary coil as per fig. 7, chart 102 and its source of electric supply can be a dry or storage battery, or dynamo. Low tension magnetos are also used, but the coil is wound on the armature (treated under "Low Tension Magnetos.")

The high tension system of ignition is the approved system now in use on very near all makes of cars. The high tension system may be either by a high tension coil and a battery; high tension coil and low tension magneto; high tension coil and dynamo in connection with a battery—or by a high tension "magneto" alone.

In this Instruction and in number seventeen, we deal only with coil ignition. Both low tension and high tension. Magnetos will be treated further on.

*Either the positive or negative side can be grounded as it makes no difference. Manufacturers as a matter of standardizing, are grounding the positive pole of storage battery (+).
**See page 275—"magneto switch"—note switch is closed to stop ignition.

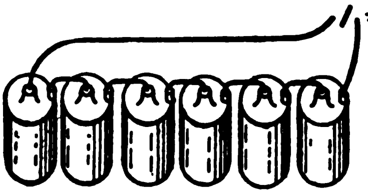

Fig. 1—Series. Zincs connected to carbon.

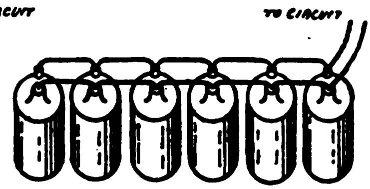

Fig. 2—Parallel. Zincs connected together. Carbon connected together.

CELL CONNECTION

Fig. 1 is the usual method. This method gives the voltage of six cells and an amperage of one cell.

Fig. 2. This method gives the voltage of but one cell and an amperage of six cells.

Fig. 3 is a method used for emergency. In this case the reader will suppose that two sets of dry cells supply the current for ignition; one set is used for a while, then the other; if both sets run down, then connect them in multiple as shown. This method gives a voltage of five cells and an amperage of two cells.

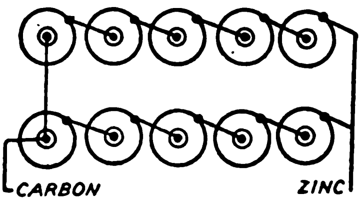

Fig. 3—Multiple Series. See text for explanation.

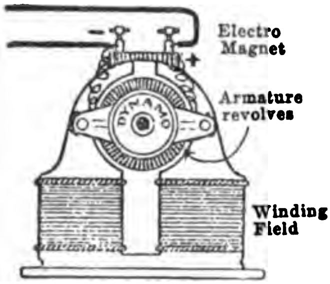

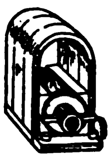

Fig. 4—A dynamo, a mechanical generator of "direct" current. Note the electro winding on field magnet. The armature is "drum" type.

Fig. 5—A magneto with "permanent" magnet. If armature is "shuttle" type (see magnetos) the current will be "alternating," if "drum" type, direct.

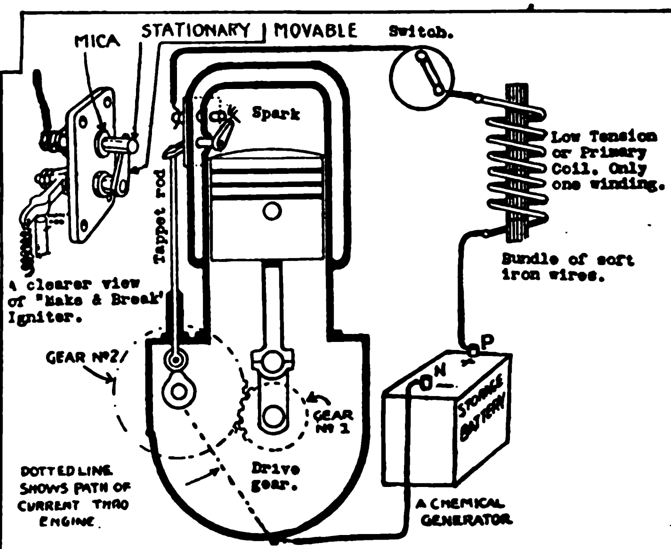

Fig. 7—A make and break low tension system of ignition.

The igniter is shown, which makes and breaks the low tension current as it flows from the positive pole of the battery to the single-wound low tension coil through switch, then to the mica insulated electrode.

*When the nose of the cam strikes the tappet rod, this rod makes and breaks the flow of current and creates a flash or spark (as by hand, fig. 6). The current flows from positive pole of battery to stationary electrode on engine, thence through moveable electrode to metal of engine—thence by way of grounded circuit to battery.

In the above illustration, the coil through which the current passes is a low tension coil, and the system of ignition is the "make and break" system. Either the dry cells, storage battery or the dynamo will supply the electricity. Either of these same sources of electricity would supply electricity for the jump spark or high tension coil also. This latter system will be treated further on. The magneto would require special connections, if used, and will also be explained further on.

The spark should occur just as piston is on top of its stroke or slightly before.

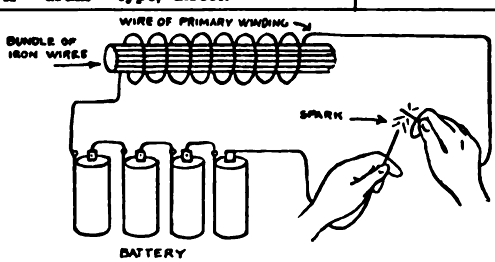

Fig. 6—Explanation of a Low Tension Primary or Low Tension Coil (Single Wound.)

By snapping the ends of the copper wires connected with a battery (after winding this wire around a bundle of iron wires) a spark will be produced. The wires must be "snapped" or separated suddenly, and the current must pass through the single-wound or primary coil.

CHART NO. 102—Cell Connections. Mechanical Generators. Make and Break Principle of Ignition.

*Note the points do not remain together when not operating—they are slightly apart. The cam or tappet arrangement causes the spark to "make" and suddenly "break," hence the term "make and break."

Low Tension Coil System of Ignition.

If the ends of the wires of a primary or low tension coil, are connected with a battery or mechanical generator and connected together, the current will flow, and if then the ends are separated suddenly a spark will be formed between them. The more powerful the current, the larger will be the spark. (See fig. 6, chart 102, this illustration explains the fundamental principle of coil ignition, therefore study it carefully.)

The Make-and-Break Low Tension Coil Ignition System.

This system is shown on page 214, fig. 7 and also page 216.

††The "movable electrode" is operated by a cam arrangement, exactly as the exhaust valve of the engine is operated. As the spark is needed only once during two revolutions of the crank shaft, the cam is attached to the half-time shaft, and operates the electrode by a rod called a tappet.

The "stationary electrode" is insulated from the cylinder with mica, and one wire of the circuit is connected to it. The "movable electrode" is operated by a cam, which is in contact with the current from the grounded wire of the battery and which allows the current to pass from it to the metal of the cylinder.

When the two points are in contact, the current flows from the positive pole of the battery by a wire to the stationary electrode, then to the movable, because the two are in contact, and back to the battery by the ground.

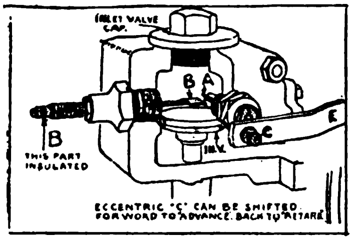
When the two electrodes are separated by the cam acting on the movable one, the circuit is broken, and a spark formed between them.

Illustration fig. 1, page 216, shows the make-and-break system with two sets of batteries connected to the switch in such a manner that either set may be used.

While any battery would give a spark, a strong one is needed to ignite the charge suddenly and completely, and to do this it is necessary to use a strong current. Therefore several cells are connected together, usually 5 or 6. One set is used a while then the other. Dynamos, storage batteries and low tension magnetos are also used.

†Wipe Spark Low Tension Coil Ignition System.

Wipe spark ignition is similar to the "Make and Break" in every respect, except that it makes a wiping and rotary motion as the electrode (A) of the igniter revolves; being operated by an eccentric rod (E) from the cam gear.



The other electrode (B) is stationary and looks very much like a spark plug. This type of ignition is never used on the automobile; but is here shown so that the reader can master the elementary principles of the different ignition systems. This system is used mostly on stationary engines.

The Low Tension Coil.

We have learned the different sources from which electricity can be obtained for ignition. Also the first principle of ignition, which is the old style "make and break" igniter using a low tension or primary coil. This system is seldom used, only on stationary engines, however, it will be well for the reader to master the principle of the low tension coil, as it is the foundation for building up a high tension coil or magneto armature winding. (See fig. 6.)

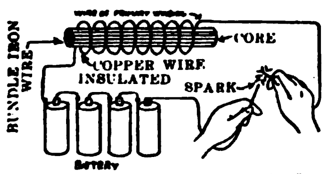


Fig. 6—Explanation of a Low Tension Primary or Low Tension Coil (Single Wound.)

By snapping the ends of the copper wires connected with a battery (after winding this wire around a bundle of iron wires) a spark will be produced. The wires must be "snapped" or separated suddenly, and the current must pass through the single-wound or primary coil.

The current is strengthened, or intensified, by the use of a simple coil, called a primary or low tension coil.

Construction: Consists of a bundle of soft iron wires, called the "core," around which is wound several layers of well-insulated copper wire. (See also coils in chart 103.)

A current of electricity passing through the wire will make the core a magnet, the magnetism ceasing as soon as the current stops flowing. The magnetism of the core acts on the current of electricity, and intensifies it, and making it strong enough to produce a good spark between the electrodes.

The reason for the current being intensified requires an understanding of electrical engineering to make it clear; it is sufficient for the repairman to understand that the current is intensified.

The positive wire of the battery leads to one terminal of the wire wound around the core of the coil, and the other terminal of the coil winding is connected to the stationary electrode.

Because the action of the cam moves the movable electrode, it can be seen that making the cam operate sooner or later will make the spark occur sooner or later. The cam is therefore arranged so that it may act sooner or later on the tappet and electrode, and is controlled by a lever, so that it can be advanced or retarded just as a timer on a high tension coil system.†

††The low tension "make and break" ignition system: two metal points (electrodes, fig. 7, chart 102) are set in the combustion space of the cylinder, one of them being stationary, and the other movable, so that it may touch the other or be separated from it.

The two points are called "electrodes," and form what is termed, the igniter. The two points are connected in the ignition circuit, so that when they touch the current passes from one to the other, and when they are separated a spark is formed between them.

†The make and break system is seldom used on automobiles. Used more on stationary engines. The "wipe spark" is similar; also used on stationary engines, see above, and "Dyke's Motor Manual."

CHART NO. 103—Diagrams of Wiring for the Low Tension "Make and Break" System of Ignition using Dry Cells or Storage Batteries (chemical source), and Dynamo or Magneto (mechanical source).

Wiring Diagrams of the Low Tension "Make and Break" Ignition System.

A "make and break" system (see chart 103); requires less care in wiring than the high tension or jump spark system, but is not suitable for high speed automobile engines.

The first difficulties were; insulating the stationary spark point, and making an easy working but tight joint for the moving spark point, although this has been largely overcome, the jump spark or high tension, has proven a superior ignition and it is to this latter system we will confine our attention in the following instructions. It is well, however, for the reader to master the low tension system of ignition in order to understand the high tension system.

Wiring for two sets of dry cell batteries: In fig. 1, chart 103, we have two sets of dry cells as the source of electricity for the make and break system of ignition. One set is used a while and then the other. **Dry cells run down rapidly,** therefore this system is seldom used.

Wiring for batteries to start on and the dynamo to run on: The dynamo, which generates a direct flow of electric current, is usually placed so that it is operated by the engine, and the usual plan is to start the engine with dry cells, and after engine is started, the dry cells, are switched off and the dynamo supplies the electric current. (See fig. 3.) This system is used quite extensively on stationary gasoline engines, as well as a great number of marine engines.

The storage battery for make and break ignition: This system (see fig. 2), is practical if the storage battery can be recharged. The storage battery will supply a certain quantity of current for a certain period of time; for instance, suppose the storage battery was a 60 ampere hour battery, and the ignition system used one ampere of current per hour; in this way we would have a sufficient quantity of electricity from the storage battery to run the ignition for 60 actual hours.

Suppose the engine only runs three hours per day—we would use three amperes of the 60 in one day; therefore we would have 57 amperes left, which would run 19 more days of three hours per day.

The storage battery delivers the same pressure until all the amperage or quantity is gone, whereas a dry cell, not only loses in amperes or quantity, but it loses its pressure in a very short time of service.

The usual pressure required to force the current through the coil is six volts (pressure). The storage battery will hold this pressure until the quantity of current is all gone. The dry cell drops in voltage rapidly, and therefore weakens the spark. When a storage battery runs out, it is restored with electricity. When a dry cell runs out of current, it is thrown away.

Sometimes we see a storage battery and a dynamo or magneto connected so that the engine is started from the storage battery and then switched to the dynamo, after the engine is running. When a dynamo or magneto is used for supplying electricity, it is usual to have either a set of dry cells, or a storage battery to start with. The reason for this is; a dynamo or magneto must first run in order to generate electric current, and the usual plan of cranking an engine will not speed up the dynamo or magneto fast enough so that it will generate current. Therefore, the dry cell and storage battery are used for starting, and after the engine is started and is running fast enough for the dynamo to generate current, the switch is thrown from the battery to the dynamo.

A low tension magneto for ignition: The subject of magnetos (low and high tension) is treated under a separate instruction.

The low tension magneto is used quite extensively for make and break systems of ignition, in connection with a set of dry cells to start with, on the same principle as the dynamo combination. The magneto, however, differs from the dynamo, in that it supplies an "alternating" current instead of a "direct" current.

No coil is necessary in connection with the low tension magneto, but the coil in the diagram (fig. 4) is used in connection with the battery for starting. The coil used with the magneto is wound on the armature of the magneto. This subject will be treated further on.

A four-cylinder make and break system of ignition with dry cells and dynamo. All of the diagrams shown are illustrated on one-cylinder engines. In fig. 5, chart 103, a four-cylinder engine, with make and break system of ignition, is connected up, using a combination of dry cells to start with, and a dynamo to run on.

Note—The above systems are not now used on automobiles, but were formerly used in the early days of motoring. **The reason for explaining** the old systems of ignition, is due to the fact that the underlying principles of the more modern systems are founded upon the principles of these early days. Therefore it is essential that they be mastered first in order to more clearly understand the modern systems treated farther on.

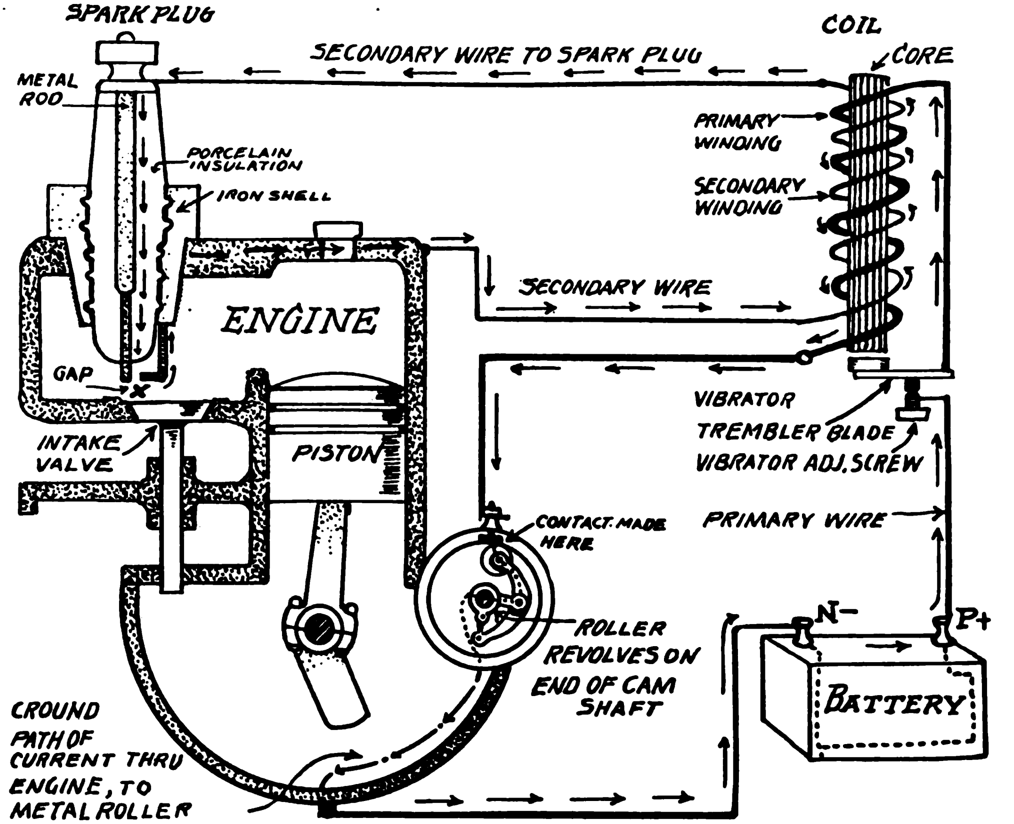

Fig. 1.—An exaggerated drawing, made for the purpose of illustrating how the spark plug is screwed into the combustion chamber of the engine, and how the current is carried from the battery through the primary winding of the coil, to commutator, etc. Also showing the secondary circuit. The lower secondary wire could be connected to the primary wire instead of grounding to engine and the path would be through metal part of engine, through commutator roller back to coil. See page 226. Trace the circuit with your pencil.

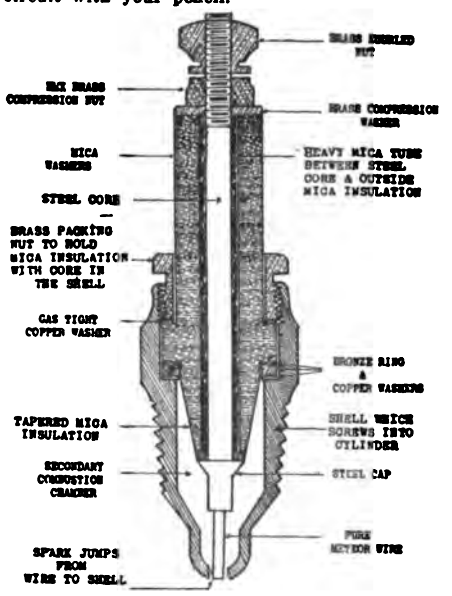

Fig. 2—Parts of a mica insulated spark plug. The mica plug construction is explained on page 238, fig. 12. The porcelain type is used most.

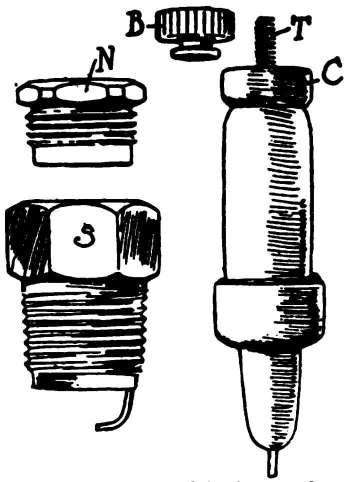

Fig. 3—Parts of a porcelain insulated spark plug seperated. Spark plugs are used with jump spark coil and high tension magneto ignition systems. See also, pages 84, 235, 238.

S—iron shell which screws into engine.
N—brass bushing which holds (C) in place.
C—porcelain with electrode (T).
T—rod, called electrode.
B—screws on (T) and holds secondary wire.

CHART NO. 104—Diagram Showing the Parts of a High Tension (also termed Jump Spark) Ignition System using a High Tension Coil (with vibrator) and *Commutator.

Note: Spark plug is usually placed over the inlet valve. See footnote page 219. *See page 225 for commutator.

INSTRUCTION No. 17.

IGNITION; HIGH TENSION COIL: Wiring of High Tension Vibrator Coil System. Purpose of the Spark Plug. The Induction Coil Principle. Magnetism. Mechanical and Electrical Vibrators. Commutators. Commutators and Distributor. Timers. Master Vibrator. The Coil Condenser.

The low tension, or make and break, system of ignition, described in the last lesson is not used very much. The "high tension," or as it is sometimes called the "jump spark" system, is the system in general use.

Purpose of Spark Plugs.

You are more or less familiar with the ordinary spark plug that is used in connection with ignition systems to give a spark inside the cylinders of the engine. In chart 104, are two views of two typical spark plugs, one showing plug as if cut in two, called a sectional view, the other view shows plug disassembled. The metal part of plug (T) acts as a conductor of the current, while the porcelain (C) represents the insulating material, which is composed of porcelain or mica. (see pages 233 to 239.)

*A spark plug is screwed into each cylinder of the engine, and when the piston is in the right position to receive a spark, a current of electricity is sent along the metal center part (called the firing pin) of the spark plug and across the small air gap at the bottom and into the outer sleeve. Although this air gap is only about 1-64th to 1-32nd of an inch wide, the air in the gap offers such a tremendous resistance to the current that it requires in the neighborhood of 16,000 volts' pressure to force a very small quantity of current across the gap. In other words the current must be of such high pressure that it will jump across a space between two points, forming a spark as it passes. See "gap" fig. 1, chart 104. Also pages 542 and 699.

The current produced by a battery and low tension coil as used for the "make and break" system, would not have enough pressure to jump across this gap, therefore must be **intensified** (or pressure increased) still more.

Where simple low tension coils are used for the make and break system, as explained in chart 102, fig. 6; coils of another kind, called **high tension induction coils** are used to **intensify** the current sufficiently to force it to jump across the open space. Therefore it is called the "jump spark" or "high tension" (meaning high pressure).

**The Jump Spark or High Tension Coil.

Construction: An induction coil or jump spark coil, consists of a core of soft iron wire, over which is wound a few layers of insulated copper wire, which is called the **primary winding** (in other words, this is our original low tension coil, fig. 6, chart 102).

Over the **primary** winding is wound a great number of layers of exceedingly fine copper wire, insulated, called the **secondary winding.** (See fig. 1, chart 104.)

When a current of electricity flowing through the primary winding from some source of electric supply is suddenly stopped and then started again, another current of great pressure flows in the secondary winding—**although the two windings are not connected**—this is called "**induction,**" or temporarily "**induced**" current.

This "**induced**" current in the secondary winding is also called the "**secondary current,**" and flows in waves, there being a wave of current whenever the primary or battery current is stopped and started again by a contact breaker of some sort.

*The position of the spark plug in the cylinder can be placed as follows; over center of piston, over exhaust valve, or over inlet valve. The first position is not the best, as it is found that it too easily becomes fouled. If screwed above the exhaust it will likely miss fire; this is caused on account of the dead gases surrounding it. The correct position is over the inlet valves, as it will be kept cool by the inrush of fresh gas, and it is in an atmosphere perfectly suited for explosion, directly the spark appears, as it is the more perfectly scavenged part of cylinder, i, e., in the direct path of the fresh gas. The plug is usually placed over the inlet valve on "T" or "L" head cylinders. In the overhead valve type, the plug is placed in the top center or in the side of cylinder. They are exposed to the full heat of the explosion when over head directly in center of bore, consequently in a high compression engine of this type, a well made plug must be used.

Many of the overhead valve engines, have the plugs in the side of the combustion chamber. See index "Overhead Valves," "Compression," "Spark Plugs" for additional information.

**Also called "induction coil," "transformer coil," "secondary coil."

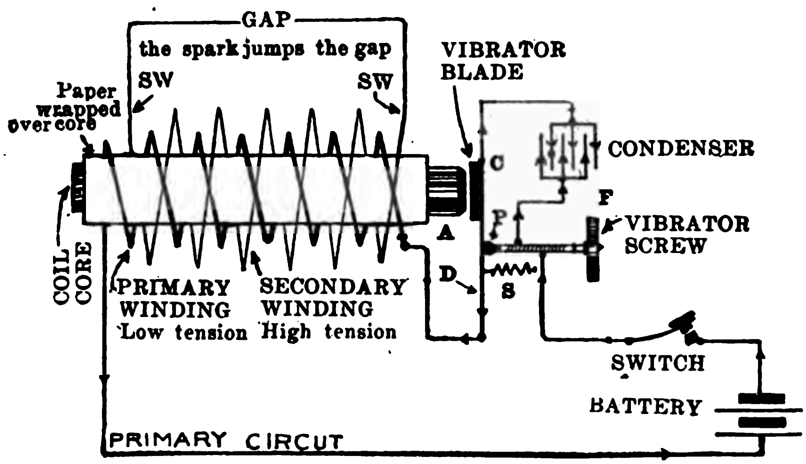

Fig. 1—Another view of a jump spark coil, also called an induction coil, high tension coil or secondary coil. The illustration explains how the primary and secondary winding is wrapped over the core and how the magnetic vibrator interrupts the flow of electricity from battery through the primary wire circuit, and how the spark jumps the "gap" of the spark plug. When switch (or timer) is closed, the current flows from battery through this primary wire wrapped around the core or bundle of iron wires (A), (trace with pencil). The bundle of iron wires become magnetized when the primary electric current flows around it. This magnetism causes the vibrator blade (C) to be drawn away from its connection with screw (F) at platinum points (P).

The moment this vibrator is drawn away from screw (F) the circuit is broken and the bundle of wires (A) loses its magnetism, therefore the vibrator (C) is again drawn back to screw (F) by spring (S), but the moment the contact is again made—(A) again becomes magnetized and draws the vibrator (C). This is repeated so fast the vibrator (C) simply buzzes. The greater the buzz, the greater the spark or voltage and more current consumed.

When this vibration takes place the current is "induced" in the secondary winding (wrapped over the primary winding) by "induction" and this induced current is intensified, that is, the pressure is raised to such a high voltage it will jump the gap as shown, or if one end of this secondary winding (SW) is connected to a spark plug and other end grounded, then it will jump the spark plug gap.

A timer is used instead of a switch but its purpose is the same, see page 222.

A condenser is connected or "shunted" around the points (P) for purpose explained on pages 228 and 229.

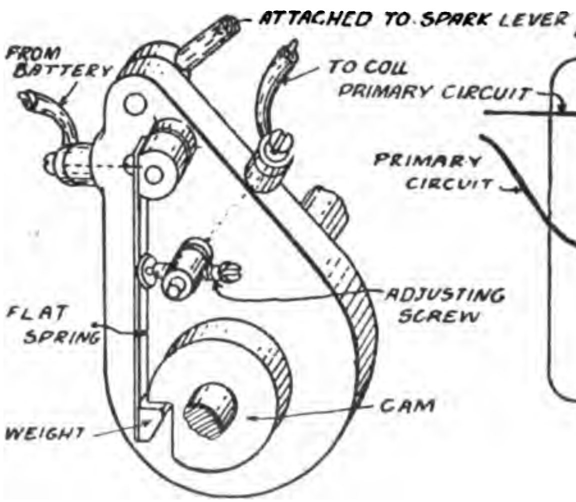

Fig. 2—A Mechanical Vibrator.
(Seldom used.)

The purpose of this device is to open and close the primary electric circuit in rapid succession mechanically, instead of the magnetic vibrator.

When this type of vibrator is used the vibrator on coil is not necessary as shown in figs. 3 and 1.

The case is made of fibre or metal, but the spring and screw are insulated from each other.

The above timer is used principally on single cylinder motorcycle engines.

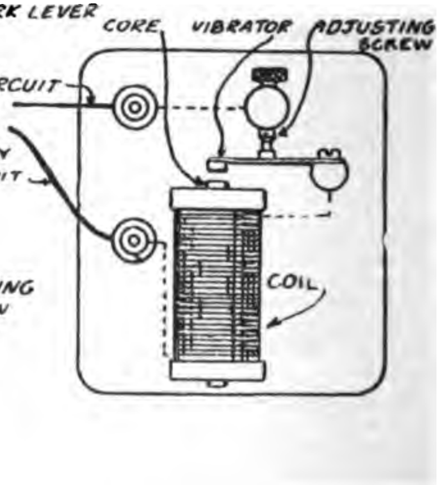

Fig. 3—A Magnetic Type of Vibrator.
(Same as on coil in fig. 1.)

This illustration shows a vibrator placed on the coil, and operated electrically.

There must now be a "commutator" or timer to close and open the circuit at the proper time, in order to operate this vibrator electrically. If engine is a four cylinder engine, a commutator with four contacts, as shown on page 222 would be required.

CHART NO. 105—Diagram explaining the double wound High Tension Coil and action of the Vibrator. The Mechanical Vibrator and the Electrical Vibrator (vibrators are sometimes called "tremblers.")

Elementary Principle of a High Tension Coil.

The reason for this separate current flowing in the "secondary" winding can only be understood after studying electrical engineering; however, we will endeavor to give the reader the elementary principle of "magnetism," "lines of force" and "induced" current, also the relation of volts and amperes to cell connections, as follows:

In order to produce a spark in the cylinder of engine sufficiently strong to ignite the compressed gas, it is necessary to have the *current producing the spark under great pressure. The pressure or voltage of a storage battery or a number of dry cells is not enough, so it remains to make this pressure greater so that it may be used with good results.

Raising the voltage of the battery current is accomplished by means of an induction coil (high tension coil) called a spark coil. In order to fully understand the induction coil, a few elementary steps must be learned first.

An ordinary horseshoe magnet is known to attract iron and steel. The magnet will have a holding effect on the iron or steel even if the magnet is separated from the iron by a piece of paper or glass. The magnet attracts the iron because of some mysterious, unseen force that is called mag netism. We cannot see the magnetism, nor can we feel it, but we can see and feel the effects of it. If a number of iron filings are attracted by a magnet, it will be noticed that the filings arrange themselves in rows from one pole of the magnet, to the other.† It is supposed that the filings arrange themselves in lines because the magnetism goes from pole to pole, or end to end, in lines. We cannot see these lines, but their peculiar characteristics has resulted in their being called "lines of force."

In other words, that unseen, mysterious force which we call magnetism is expressed in "lines of force." All the lines of force between the two poles of the magnet comprise a "magnetic field."

Now, the magnetism or "magnetic lines of force" manifest themselves not only around a magnet, but around any current carrying wire. This can very easily be proven. In fig. 1, a battery is being exhausted through a conductor. If a compass is held near the wire shown, the needle of the compass will suddenly take a turn and then remain still. The current passing through the wire causes magnetism to exist around the wire for a certain distance, and this magnetism, acting upon the steel needle of the compass, causes it to turn.

If this simple experiment is tried it will be found that the compass needle will turn **in the direction of the flow of "lines of force" around the conductor. The current in the wire flows from the carbon or positive side and in the direction shown by the arrow. It should be borne in mind, then, that around every conductor of electricity there are lines of "magnetic force" or, as we shall call it, a "magnetic field."

The magnetism from the magnet is called "natural magnetism." But magnetism may be produced in another way by the use of what is called an "electromagnet." The apparatus is shown in fig. 2. An iron bar has packed around it some paper or other insulating material. A coil of copper wire is slipped over the iron, which is called the core. The two ends of the coil or wire are attached to a number of dry cells, connected in series. If a piece of metal such as steel is placed near the end of the core it will be attracted by the core. If the wires from the battery are removed the pieces of iron or steel at the end of the core, are no longer attracted.

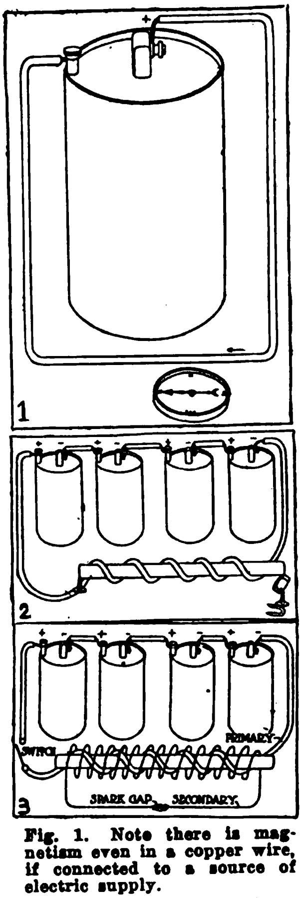

Fig. 1. Note there is magnetism even in a copper wire, if connected to a source of electric supply.

Fig. 2. A primary single winding of copper wire (usually of larger size than the second winding), around a soft bar of iron will cause bar to become magnetized.

Fig. 3. If another winding (smaller wire), is wrapped around the primary, a high tension current of electricity will be "induced" into the second winding.

In other words, as soon as a current is passed through the copper coil, the iron core is magnetized, but as soon as the current stops flowing the magnetism stops. We do not know why the core becomes a magnet, except it be by the presence of a magnetic field around the copper coil. This magnetic field pierces any thing. This is here evident because the core is insulated by paper. It could just as well have been wood or glass or stone.

It has just been shown that the current flowing through a coil of wire affects an iron bar within it so as to make the bar be-

*Note—"Current" means electricity or the flow of electricity.

**Through an error, compass needle in fig. 1, is shown parallel to current flow, instead of lines of force. Needle should point towards you. †See page 267.

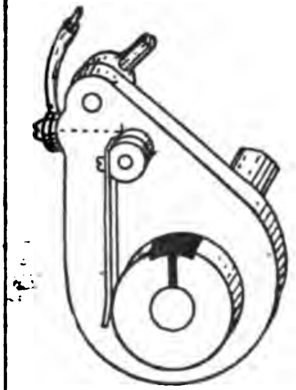

Fig. 1—Simple form of brush type of commutator.

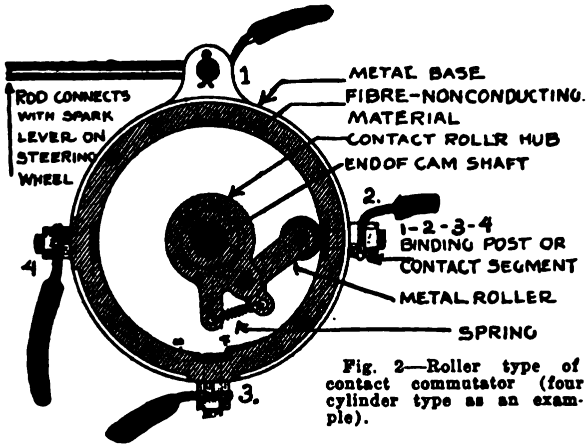

Fig. 2—Roller type of contact commutator (four cylinder type as an example).

Fig. 1—The revolving part is fibre (insulation). The black part is a metal strip or segment grounded to cam shaft. The blade or brush is insulated from the base. This brush connects with primary winding of coil, thence to battery and one end of battery is grounded. When the segment touches the brush, the contact is completed and causes the vibrator to vibrate.

Fig. 2—The principle is the same as in Fig. 1, except a roller makes the contact with segments. Each segment is connected with the primary winding of coil. There are as many segments and coils as there are cylinders.

Fig. 3—This type of timer is used in connection with a coil without of vibrator. It makes a single hot spark as explained There are as many cams as there are cylinders. On the above, there are four cams. Therefore, it is suitable for a four cylinder engine. The above timer is the Delco.

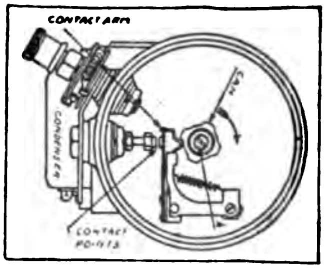

Fig. 3—The modern type of timer.

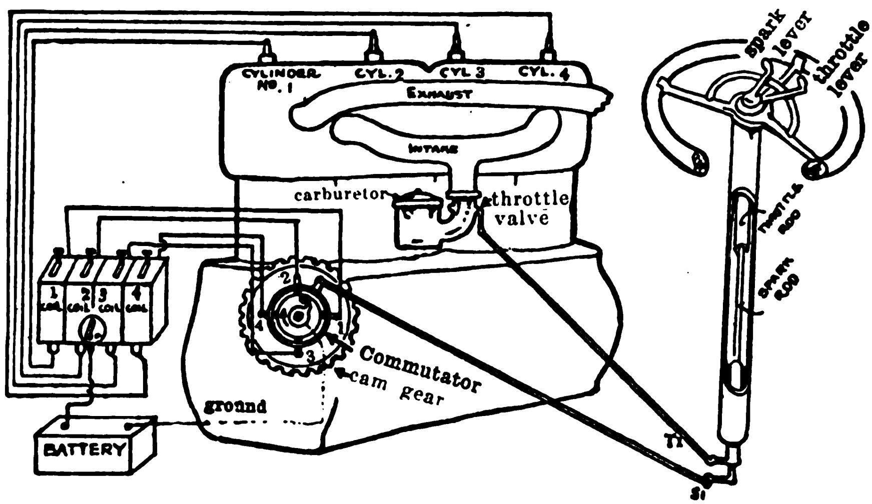

Fig. 6—Note the manual (hand) method of "advancing" and "retarding" the commutator. (Four cylinder engine as example.) If the roller is revolving to the right, by shifting the commutator housing to the left, contact would be made earlier—this would be called "advancing" the spark. If shifted to the right, would be made later—called "retarding."

When using a vibrator coil (which is the case here), the time of spark is set earlier than when using the single spark system—because plenty of time must be given the spark to ignite the gas so it will ignite or combust on top of the stroke instead of after the top. Note connections to commutator for firing order of 1, 3, 4, 2.)

CHART NO. 106—The Commutator, Timer and Purpose of each. Commutator Control.

Above timer, fig. 3, is open-circuit type. The closed-circuit type per pages 242 and 378 is now in general use.

come a magnet. It will also affect another wire placed alongside of the wire carrying the current. These same lines of force which will make a magnet out of a piece of soft iron will set up another current of electricity in another wire close to it, but which has no electrical connection with it.

That is, if we would take a coil of wire and attach the end of the coil to a battery and then wind another coil around this first one and insulate it from the first, we would find that every time the current in the first coil, that is, the one connected with the battery and which is called the primary coil is interrupted, or commences to flow or stops flowing, there is a current set up or "induced" in the other coil, which is called the **"secondary" winding.**

As long as the current in the first coil continues without change or interruption, it does not set up an "induced" current in the secondary coil, fig. 3.

The current is "induced" in the secondary coil only when the flow of current in the primary coil changes, usually by opening or closing the circuit. The effect of the primary coil upon the secondary has been found to be increased if we put a bar of soft iron inside the two coils (which is done in fig. 3). The construction is just the same as if we took the electro-magnet referred to in Fig. 2 and wound the secondary coil outside of the primary coil.

The secondary current acts in the same manner as the primary current; that is, it flows through wires and can be made to do work, and it can be grounded; the current leaving the secondary winding at one terminal and returning to the other. The difference is that it has exceedingly high pressure (voltage), and little volume (amperage), and flows in a reverse direction, while the primary current has low pressure and great volume, but in both cases the total currents are equal.

Therefore we have learned the first principles of a high tension coil; how the iron core is wound with a "primary" wire, and over the primary winding another winding called the "secondary," is wound.

When the circuit of the primary coil, which is connected with a source of electric supply of some sort, is closed and opened suddenly, the current is "induced" in the second winding, and at the same time it is "intensified," meaning, the voltage is raised so high it will jump a gap as shown in figure 3. **The method for making and breaking this contact at the right time,** will now be treated.

The Vibrator—its purpose.

As the secondary current only flows when the primary current begins to flow, and is suddenly interrupted, there must be an arrangement that completes the primary circuit, so that the battery current **stops flowing or is interrupted from flowing.**

This arrangement is called a "vibrator," and it may operate in two different ways; **"electrically or magnetically,"** and **"mechanically."**

The Mechanical Vibrator.

The "mechanical vibrator," is shown in chart 105, fig. 2. When this type of vibrator is used, the **vibrator on the coil is not required,** as the vibration of the flat spring against the adjusting screw causes the contact to be suddenly opened and closed, by the cam, during which time the **flat spring vibrates mechanically,** causing an induced current to flow in the secondary winding of the coil.

It consists of a flat spring with a small weight on one end, and the other end is attached to a post. The weight rests on the iron rim of a small cam with a notch in it, so that when it turns the weight drops into the notch. One wire from the primary circuit is attached to the flat spring and the other wire of the primary to an "adjusting screw."

When the weight called the bob, is in the notch of the cam, the float spring makes contact with the "adjusting screw," and the current flows, but the cam in continuing to turn moves the weight out of the notch, which separates the flat spring from the screw, and breaks the circuit.

Because of the springiness of the flat spring, it vibrates when the weight drops into the notch, making and breaking the current. By making and breaking the contact in this way, the primary current flows through the primary winding in waves, flowing and stopping each time that the vibrator makes and breaks the circuit, which produces a corresponding current in the secondary winding, called an "induced" current, as previously explained.

The interruption method fig. 2, chart 105, was used extensively on single cylinder motorcycle engines and a modification of this principle is used on the modern ignition systems, as the Delco and Atwater-Kent systems, but instead of the flat spring, a different method is employed as shown in fig. 3 chart 106, which gives but a single spark. The principle of "mechanically" closing and opening the circuit, however, is similar. (See also pages 247 to 252 and 378.)

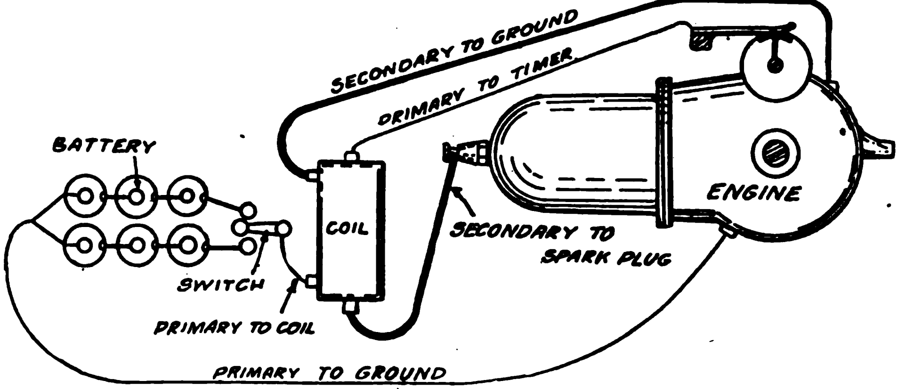

Fig. 1.—One Cylinder Engine with a Vibrator Type of Jump Spark Coil and Two Sets of Dry Batteries for Ignition. Only one set of batteries in use at the time. Commutator revolves one-half the speed of crank shaft.

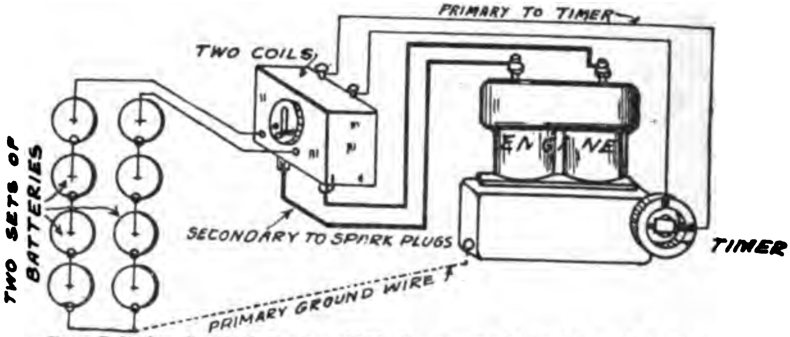

Fig. 2.—Two Cylinder Vertical Engine (180 degree crank shaft) with a **Vibrator Type of Jump Spark Coil** and Two Sets of **Dry Cells for Ignition.** Note position of segments on commutator. **Commutator** revolves one-half the speed of crank shaft. (This type of engine is seldom used.)

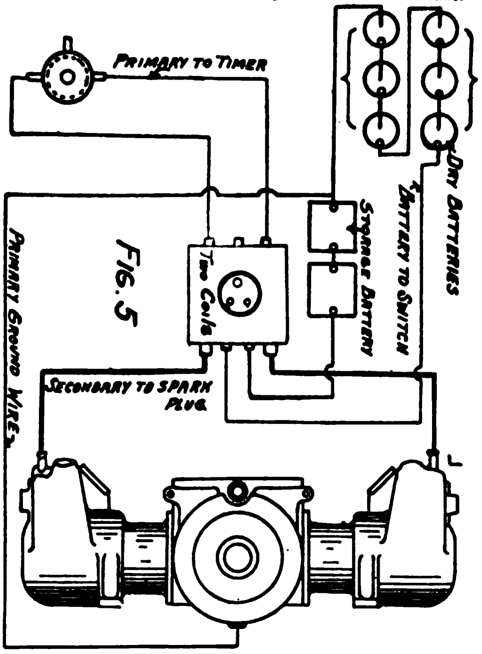

Fig. 3.—A Two Cylinder Opposed Type of Engine with a Two Cylinder Jump Spark Coil and a Set of Dry Cells and a Storage Battery, either of which may be used. The two contacts on commutator placed opposite. Revolves ½ speed of crank shaft.

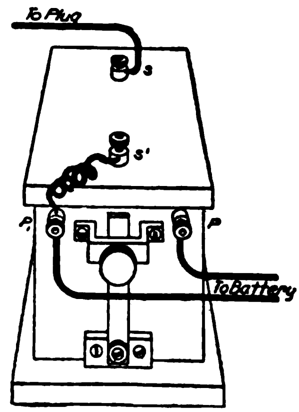

Fig. 4.—A Single Cylinder Vibrator Type of Jump Spark Coil. This type is usually called a "Box Coil." Quite frequently a single cylinder box coil has but one secondary connection on top. In this case the secondary connection shown at front of the coil is connected inside of the coil to the primary wire which connects to binding post P.

CHART NO. 107—Wiring Connections of the High Tension Vibrator Coil System of Ignition. (Magnetos not shown here).

The Magnetic Vibrator.

The magnetic vibrator depends on the magnetism produced in the core of the coil when the primary current passes. (See figs. 1 and 3, chart 105.) A flat spring, called the vibrator spring or blade, is so placed that one end of it is opposite the end of the core, the other end being firmly supported. Touching the vibrator spring near its free end is the point of contact with the "adjusting screw."

Connections: One terminal of the battery (fig. 1, chart 104), is attached to the adjusting screw; the vibrator spring is connected to one of the primary winding of the coil; the other end of the primary winding is connected to the commutator, which we will call a revolving switch. When the "commutator" switches the current through the primary winding the "core" becomes a magnet and attracts the free end of the vibrator spring, drawing it away from the adjusting screw. As soon as the attraction draws the vibrator spring out of contact with the adjusting screw, the circuit is broken; the current stops flowing in the primary coil, the core ceases to be a magnet, and the vibrator spring being no longer attracted by the magnetism, it springs back and again makes contact with the adjusting screw. This again closes the circuit, the vibrator spring is again attracted by the magnetism—thus the circuit through the vibrator spring and adjusting screw is broken and made again **as long as the commutator keeps the primary circuit closed** through its contacts.

The strength of the secondary current, and consequently the strength of the spark, depends on the correct adjustment of the vibrator spring by the adjusting screw As the construction of a coil is very delicate, it is not expected of the driver that he be a coil expert, but he should know how to adjust the vibrator properly.

Succession and Single Spark.*

The high tension coil using a magnetic vibrator in connection with a commutator (fig. 1, chart 104); causes a "**succession**" of sparks instead of a "**single**" spark. The disadvantage of this type of coil is the possibility of the vibrator platinum points sticking, consequently a missing of explosions. Another disadvantage **is that it** makes several weak sparks, the hottest one igniting the charge. This causes slow ignition. A good "single" hot spark has proven the most effective, as used on the Delco and Atwater-Kent systems, employing a mechanical type of vibrator; (fig. 3, chart 106 and page 247).

The Commutator.

Because the secondary current is only needed when it is time for the spark to pass and ignite mixture, the primary current is switched into the primary winding only once during two revolutions, (on a single cylinder engine), and the switching is done by a "commutator" or "timer."

Before proceeding further we will make a distinction between a commutator and a timer. Heretofore the word "timer" and "commutator" have been used to apply to the same device. Suppose we call the device which makes the contact by a brush or roller contact, as per figs. 1, 2 and 6, chart 106, a commutator. This device is always used in connection with a magnetic vibrator type of coil.

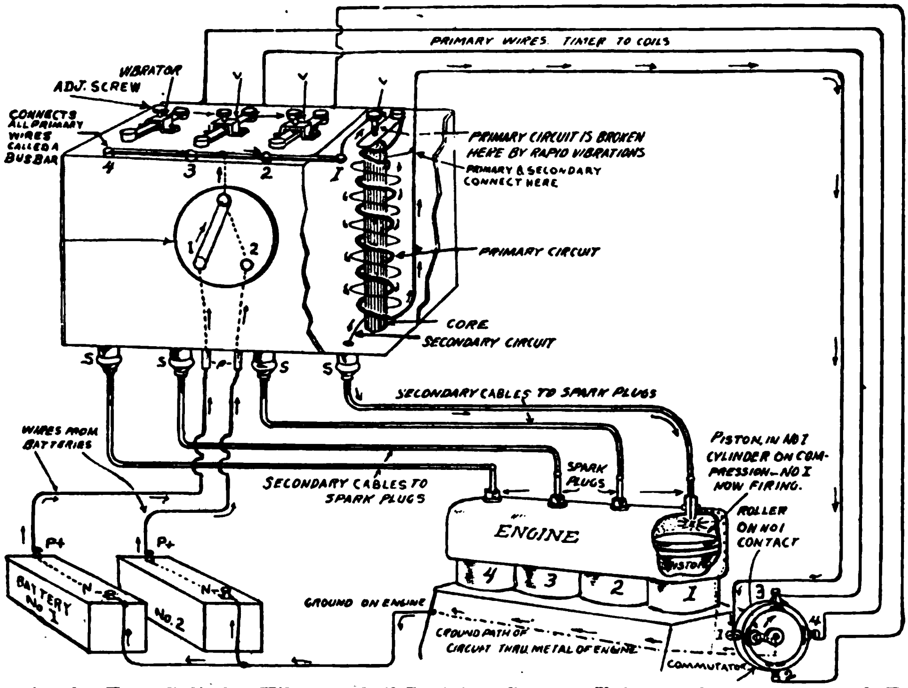
The Timer.

The timer, we will class as a mechanical method of causing the contact to be closed and opened, as per fig. 3, chart 106. This device makes a single spark and is generally used in connection with a **coil without a vibrator.**

There are two principles of the timer; one, where it is used to **open the circuit** which is otherwise always closed. This operates on what is termed **the closed circuit** principle. The opening of the closed circuit **interrupts** the flow—therefore it is termed "an interrupter" or "contact breaker," (see page 243).

The other, when it is used to close the circuit which is otherwise always open. This operates on what is termed the **open circuit principle**: (treated further on).

*See page 250.



Circuit of a Four Cylinder Vibrator Coil Ignition System Using a Commutator and Two Sets of Batteries.

This illustration explains the primary wiring connection from the battery, through one of the coils and connections to the other three coils and to the commutator, back to battery. Also the secondary circuit from coil to spark plugs back to coil.

Primary Circuit: Place your pencil on the drawing at the (P+) positive pole of No. 1 battery and follow out the circuit.

We will begin with the positive pole connection of No. 1 battery; there are two sets of batteries, but only one set used at the time. If one runs down, the other one is thrown into service by switch on the coil. The switch is now on No. 1 contact and the circuit is from No. 1 battery to switch, through switch lever to bus-bar on front of the coil, which connects to the contact screw "V" of coil, thence through the platinum points, through the magnetic vibrator spring, to the primary winding which is wrapped around a core or bundle of soft iron wires.

The other end of this primary wire of coil connects with the segment on the commutator; the current is closed here at the proper time. The commutator roller contact revolves as explained previously. When this contact is completed the primary circuit is closed on one of the four coils, (it is now closed on No. 1 coil). When this circuit is closed, the bundle of iron wires (core) becomes magnetic and draws the vibrator down, but the moment the vibrator is drawn away from the contact with the vibrator screw, the circuit is broken and the vibrator springs back and makes contact again, but is immediately drawn down again; this, of course, is quick and rapid. This vibration is kept up as long as the contact is made on the timer, which, of course, is only for a moment, but during that time the vibrator makes several vibrations or "buzzes" as explained on page 220.

Secondary circuit: When these vibrations occur, the current is "induced" into the secondary winding of fine insulated wire wrapped around the primary winding of coil, called a "secondary winding." (How and why this current is induced into the secondary winding without any metallic connection was treated on page 221.)

This secondary winding, of course, has two ends; one end goes to a spark plug and the other end connects to one side of the primary wire, which grounds it through the commutator roller to engine, when roller makes contact, thence the circuit is to metal shell of spark plug in engine, across the spark plug gap, to the insulated part of spark plug, back to coil—see also page 218. A seperate coil unit is provided for each cylinder.

The duty of the commutator is to make contact at a certain time in order that the right coil will operate and supply an electric spark to the right cylinder at the right time.

When one wire on any wiring diagram passes over another wire without making contact, a half circle is made, as shown above.

CHART NO. 108— Explanation of how a Four Cylinder Engine is Operated by Four Vibrator Coil Units, Commutator and two Sets of Batteries. Note the firing order is 1, 3, 4, 2. This change is made on the commutator.

See page 356 for electrical signs or symbols—of wires crossing, etc.

†**A commutator** might be termed a revolving switch which brings two pieces of metal, connected in the primary circuit in contact with each other as it revolves. One part of the commutator is stationary and the other movable, being attached to the half-time shaft (cam shaft). The usual location for a commutator on an engine, is on the end of the cam shaft, as shown in chart 106, fig. 6. (Also see Ford supplement.)

Construction: Commutators are made in various forms, some of which are shown in chart 106. (It is now seldom used.) The simplest, being one shown in fig. 1, consists of a small disk of hard rubber, wood fibre, or other insulator, in which is set a piece of metal that makes contact with the shaft to which the disk is attached. A flat metal spring, called a brush or blade rests on the circumference of the disk. and as it turns the metal plate is brought in contact with the spring.

One wire from the primary circuit is connected to the brush; the shaft being of metal, and resting in metal bearings, is in contact with the metal of the engine and consequently the electric current may pass from it to the primary wire that is grounded on the engine. Thus when the wheel has turned so that the piece of metal called a contact, makes connection with the brush (the brush or blade being insulated from the base), the current passes from the brush to the contact, to the shaft, and then through the metal of the engine back to the battery. As the wheel in continuing to turn moves the contact away from the brush, the circuit is broken. and the current stops.

Each time that the contact touches the brush or blade, the battery current passes through the primary winding of the coil, making the vibrator operate and causing the secondary current to form its spark in the cylinder.

Commutator segments: The metal contacts in the fibre housing (fig. 2), to which wires from coils are connected, are called "segments." There are as many segments as there are cylinders. These segments are placed certain distances apart according to the number of cylinders, for instance; a "two cylinder" commutator would have two contacts; if it is of the opposed cylinder type. The two contacts would be placed 180 degrees apart. If a "single cylinder" engine, only one spark is necessary during two revolutions of the crank shaft, therefore the contact roller would revolve one-half the speed of the crankshaft and there would need be but one contact segment.

If a "four cylinder" engine, there would be four contacts; placed 90 degrees apart. Because the contact roller revolves one-half the speed of the crank shaft, there would be four sparks during two revolutions of the crank. If a "three cylinder" engine, the contacts would be 120 degrees apart. The roller contact also revolves one-half the speed of crankshaft in this instance. If a "six cylinder" engine the contacts would be 60 degrees apart, as six impulses or contacts are necessary during two revolutions of the crank shaft, therefore the roller contact would revolve one-half the speed of the crank shaft also. On an "eight," the contacts would be 45 degrees apart.

How the Commutator or Timer, Helps Control the Speed.

The commutator *is connected to the spark lever on the steering wheel. (See fig. 6, chart 106.) When the spark lever is pushed forward the commutator is shifted forward so that the metal roller makes contact earlier with the contact segment—this is called "**advancing**" the spark.

If the commutator is shifted back instead of forward, the contact is made later—this is called "**retarding**" the spark.

There are two methods for advancing and retarding the spark; (1) by hand, called "manual" method, per fig. 6, chart 106; (2) by a governor arrangement, as per chart 117, which is automatic. Both are explained under the "ignition timing" instruction.

The setting for the time of spark to occur. is done by placing the contact at a certain position, as explained under "ignition timing."

The gas throttle lever is the lever used to run on and is the lever used to increase or decrease the speed of an engine. This is done by opening and closing the throttle, as explained under the subject of carburetors (see pages 67 and 68.)

It is well to run with the spark lever as well forward. or advanced as possible, as it will tend to keep the speed of the engine up and consume less gasoline and create less heat. If the spark lever is too far advanced then the engine will pound or knock because the igniton will take place before the piston is over the center. **A retarded spark** produces heat—see page 319.

The amount of advancing and retarding of the spark by hand, must be learned by actual practice in order to get the best results.

**The Coil Condenser.

We have explained the essential principles of coil ignition; how the current is passed through the primary winding from a battery or dynamo; how the contact is made on the commutator and timer; how the flow of current is broken suddenly by means of a vibrator or timer and how the intensified spark is utilized for ignition.

—continued on page 229.

†**Note**—A commutator is really the segments on a dynamo connected with the armature coils, and on which brushes rest. It really should never have been applied to the ignition, but is so well known as an early form of contact, hence we will use it as explained. The Ford uses what is termed a commutator. See page 225 for difference between a commutator and a timer.

*The advancing of the spark and relation of the speed of engine to the spark is treated under "ignition timing" also. **See pages 228 and 245 for coil condenser and page 278, magneto condenser.

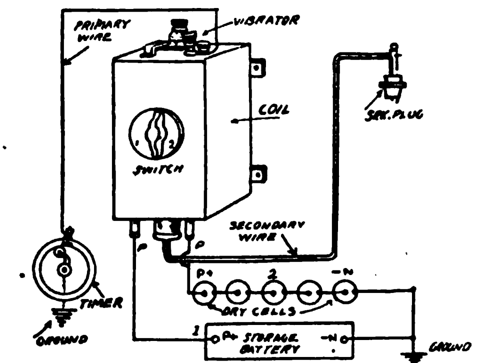


FIG 1. SINGLE CYLINDER

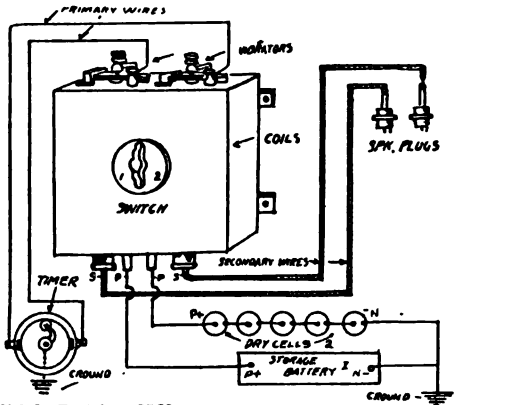

FIG 2 TWO CYLINDERS

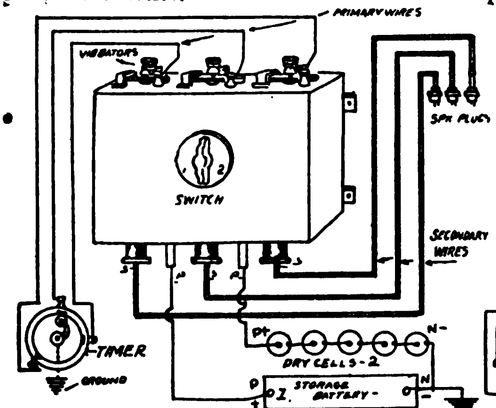

FIG 3. THREE CYLINDERS

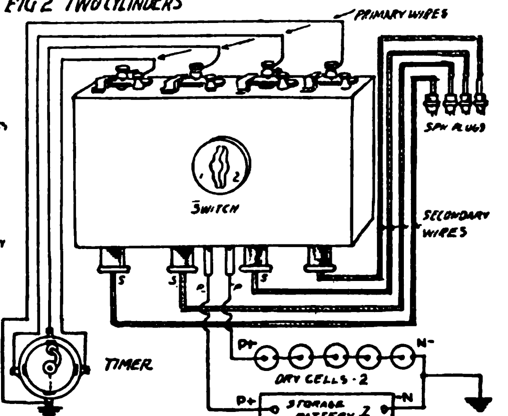

FIG. 4 FOUR CYLINDERS

The Condenser—below.

A condenser is connected with the primary circuit of all high tension coils with or without vibrators, also in connection with primary winding on high tension magnetos.

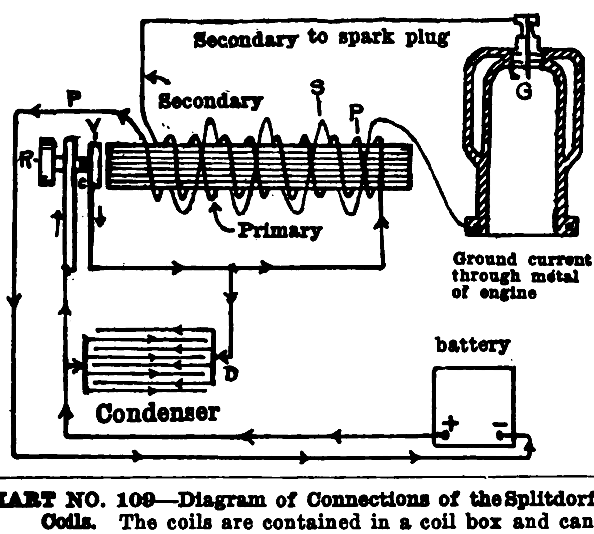
The purpose of the condenser is to intensify the spark at the points of the spark plug and also to prevent excessive sparking at the end of the platinum contact points (C) on the vibrator. If sparking at the vibrator is permitted to continue the point of the latter will wear and become pitted and will stick together.

A condenser is usually placed in the bottom part of the coil box and consists of a number of conductors, which in this case are leaves of tinfoil, separated by paper, covered with paraffine. Paraffine paper is usually employed, but mica or some other insulating material may be used.

The alternate layers of tinfoil are connected together and the remaining layers connected together as shown at (D). (see also page 229). The two terminals of the condenser are connected or "bridged" across the points (C) in the circuit as shown.

The function of the condenser is to act as a buffer to the current at the moment that the circuit at contact points (C) are broken. Its first duty, undoubtedly is to absorb the spark at the contact points.

Not only does the condenser absorb the spark from the contact points (C), but it reverses the direction of the current in the primary wire (P) and changes the poles of the magnet or core. For instance, end of core which was north pole of magnet suddenly becomes south and vice versa. versa.



The reason for it is this: We have seen that any change taking place in an electrical conductor induces electric currents in neighboring conductors, according to the intensity of the change. Now, the sudden change which is caused to take place in half the tinfoil of the condenser, when the current is broken by the vibrator blade (V), causes powerful currents to be induced in the other half of the sheets of tinfoil which are connected to the adjustable screw (R) and therefore to the primary winding; and as these induced currents flow in the opposite direction to the currents causing them they send a current through the primary in the opposite direction to the current that was flowing before the vibrator blade broke contact. Thus the current in the primary is not merely stopped but actually reversed. The effect being greatly to intensify the high tension current in the thin, secondary wire and therefore to produce a more powerful spark at spark plug (G). See page 273, magneto condenser.

CHART NO. 109—Diagram of Connections of the Splitdorf 1, 2, 3 and 4 Cylinder Vibrator Type of Coils. The coils are contained in a coil box and can be removed. Each coil is called a "Coil Unit." **A Condenser;** principle and connections. See page 808 for a "coil-box" and "unit."

And now we come to the condenser which is usually built in the lower part of the coil where it is securely enclosed. Its functions are as follows:

We have seen that the intensity of the secondary current or spark depends upon the suddenness with which we can break the primary current and destroy the magnetic lines of force.

One might therefore imagine that the mere act of mechanically dividing the circuit would suffice, but it is not so, for this reason:—The effect of separating the contact points is mainly to induce a high-tension current in the secondary coil, but unfortunately this induction law does not confine its attentions entirely to the secondary winding, but proceeds to induce a high-tension "follow-on" current in the primary coil itself, thus defeating our efforts to get a sudden cessation of current here.

Not only so, but this current, having a high potential (i. e., is capable of jumping across air gaps), promptly makes a temporary arc between the points which have just separated. It therefore performs the double iniquity of (1) destroying the strength of the spark by preventing the primary current from stopping instantaneously and (2) of burning up the platinum points by the hot electric arc which is formed at the break.

We must therefore take steps to stop this and have accordingly, recoursed to the condenser.**

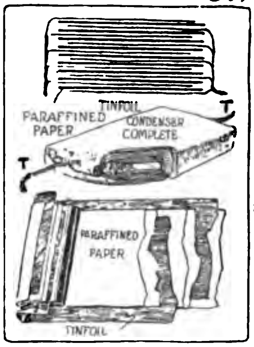


Fig. 1—Construction of condenser

This is composed of a large number of small sheets of tin foil, insulated from each other by sheets of mica (or in the case of a coil by paraffin paper) and tightly pressed together. All the even numbers are connected up to form one pole, and all the odd numbers to form the other pole.

The condenser is "bridged" across the contact points C, fig. 5, page 228, or contact points of a magneto (page 274), in such a way that when the points separate, the condenser bridges the gap and acts precisely as a spring buffer. The high-tension "follow-on" is, so to speak, forced into the condenser, which on becoming charged instantly forces it out again by a species of electrical rebound not only checking the current but momentarily reversing its direction, which is of course even more effective.

The intensity of the secondary or firing spark is thus increased ten-fold and the primary spark at the contact points reduced almost to invisibility. (see also page 273.)

High Tension Coil Circuit.

The manner in which the parts of the high tension ignition circuit are connected together is shown on page 218, fig. 1. From the battery is led a ground wire, attached to any convenient part of the engine.

When the commutator connection on engine makes contact, the current flows from the battery (if a battery is used), from the positive (+) pole through the vibrator and the primary winding of the coil, through the contact segment of the commutuator, through the roller, and by the metal of the engine and the ground wire back to the battery at negative pole (N—).

As soon as the primary current causes the vibrator of the coil to operate, the "secondary" or "induced" current is formed, and goes to the spark plug, where it jumps the "gap" between the points, at "X" and returns to the coil through the metal of the engine and the secondary wire. We explained on page 221 how the current is "induced" from the primary winding to the secondary winding.

The usual trouble in the operation of the jump spark system is the fouling of the spark plug by carbon from a mixture that is too rich in gasoline, or by the burning of lubricating oil. This carbon deposit short circuits the points; that is, it is easier for the current to go from one point to the other by running over the carbon, which is a conductor, than by jumping across the gap on the plug. The result; engine misses explosion (see charts 112 and 113).

High Tension Coil—Wiring.

The following are examples of the high tension vibrator coil system of ignition, using a commutator. †The coil box is usually placed on the dash, but wherever its location may be, it should be carefully protected from moisture. The coil box contains as many coils as there are cylinders. Each coil is called a "unit."

Fig. 1, chart 107, page 224. Connecting a one cylinder engine with a high tension coil system; when the engine of an automobile has but one cylinder, it is usually placed in a horizontal position under the body of the car. The location of the battery, coil box or other parts of the ignition system depends on the design of the car.

*The switch is usually placed on the coil box. One wire from each set of batteries, usually from their positive poles, is connected to one of the switch terminals,

*In this illustration the positive (+) side is grounded, and the negative (—) side is connected to switch. However, it makes no material difference. In fact it is a good idea to occasionally change the flow of current, to prevent the platinum points of the coil "pitting" as explained under description of the Atwater-Kent Depolarizer Switch, chart 117, fig. 5.

†See page 803 for illustration of a "Coil-box" and "Coil-unit." **See page 228 fig. 5, and fig. 1, this page.

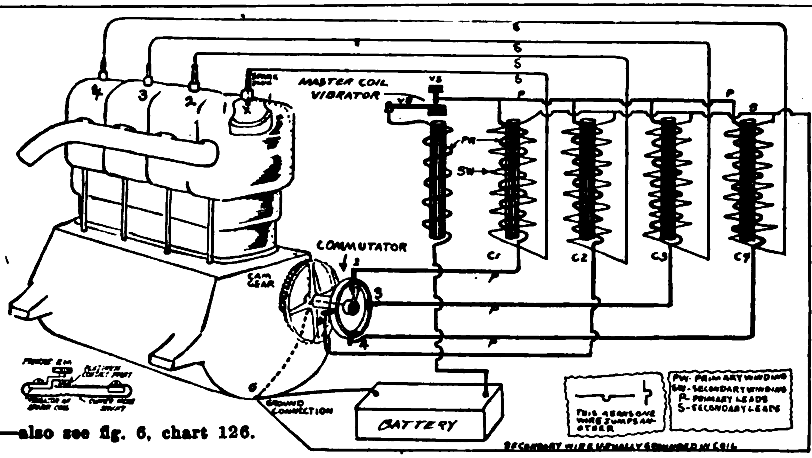

Fig. 2M—also see fig. 6, chart 126.

Fig. 1—A master vibrator coil on a four cylinder engine as an example. SW—secondary winding. PW—primary winding. P—primary wire. VB—vibrator. VS—vibrator screw. C—coils. BB—buss bar, connecting all primary windings at one end. SG—secondary ground wire. Fig. 2m shows how the vibrator on the coils C1, C2, C3 and C4 are short circuited.

The purpose of the master vibrator coil is to do the vibrating for the other coils.

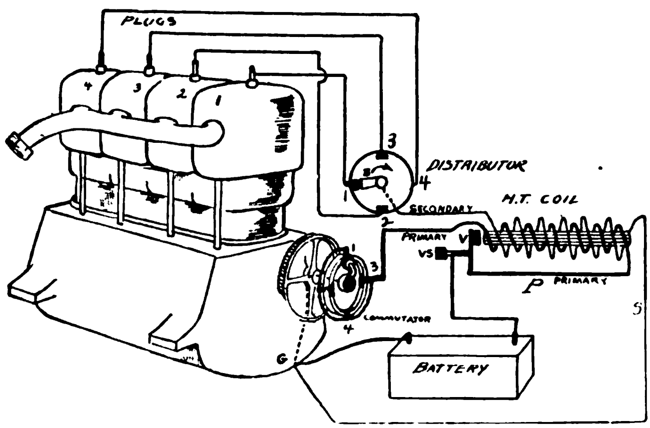
For instance; quite often multiple cylinder coils with several vibrators cause considerable trouble from the "sticking" or welding together of the platinum points, causing missing. Where a multiple unit coil is used, a great deal of care must be excercised to keep in proper adjustment.

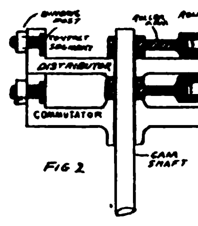
By placing a single wound master vibrator coil in series with the primary circuit, and by short circuiting all of the vibrators on the coils, the one master vibrator will do the work for the others.

It will be noted however, the other coils are used for making the spark otherwise. Also note there is but one winding on the master vibrator coil; its purpose merely being that of vibrating.

On the above diagram, note the firing order is 1, 3, 4, 2. No. 1 cylinder is now firing, as coil (C1) and contact on commutator (1) is in operation. The next cylinder to fire will be No. 3 Trace diagram with pencil.

Note all of the secondary wires are "grounded" on one end. This is usually done in the coil box, all connections being made to a binding post. A ground wire is then run to the frame of engine from the binding post.





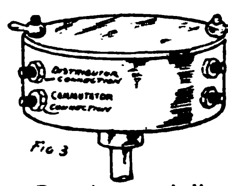


Fig. 1A—A high tension distributor or synchronous system of ignition. P—primary winding. S—secondary. Note one end grounds to engine; usually grounded on the coil. VS—vibrator screw.

Fig. 2—Note distributor and commutator are together. The wiring diagram shows the two separated merely to explain the action.

A distributor system uses but one vibrator coil. Thus doing away with a great deal of complicated wiring. Instead of a commutator being placed on the end of cam shaft, a combination of a commutator and distributor as shown in Fig. 2, is placed there. When one makes contact, the other does also (this is called synchronously, or meaning at the same time).

The purpose of the distributor is to distribute the secondary current to each spark plug at the right time. Note No. 1 is now on contact on commutator, also on distributor. No. 3 will fire next. (See text.) Note all the terminals are connected together on the commutator.

HART NO. 110—A Master Vibrator High Tension Coil Ignition System. .A High Tension Distributor or Synchronous System. (Note the master vibrator system would also be termed a synchronous system.)

See page 264 for K. W. Master-vibrator.

so that swinging the switch blade from side to side throws one or the other into circuit. The negative terminals are grounded by being connected to the metal of the engine, using one wire for both.

The primary terminal of the coil box is connected to the binding post of the commutator; when the commutator in revolving makes contact, the current flows through the shaft to which the commutator is connected and through that and the metal of the engine to the ground wire and battery. Thus the only primary connection to be made are from the two sets of batteries to the switch; from the batteries to the ground; from the primary binding post to the commutator. The secondary terminal of the coil box is connected to the spark plug.

Fig. 2, chart 107, page 224: Two cylinder engine with high tension vibrator coil, using two sets of dry cells: The coil box contains two coils, one for each cylinder and is usually located on the dash. The box containing the batteries is usually under the seat.

The connections from the batteries to the switch are the same no matter how many coils there may be; that is, each set is connected to a switch point. and one ground wire for both.

The commutator has two binding posts, one for each contact point and one primary terminal is connected to one of the contacts, the other primary terminal being connected to the other contact. In the commutator shown in fig. 2, chart 107, the crank is supposed to be 180 degrees, which in chart 52, fig. 3, was shown to produce two power strokes in one revolution, followed by a revolution without a power stroke. The contact points of the commutator are separated by a distance that requires the crank shaft to make a half revolution or 180 degrees, in order that the moving part may move from one contact to the other, or 90 degrees, and then a revolution and a half to move it to the first contact point again. This, of course, is uneven firing. The placing of the segments on commutator therefore must be 90 degrees from first to the second segment, then 270 degrees to the next (commutator revolves one-half speed of engine crank).

If the crank shaft of this vertical engine were 360 degrees, as in engine fig. 2, chart 52; the contacts would be on opposite sides of the commutator like the commutator shown in fig. 2, chart 109, so that the crank shaft would make a full revolution to turn the moving part from one to the other, because a crank shaft of this kind permits a power stroke every revolution. Because a horizontal two cylinder opposed engine permits a power stroke every revolution. this last described commutator is also used on it. (fig. 3, chart 107.)

Fig. 1, page 226: Four cylinder engine with a high tension vibrator coil system, using two storage batteries: The more satisfactory system for a four cylinder high tension vibrator coil system of ignition (we will make exception of the magneto and Delco, Atwater-Kent and systems of this kind, which are treated later), is with a storage battery as shown in fig. 1. One battery is used for regular work, the other for a reserve. Or a set of dry cells could be used as a reserve. The wiring of a four cylinder vertical engine is the same in principle as that of engines with fewer cylinders, there only being an increase in the number of parts.

It must be remembered that, for reasons given in chart 53, the order in which the explosions occur in the cylinders is **not regular**, 1, 2, 3, 4, but **irregular**, being 1, 3, 4, 2 or 1, 2, 4, 3. While either of these may be used according to the action of the exhaust valve, the former, 1, 3, 4, 2, is in most general use as the engine is considered to run with less vibration than with any other firing order; therefore, we will connect this commutator and coil for a firing order of 1, 3, 4, 2.

The wiring connection for this irregular firing, is made by changing the connections on the commutator, causing the spark to occur in the proper cylinder at the right time.

Referring to fig. 1, chart 108, it will be seen that **connections are made between the primary terminals** of the coil box and the commutator, so that the current of No. 1 coil leads to the contact on the commutator which makes connection to cylinder No. 1, which is now at the end of the compression stroke and ready to fire.

As the commutator revolves, the next contact to be made is No. 3, on commutator which is the next cylinder to fire. Cylinder No. 4 fires third; therefore coil No. 4 is connected to the next commutator contact to be made. The next cylinder to fire is No. 2; therefore No. 2 will fire after No. 4.

The connections between the **secondary terminals** of the coil box and the spark plugs are in regular order; coil No. 1 to spark plug No. 1, coil No. 2 to spark plug No. 2, and so on.

It must be understood that the proper connections are made in the coil box by makers to permit the secondary current to return to the secondary winding over the commutator and ground wire. In fig. 1 this connection is made inside of coil where it says, "primary and secondary connect here."

The Master Vibrator Coil.

With the "high tension" vibrator coil system, just described (chart 108, page 226); as many coil units, each with vibrators, would be provided as the engine had cylinders. If a four cylinder engine; four vibrator coil units would be necessary. If a six cylinder engine; six vibrator coil units would be necessary.

It will be noted that with this number of vibrators, one or more would be constantly sticking, unless a great deal of attention was given to them.

Therefore, by using a **master vibrator, only one vibrator coil is used,** which is connected with the other coils as shown in fig. 1, chart 110.

The master vibrator coil has but a **single primary winding,** and is connected in series, so the primary current must travel through it before reaching any of the coils. The usual commutator is employed.

The master vibrator coil can be connected with a "multiple" of coils, by **screwing down the vibrators** on all coils and short circuiting them by connecting as shown in fig. 2M, page 230 and fig. 4, page 264. Note the coils are the regular double wound, high tension coils, as shown on pages 220 and 226.

The advantage of such a system is that there is but one vibrator to keep in adjustment, since this vibrator serves for all the cylinders; whereas, with one for each unit, all have to be kept in adjustment and the difficulty of keeping several adjustments is a considerable factor.

The disadvantage is the great amount of wiring necessary with the multiple coil system. Although the master vibrator is easily connected and requires very little wiring, the "distributor" system which will be explained next requires considerably less wiring. The master vibrator is an excellent addition to be applied to a multiple system of ignition, already installed.

*The "Distributor" or Synchronous System of Ignition.

In the foregoing examples it will have been noted that the amount of wiring required for engines having more than one cylinder becomes increasingly complicated. A system now generally used, known as the "**distributor system,**" very considerably simplifies the wiring, and at the same time more accurate timing of firing of the respective cylinder is obtained. (See fig. 1A, chart 110.)

One tremble coil only, is necessary, this having the high-tension terminal joined up to the "distributor," which is a special form of rotating switch highly insulated, which directs the high-tension current to the cylinders in the required order.

The distributor brush (B), rotates at the same speed as the commutator roller contact maker, and in perfect unison with it; that is to say, when the low tension circuit is completed, the high tension circuit is completed likewise. The diagram should make the system clear, it being borne in mind that the distributor is rotating as well as the contact maker, and in perfect "**synchronism**" with it.

The secondary distributor is made in combination with a commutator, each with as many contacts as the engine has cylinders and with the moving parts of each attached to the same shaft and revolving. (See chart No. 110, figs. 2 and 3.)

The battery is connected to the single coil in the usual manner, and a wire is run from the primary terminal of the coil to the commutator, where it is connected to the four points. Thus when the commutator revolves, the current is passed through the one coil every time that contact is made.

If with this arangement a wire was run from the secondary terminal of the coil to the four spark plugs, sparks would pass in all four cylinders whenever the timer made contact. Instead of this, **one secondary wire** is run from the secondary terminal to the moving part of the distributor, and from each contact point of the distributor to the proper spark plug.

When the commutator makes contact, and the secondary current is formed, it flows to the distributor, which at that instant has made contact with one of the points, so that the secondary current flows across the contact and to the spark plug that is connected.

The advantage of this system is that there is only one vibrator to keep in adjustment, and fewer parts. The **disadvantage** is that the coil has no rest, and the constant use tends to heat it, and destroy its **insulation.** The constant action of the vibrator is liable to burn the vibrator points, and destroy them.

Therefore the modern ignition system, using a "distributor system" of a similar principle, as the Delco and Atwater-Kent systems; the "vibrator" is not used. The timer being of slightly different construction obviates the necessity of the vibrator. This latter system is explained further on in this instruction.

*The principle of this system is similar to Delco and Atwater-Kent modern battery and coil ignition systems, except the systems mentioned, use a form of timer, called an "interrupter," thereby dispensing with the vibrator on the coil—(treated separately farther on).

INSTRUCTION No. 18.

SPARK PLUG AND COIL TROUBLES: Spark Plug Tests and Gaps. Size of Spark Plugs; Regular, A. L. A. M. or S. A. E. Testing Coils and Spark Plugs. Ignition Wiring Troubles. Dressing Platinum Points.

Inasmuch as we will deal next with **coil ignition systems without the vibrator**, it is well to review the troubles caused by vibrators and their relation to the spark plug. We will also refer to troubles caused by defective wiring, commutator, etc.

When the engine stops, one or more of the following, is likely the cause; (1) out of gasoline; (2) carburetion defective; (3) ignition defective.

Under the subject of "carburetion" will be found the carburetion, gasoline and kindred troubles and remedies.

If the trouble is not with the carburetion, then the trouble is likely due to ignition. The following may be the cause; broken or loose wire or switch, run down **battery**.

*****If the engine misses explosion**—the trouble may be due to carburetion at fault (see carburetion). If the trouble is not with carburetion, **then the chances are the spark plug is missing** on account of being fouled. The spark plug causes more trouble in this respect than any other part of the ignition system. (see pages 218 and 237.)

The cause of spark plug sooting and pre-ignition: †A poor grade of oil will turn to carbon (soot), and will deposit on the end and inside of the spark plug and "short circuit" the plug so that the spark will not occur at the point and consequently cause missing of explosion.

Poor oil will also leave carbon or soot deposit on the end of the piston and inside of the combustion chamber. This deposit hardens, and sharp points of it will project. This projection will become heated white hot, causing the gas to ignite before it is time This is called premature or "**pre-ignition.**"

Therefore, spark-plug troubles are usually as follows; short-circuited from carbon, cracked porcelains, electrodes burnt away, not pressure tight, moisture condensing on insulator.

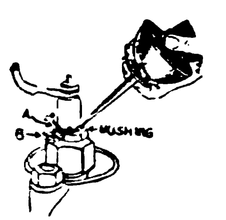
*Spark Plug Tests and Gap.

To test to see if the spark plugs are missing, see page 237, figs. 1 and 2. Another method, if a vibrator coil is used, is explained in fig. 1, page 236.

To see which spark plug is missing, see pages 237 and 236.

To test the spark plug itself, see fig. 2, page 236.

To see if spark plug is leaking around the porcelain at the top (A) of bushing or below (B) where bushing is screwed into the shell of plug—squirt gasoline at these points, engine is running and note if bubbles appear.



Plug Gap.

The gap is the distance between the points on the plug shell and electrode (see fig. 3, page 218), It is important that this distance be exact.

‡**A magneto** should not have too wide a gap, because when engine is running slow, the current is weaker. See also, page 275.

Where a vibrator coil is used, the usual distance is about 1-32 inch. **With a "single spark" system**, however, as the Atwater-Kent, where the spark is very quick the gap must be very small, about .025 of **an inch. In fact this is the average distance.**

It is also essential that the battery be kept charged so it will deliver its proper voltage with a "single spark" system—as it is quick and **must have pressure enough behind the coil to cause a hot spark.**

††**If points are too close**, it will be impossible to run slowly, for the actual area of the flame will be too small.

††**If gap is too wide**, misfiring (on a high compression engine) is apt to take place, especially when one tries to accelerate suddenly, after going slow. The effect of opening throttle and admitting a full charge is to increase compression and it is well known that resistance increases with pressure.

The coil will operate up to 1/32 inch, but bear in mind the greater this distance, the more strain on coil and "leaner" the spark.

The space between the spark points must be considered an insulator, and it must be remembered that the compressed charge in the cylinder through which the spark is required to jump is a better insulator than uncompressed air.

A spark that will jump the point or gap of a spark plug when the plug is out of the cylinder may not have strength enough to jump when the plug is screwed in the cylinder and under compression. So the spark must be especially strong and should be able to punch a hole through a visiting card held between the points.

****Therefore the gap depends upon**; (1) the kind of ignition system; (2) the amount of compression of engine.

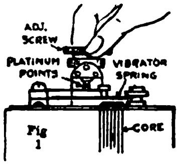
†See repair subject, "pre-ignition and carbon removal" pages 639 and 623. *Location of the spark plug is usually over the inlet valve, see page 219. Also see page 239 for size of spark plug for different cars. **Where engines are high compression the gap is not made less, but the coil is supposed to be made stronger to take care of the extra high resistance. With magneto ignition the gap is important, see page 275.

***See page 171. ‡See pages 275, 299, 298, 297, 312. ††See also pages 250, 275.

†**If porcelain of plug is continually sooty**, the mixture is too rich; if the sooty deposit is greasy, then too much lubrication—see pages 586, 630.

Adjusting Vibrators.

The usual way of adjusting a coil trembler or vibrator is the rather rule-of-thumb method of screwing down the trembler screw till there is a sharp musical "buzz" obtained, and, as near as it is possible to determine, to adjust the screws so as to obtain the same note from each trembler.

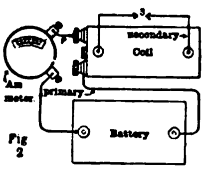


Current consumption of the coil depends largely on how close the vibrator contacts are set. Very often it happens that a good deal of current is wasted in having too close contact, and at the same time the platinum points on both the vibrator and the adjusting screw are soon "pitted" and worn out from the excessive sparking.

There is a further serious disadvantage; insomuch that the firing point cannot be synchronized for each cylinder, the closely-set trembler firing the charge earlier than the lightly-set one, and thus it happens that an engine rarely gives off the full amount of power. Perfect synchronism is required in obtaining full power. This explains why some engines often give more power on the magneto. The fault lies in bad setting of the coil and sticking vibrators.

*Testing a Vibrator Coil.

A special ammeter reading very low (0 to 3 amperes), for adjusting coils is a most useful accessory, as it is only necessary to connect it in the primary coil circuit, one terminal being joined direct to the terminal on the coil, and the other joining to the battery terminal, the usual connection being temporarily taken off. (see fig. 2.)



A 6 volt fully charged storage battery or four fresh dry cells can be used. Separate the secondary terminals (S) ¼ inch.† Adjust vibrator until needle on ammeter shows 1⅓ amperes.

If there is a continuous flow of blue sparks and there is volume to the spark instead of being yellow and thin, then the coil is well adjusted and is o. k. Try blowing on the spark to see if it spreads, this indicates volume, which is desirable.

If the flow of sparks is not constant, this indicates that the vibrator points are probably "pitted."

If there is a short circuit in the coil, or points stuck, the needle would go far beyond its normal range, indicating the passage of excessive current.

If there is a bad connection inside of coil, the needle would jump about instead of remaining steady.

A loose terminal or connection would cause a low and unsteady reading.

If ammeter shows over 1.8 amperes, the coil may be wound for a higher amperage than 1⅓, and if adjustment of screw does not reduce same, then the vibrator spring is too strong and stands away too far from the core. In this case bend the vibrator spring down and readjust screw.

A light contact on a coil trembler means economy of current, but if too light the engine will not run properly; above a certain speed it will be weak as the result of a feeble spark at the plug.

Dressing Platinum Points.

Every time the contact separates, a minute quantity of platinum is transferred from one contact to the other. If the current is reversed by means of a reversing switch, the lost platinum will be transferred back to some extent. This is called depolarizing. Therefore, when using "direct" current for vibrator coil ignition, it is a good idea to occasionally change the connection on the battery. The current flowing in one continuous direction causes this pitting of points. Where "alternating" current is used, as with a magneto, the points do not pit as much, because current is changing direction of flow.

Testing Platinum Contact Points.

Imitation platinum will also cause "pitting." You can test to see if genuine platinum by putting nitric acid on it. If it eats into the metal it is not genuine platinum. A jewelers-stone can also be used for this test—ask any jeweler.

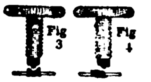


Fig. 3 shows pitting, and is the state a properly set contact-point finally arrives at.

Fig. 4 is the result of a badly-set contact, which is worn unevenly, the platinum would have to be filed away right down to the steel and the spark would then soon eat the rivet hole and cause serious misfiring.

Dressing Contact-Points.

To dress the platinum points, remember that the main requirements are to remove only as small amount of the valuable metal as possible and trim the surface dead level and smooth, and in making the final adjustment of the screw, do not set the platinums closer than necessary to give a good, steady buzz of the vibrator.

For dressing the points (also magneto points), suitable small jewelers files are sold at accessory shops. It is a very thin and finely cut file.

If surfaces are merely blackened insert a strip of 00 emery paper between the two points, and pull the paper through them a few times.

An oil stone is excellent for dressing points—see page 809.

Platinum and Tungsten Contact-Points.

Insist on genuine platinum points when purchasing new screws or vibrator springs. Platinum-iridium and Tungsten metal points are both used. Imitation points will "pit" and burn together and cause missing.

Platinum iridium alloy, which consists of 80% platinum and 20% iridium, should be used on all **magneto contact-breaker points.** Pure platinum would hammer under action of interrupter, therefore iridium which is harder is used with it.

Tungsten points are quite often used on coil and battery systems due to its extreme hardness and infusibility, but its disadvantages for magneto use are oxidation of points when heavy currents are carried. The oxidation results in a high resistance oxide which makes it difficult to start, and the arcing makes it very difficult to distinguish when a condenser is defective. When platinum iridium contacts are used, extreme arcing **is always an indication of a defective condenser.** Tungsten points therefore require a greater condenser capacity to overcome arcing than platinum does.

Platinum iridium is best for all contact points but as stated, tungsten can be used on coil and battery systems—see also page 304.

Above applies to contact points on vibrator coil screws and springs.

Spark Gap Suggestions.

Do not set spark plug gaps over 1/32 inch apart. A longer gap will likely cause a misfire.

*When testing the spark, by removing wire from plug, do not separate the terminal wire from plug or engine frame more than ⅜ inch, as it will strain the coil and break down the insulation.

CHART NO. 111—Adjusting Vibrators. Dressing down "Pitted" Platinum Points.

On the Ford, the magneto generates "alternating" current, therefore, the pitting of points is not so bad, but when the car is run continuously at high speed, naturally the magneto generates a higher voltage, hence pitted platinum points. (See Ford Supplement.) †See page 739 for a simple method of arranging a handy gap when testing. *See also, pages 302, 398.

Setting Gap of Spark Plug.

First set gap at .025—if engine misses, then try this; remember that the gap should be just as wide as the ignition system will stand.

To experiment—try setting the plug point on say—one cylinder until it misses on a hard pull up hill with throttle closed or as much closed as it will pull the hill comfortably.

Then slightly close gap and try hill again and continue experimenting in this way until the missing stops. When correct distance is found then set the other plugs accordingly. See also page 543.

Spark Plug Construction.

Location—usually over the inlet valves on "L" type cylinders and on the side, of "I" head cylinders. See page 219, why spark plugs are placed over inlet valves.

Where plugs are used on overhead valve engines or high compression engines the plug must be of good construction—gas tight and free of electrical leaks—and are usually placed on side of engine (see Buick).

Construction—There are two types in general use; the "separable" type plug where the insulation or core can be removed as per figure 3, page 218, and the "**integral**," or one piece plug per figs. 5, and 10, page 238.

The parts of a plug are; the **shell** or body which screws into cylinder (see 3, page 218); the **insulation** which is held in the shell by **brass bushing** (N); the **electrode** which passes through insulation. **Washers** are used as a gas tight packing, per fig. 2, page 218.

The **insulation** is sometimes made of mica, but owing to the construction, which is usually with washers, it leaks or permits current to pass to the electrode especially when oily. **The best insulation is porcelain** and this, unless of best grade (not porous)* will also leak, thereby weakening the spark.

Where mica is used on plugs on aeronautic engines, per fig. 12, they are used but a brief time and new ones substituted.

†**Separable plugs have tendency to leak and cause missing**, especially at low speeds and hard pulls or on high compression engines. The **integral** plug appears to **gain a** point in its favor here.

Electrode should be made of **nickel alloy**—if not properly made it will expand under intense heat and break the porcelain.

Cement—is placed around electrode—as it dries, it becomes porous and porosity **means** electrical leaks.

Therefore, it is plain to see that "leakage of gas" and "leakage of electricity" are the troubles to be overcome in spark plug construction. Leakage of gas causes "**leakage of compression**" and leakage of electricity causes a "**weak spark.**"

Poor throttling, poor pick up, missing on hard pulls and high speeds are frequently caused by using a poor grade plug. Of course there are other conditions which will cause this, (see page 171), as carbonized insulators, or too close or too wide a gap at the plug points, or improper carburetion adjustment, but assuming that these troubles are corrected the leakage of gas and electricity are two essentials seldom noticed.

Therefore, the highest priced plug is often the cheapest. Likewise a poor grade coil when hot, will lose its efficiency.

Spark Plug Sizes.

Different threads are explained on page 238. **Different lengths**, see page 237 and 238.

Cleaning a Spark Plug.

Don't mar or glaze the porcelain as it will cause "**porosity**" and "**electrical**" leaks. See pages 237, 592.

**Vibrator Coil Troubles.

We will not deal with the modern "single spark" coil troubles here but principally with the vibrator type coils. The single spark coil is dealt with further on.

Vibrator points sticking; where the vibrator type of coil is used. This is frequently the cause of missing of explosion. The points burn together as explained on page 234. The cause of this, is due to the "direct" current flowing in one direction continuously. (see page 248, "depolarizer switch.") Another cause is that of using too much pressure or voltage. For instance, coils are usually wound for 6 volts. If each dry cell gives 1¼ volts when working, and five cells used, the coil points do very nicely. If, however, eight cells are used, the excess pressure is more than the condenser in coil can take care of; result excessive sparking at the platinum points on vibrator and screw.

To test the vibrators, see chart 112. **To adjust** vibrator and clean the platinum points, see chart 111.

‡**Other causes of missing**, as before stated, is due to loose wires or connections on battery or run down battery—see page 241 for loose connections and wiring and for testing batteries.

**To test a high tension coil, see page 236.

See pages 250, 251, 253, 254, 275, 285, 288, 292, 299, 298, 312, 296, for distance to set spark plug gap.

**See index, "Testing Coils."

‡See pages 299, 298 and 297—for magneto interrupter adjustment. See pages 298 and 171 for missing at low and high speeds.

†Separate plugs should have good gaskets and drawn tight—see page 239.

*Its difficult to obtain a porcelain which will not absorb oil and cause leakage of electricity through it. Best grade come from France and Bohemia.

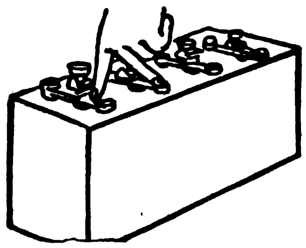

Fig. 1—Testing for missing with vibrators on the coil.

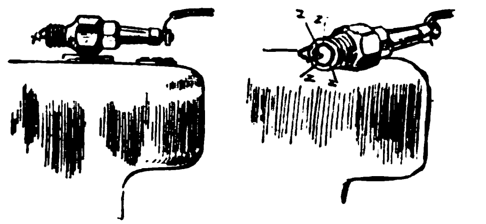

Fig. 2—Testing a Spark Plug.—Place the spark plug on the cylinder with wire connected and switch on. Crank engine slowly. If the spark occurs at the gap "X" the plug is O. K. If it sparks up inside of the shell, between the porcelain and shell at "Z," it is fouled and misses. It must then be taken apart and carbon removed.

Causes of Spark Plug Missing.

The cause of **missing of explosion is usually due to the spark plug** becoming fouled by carbon, soot depositing on the porcelain insulation, causing the plug to become short circuited. Generally caused by using a poor grade of oil or loose piston rings, which permits the oil to pass too freely into the head of cylinder.

Other causes are **sticking vibrator points** as explained on page 234.

When starting to test, for the trouble, first determine if the missing occurs when running slow or when running fast, or if at all times. Also be sure the **carburetion** is right.

Testing for Miss with Vibrators.

We will assume the engine is a four cylinder engine.

To ascertain which, if any of the four plugs are fouled with oil, short circuited with carbon or inoperative from some other cause, open the throttle two or three notches to speed up the engine; now hold your two fingers on two outside vibrators so that they cannot buzz. The evenness of the exhaust will show that the other two are working correctly and that the trouble is not there; or an uneven exhaust will indicate that it is between the two that are free.

If the two cylinders fire evenly change the fingers to the two inside vibrators and again listen to the exhaust. Having ascertained in which pair the trouble is, hold down three fingers at a time until you find the one which does not fire.

Cylinder No. 1, we will say, is the front cylinder, and they number in rotation 1, 2, 3, 4. No. 1 coil unit would be the one farthest from the steering post (left side drive) and they number 2, 3, 4 to the left.

Testing Spark Plug.

Then remove the spark plug and test the plug as shown in fig. 2. If the plug is O. K., then you know the trouble is not in the plug. If plug is not O. K., then clean it or put in a new one.

Remember the plugs may spark in the open air, but when under compression fail to spark, because the resistance is greater. Therefore, be sure the points are not over 1/32 of an inch apart at the extreme, for vibrator coil use.

Vibrator Coil Cause of Missing.

In rare instances one of the coil sections will become short circuited or insulation **become punctured on the secondary winding.** Caused by using too many batteries or too high a voltage. In this case the plug would not spark at all, therefore it would be advisable to try changing positions of the coil units in the box, if the plug sparks O. K. on one of the other coil sections, then you may know that particular coil unit is defective. **Therefore, inspect the platinum points on the vibrators and contact points**, as they may be partially burned away or badly pitted if this coil section still fails to give a spark, then it is evident it is burnt out inside.

In some instances a coil may have its insulation short circuited for only half its length of winding and would give a spark. If short circuit was near the beginning of winding it would not spark at all. See page 416. See page 241, for testing for a broken wire.

Testing the Coil.

If multiple cylinder engine, test each unit separately until it is determined which coil is missing. After assuring yourself the missing is not caused by a spark plug, weak batteries, carburetion, or other causes, then test the coil itself, as explained above, see also pages 249 and 253 for testing the modern non-vibrator coil.

On a non-vibrator type coil, the spark could be tested up to a jump of ½ inch on a test—continuously.

On a vibrator coil, ⅜ inch. Don't place the distance further, as it is likely to damage coil.

To test a magneto—see index. **To test for a broken wire**—see page 241. **To test for grounds and short circuits**—see index.

Other Causes of Missing.

When mis-firing occurs, particularly when running at high speeds, it would be advisable to inspect the commutator, as the fibre may be worn so that the roller touches only the high spots, or it may be that the roller has worn out of round and consequently forms imperfect contact on all of the points.

At slow speeds, is apt to be the result of improperly seated valves or air leak in the carburetor or cylinder head gaskets.

A weakness in compression may be detected by lifting the starting crank slowly the length of its stroke for each cylinder in turn. In rare instances an exhaust valve may become warped by the engine becoming overheated, in which case the valve seat will have to be reground or the valve replaced.

Other causes of missing explosion is due to weak batteries, therefore test the batteries as explained on page 241.

CHART No. 112—Missing of Explosion; Source of the Causes.

The coil in this instance is the old style vibrator type and matter refers principally to the vibrator coil and commutator system. The spark plug test is applicable to all systems.

Finding the Missing Spark Plug.

Fig. 1—Relief cock test: Open the relief cocks, one at a time. Watch for the flame shooting out of each opening and listen for the sharp reports of the explosions. The cylinder without flame, out of which issues only a hiss, but no sharp report is the one at fault.

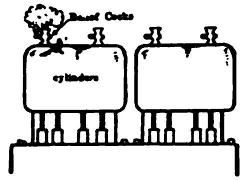

Fig. 1.

Fig. 2—Another method is that of short circuiting one plug after another. This may be done by holding a screw-driver or other instrument so that it will make connection between the head of the spark plug and some part of the engine. When short circuiting, note if engine seems to slow down, if so, that plug is O. K. If there is no difference, then the plug is likely at fault. Hold the screw-driver by its wooden handle, else you may receive a shock from the ignition current.

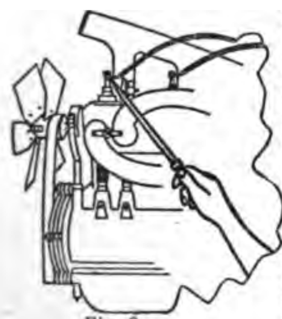

Fig. 2.

Spark Plug Causes of Missing.

Fig. 1—Missing may be caused by the spark arcing from shell to the terminal—cause: porcelain too short and gap too wide at points.

Fig. 2—Points may have come together—cause: screwing plug into cylinder bent points together.

Fig. 3—Wire may have become loose from terminal—cause: terminal not screwed down tight.

Fig. 4—Shows method of adjusting the distance between the points of the plug; distance should be about 1/32 of an inch apart for coil ignition, and 1/64 of an inch for magneto ignition .025 average.

To test for a missing spark plug; first, open the relief cock to each cylinder, as shown in fig. 1. If a blaze emits from the relief cock, then the cylinder is firing. It is advisable, however, to see that it fires regularly. The missing may not be in the plug at all and a slight movement of the adjusting needle valve one way or the other on carburetor will remedy the trouble. If the missing IS in the PLUG, then it must be cleaned.

When an engine begins to misfire suddenly, from some unknown cause, the first thing a driver should do is to note whether the firing is regular; that is if it occurs in only one or two cylinders at regular intervals in the cycle of explosions; or, if it is intermittent in one cylinder or in different cylinders.

A regular misfire in one cylinder, that is, misfiring that occurs once at the same time in every cycle of the engine, generally is caused by a defective plug or a disconnected high-tension wire. A defective valve also is probable.

Intermittent misfiring in one cylinder may be due to a defective plug or loose terminal connection or a valve that is not closing tightly.

Other causes of missing are: Worn timer, loose connection, platinum points on coil or magneto, spark plug, carburetor needle valve and auxiliary air valve need adjusting; air leak around intake; battery weak.

Spark Plug Location.

Usual location is in neighborhood of inlet valve, which is correct, as it should be surrounded by fresh gas that enters during inlet stroke. If located on exhaust side dead gas will collect about plug electrodes and cause missing.

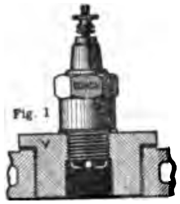

Fig. 1: Valve cap too thick—out of path of gas.

Fig. 2: Recess around plug shell retains heat.

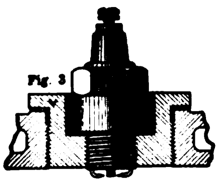
It is also desirable to have plug where water jacket surrounds it, as in fig. 4, to avoid overheating, else plug electrodes are liable to become overheated and become incandescent and cause pre-ignition.

Poor location is shown in fig. 1. When set in a thick valve cap (V) with short threads, dead gas accumulates in recess and causes missing at slow speeds. Fig. 2 shows another poor method. The recess accumulates heat and metal extension is liable to become red hot and warp electrodes altering size of gap.

Good location is where spark plug points or electrodes just reach the combustion chamber where cool fresh gas will come in contact and flame will spread with maximum rapidity as in figs. 3 and 4.

When plug extends too far in combustion chamber there is danger of valve head striking it.

Spark plug lengths — see page 238.



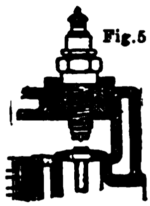


Fig. 3: Correct position of plug in valve cap.
Fig. 4: Correct position when set in water jacket.
Fig. 5: Plug reach too long, liable to strike valve.

*To Clean Spark Plug.

If the trouble is suspected of being a short-circuited plug, due to carbon, etc. (see page 238), unscrew it and clean it as follows:

To clean a spark plug: Unscrew the bushing which holds the porcelain in the shell, remove the porcelain (or mica) and soak the shell and porcelain in kerosene or gasoline. Clean all carbon off each. Don't scrape porcelain, as it will roughen the glazed part and cause it to retain carbon. If the oil is burnt on the porcelain, muriatic acid will remove it. In placing the porcelain back into the shell, be sure the copper washer is placed back and bushing screwed tight to prevent leaking.

If then impossible to get a spark at the plug, when laid on cylinder, then start inspection by testing batteries as shown on pages 241 and 450.

If still unable to obtain a spark, then examine the connections on the battery; one of them may be loose or broken under the insulation or not soldered to the copper connection, as shown in fig. 6, page 241, or connection to **storage battery terminal** may be loose.

If trouble is not now removed, then trace the wiring from the batteries to the coil. See if the wires have been allowed to get next to the hot exhaust pipe; if this is the case, make a metal "T" joint, as shown in fig. 11, page 241.

All terminals should be carefully inspected and all connections soldered.

The ground wire fig. 4, page 241, should be carefully cleaned and scraped, as well as the part of frame it is grounded with and drawn tight.

If wires are suspected of being broken, see index "testing for open circuit."

CHART NO. 118—Testing for Missing Explosion. Spark Plug Troubles, cause and remedies.

*Alcohol is also suitable for cleaning plugs, see also page 592.

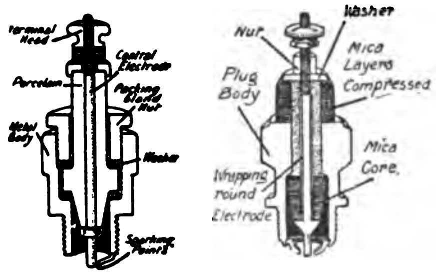

Fig. 10M.

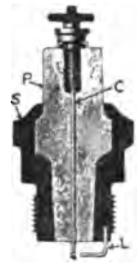

Fig. 10.

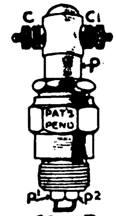

Fig. 11.—Double spark plug—shell is not grounded. P1 and P2 are separate porcelain insulators.

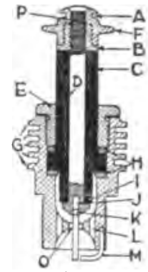

Fig. 12.

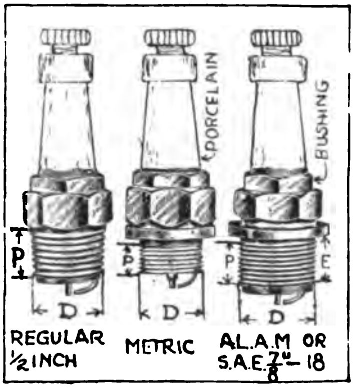

Fig. 4: Regular length of ½ in. Metric, and ⅞ in. spark plugs.

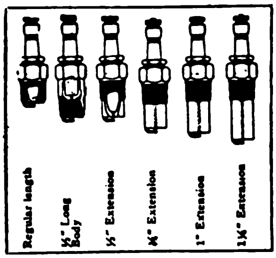
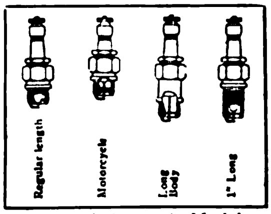
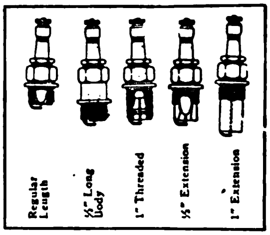


½" Pipe Thread Models



Metric (18 m/m) Models



⅞"-18 (S. A. E. Models)

Integral, or one-piece spark plug, see also fig. 10 & 10M.

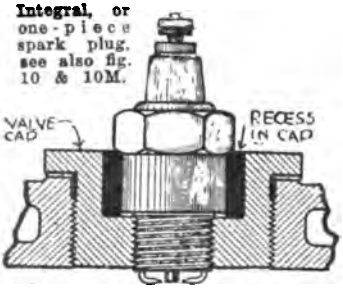


Fig. 5: Note long body to raise the hexagon part of plug above the recess in the valve cap so a wrench can be applied. Different kinds of valve caps require different lengths of plugs. (see page 237.)

Spark Plug Threads.

Spark plugs are made with three standard threads—see fig. 4; the ½ inch pipe thread; ⅞-18 S. A. E.; and Metric.

The ½ inch size is a thread which is a standard ½ inch iron pipe size and has a slight taper.

The ⅞-18 size, is the size which was adopted as a standard by the Society of Automotive Engineers, for automobile use. It was formerly known as the A. L. A. M. The thread is ⅞ inch in diameter, with 18 threads to the inch (see page 703, 612 and 705). It is used on a majority of the cars today.

The metric size is smaller than either of the above. Its diameter is 18 millimeters or approximately 11/16 inch. This is the size thread for spark plugs, adopted by the Society of Automotive Engineers for **aeronautic engines.** It is also used on the Packard, Pierce and many motorcycles. It is used extensively abroad.

Spark Plug Lengths.

The length of a spark plug depends upon the engine it is used on. If the valve cap in engine is deeply recessed as in fig. 5, a **long body** plug is required, otherwise the wrench could not reach the hex. If on the other hand, it was not recessed, a **long thread** would be required. If however, the valve cap plug should not screw well down into combustion chamber, then **an extension** is required, for it is important that the points of the plug extend to the combustion chamber. It is well to note here however, that the plug points must not extend too far—see fig 4, page 237. This extension, of course, depends upon the distance the plug is to extend, therefore they are made with ½ inch and 1 inch extension. By referring to above illustrations this will be made clear.

Aeronautic Spark Plug.

Fig. 12: Aeronautic type spark plug is designed for great heat and high compression. Type shown in fig. 12. It is of mica construction and very costly to construct. Note the heat radiation flanges on shell. Also baffle plate, (O) which tends to keep oil from the mica, stem (P) made of brass or copper for heat conductivity, electrode (J) is swedged at bottom of stem (K). Core is mica washer sections (I) with a mica insulation tube at (D). Usual gap opening is .015". See also, page 839.

CHART NO. 118A—Spark Plug Sizes Explained.

See page 612 for S. A. E. spark plug shell and page 705 for size taps to use for spark plug threads. For spark plug wrenches, see pages 611 and 612.

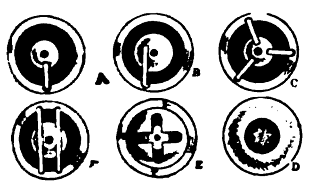
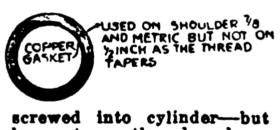
Abbreviations: M. T.—Motor Truck; E. — Engine; M. E.—Marine Engine; Ae. — Aeroplane; G. E.—Gas Engine; M. C. —Motorcycle; F. E. — Fire Engine; T. — Tractor.



Different kinds of plug points or gaps.



Gaskets for Spark Plugs.

Copper, asbestos lined gaskets are used between bushing and shell on all "separable" plugs, to make it leak proof. They are also used on ⅞ and Metric plugs between shell and where screwed into cylinder—but not on the ½ inch plug, because it has a taper thread and no shoulder on shell. See also pages 607, 717, 238.

CHART NO. 113B—Spark Plug Sizes used on leading Automobiles, Trucks, Motor Boats, Motor cycles and Stationary and Aeronautic Engines.

Wire Used for Winding a Coil.

Copper wire which is insulated is used for the winding of the primary and secondary winding of a high tension coil or magneto armature.

The primary winding of a coil or (magneto armature) is called primary winding wire. It is usually a single strand of soft copper wire insulated with cotton. This wire is not so long as the secondary winding. The current which passes through this wire is of a low voltage, usually about 6 volts. The quantity or amperes of current is greater than in the secondary winding.

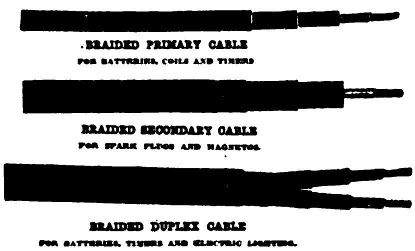
The secondary winding wire of a coil or (magneto armature) is wrapped over the primary winding and it is considerably greater in length. The insulation is silk thread, wrapped around a very fine single strand of flexible copper wire. The pressure or voltage passing through this wire is in the thousands, hence the reason it must be well insulated, but the amperage is practically none at all.

The winding of a Bosch DU4 magneto armature, usually consists of 8 layers of No. 20 or 22 wire, to form the primary winding, and 70 to 72 layers of No. 36 silk covered wire to form the secondary winding.

The reader, however, never has occasion to bother with wire on a coil or magneto armature as this is the work of a specialist.

Wire for Ignition Systems.

There are three kinds of ignition wire for general use with the ignition system of a car, as follows:



Primary wire or cable, made of several strands of fine wire in order to make it flexible and insulated, oil and moisture proof. This wire is usually used between the battery, coil and timer, for all low tension work, and must be of sufficient size to carry the current, usually No. 14 size is used. (see pages 425 and 427.)

Secondary cable is also made flexible and the insulation on wire is much heavier. This is used to conduct the high tension current from the coil or magneto to the spark plugs. It should be kept free from all metals as much as possible. Size is usually No. 16 or 14.

Duplex cable is also flexible, but generally two to four wires are run in one insulation, of course, being separated from each other by insulations. This wire is generally used for lighting and low tension work.

Metal conduit; a good plan in wiring a car, where several wires are run together, is to enclose the wires in a metal conduit. (see page 426.)

The wires running from coil, or magneto distributor to the spark plug, **carry the high tension current and are called secondary cables.** This current escapes more readily than from the wires running from the battery to timer or coil. The wires running to the plugs are called "high tension" wires because the tension or voltage is high and current will often jump through the insulation and short circuit (cutting out spark plug) to any metal part it happens to be in contact with. For this reason these wires must be carefully protected and very heavily insulated. (see fig. 12, page 241.)

The primary wires running from the battery to timer or to interrupter on magneto are "low tension." They do not need have as heavy insulation, but the connections should be well made and clean because the pressure is so low the current will not pass over dirty or loose connections, and a loss of current will result. All connections ought to be soldered and taped. (see figs. 6, 7 and 8, page 241.)

The wires running from the battery or timer to the coil connection, are called the primary lead wires, also battery wires. These wires must be of sufficient size to carry the current, as they carry a greater quantity of current than the secondary wires. The secondary wires have much **heavier insulation** and from outside appearances would seem to be larger, but are comparatively small, as they carry a high voltage but low amperage.

Don't use lamp cord wire under any circumstances as it will give unsatisfactory results and cause missing if damp. (see page 425.)

The size of primary wire generally used is No. 14 or 16 primary cable—the secondary wire is simply called "secondary cable." Both must be waterproof and heat proof—(see pages 425 and 427.)

Wire for the elctric horn is usually No. 18—(see page 425.)

Making Connections.

A grounded connection should be filed or scraped bright before attaching the wire, and the connection when made should be covered with vaseline or paraffine. A copper washer should be placed under the head of the screw, to hold the wire firmly in position—and tightly drawn up.

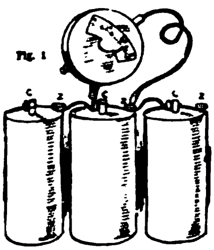
All connections must be bright and clean, for a dirty connection will add resistance. Binding posts, screws, and the ends of the wire must be scraped clean before the wire is attached—this is very important on low voltage wiring.

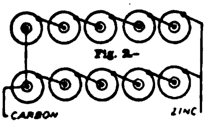
All connections should be made as firm as possible, using pliers to tighten the binding screws. The best connections are made by brass or lead terminals soldered to the ends of the wires. When a connection has been screwed tight, the binding screw and terminal should be covered with vaseline or paraffine, to prevent corrosion, and the whole wrapped with electric tape. This tape comes in rolls, and is sticky, so that it will stay in position when once applied. In addition to being an insulator, it prevents moisture from getting at the terminal.

Short lengths of wire provided with terminals are sold for making dry battery connections, and it is well to use them when dry batteries are used.

No possible cause for leakage of the current should be allowed; a single strand of fine wire projecting from a flexible cable will be enough to cause a short circuit if it should touch metal. (see pages 427 and 422.)

CHART NO. 114—Winding of an Ignition Coil. Ignition Wire—(also see pages 425, 426 and 427), **Making Connections.**





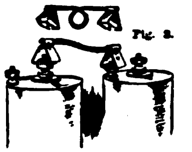


Fig. 1: Missing of ignition may be due to weak batteries. To test, use an amperemeter. Test **each** cell separately by placing terminal of meter on terminal of battery. Each battery ought to show 15 to 25 amperes. If less than 8 amperes, replace. If one should test say, 10 amperes and another 20, then the good battery will be brought to the level of the poor battery. Remove it and put in a fresh one. To test a storage battery (see index).

Fig. 2: An emergency dry cell connection. Usually two sets of dry cells are provided when ignition is on dry cells alone. Only one set at a time are used, however. If both sets should run down, a multiple connection of the two sets can be made, as shown above, which will suffice to reach home. Dry cells are now seldom used.

Fig. 3: Quite often missing will occur from loose connections at the battery terminals. See that they are always tight. On some connections, the wire may be broke or not soldered well to the terminal. A good connector called the "Bull Dog" is shown.

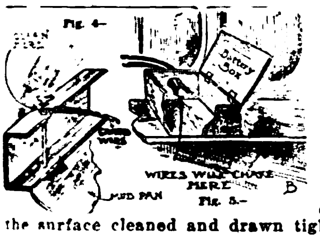

Fig. 4: On many cars one wire is grounded—therefore it is essential that the grounded connection is well cleaned and then tightened. A copper terminal should be soldered to the wire—the surface cleaned and drawn tight with a bolt.

Fig. 5: When metal battery boxes are used and dry cells placed in them, dampness will short circuit the batteries through the paper insulation around them. Therefore keep box dry inside, also watch wire where it passes through the metal box.

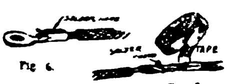

Fig. 6, 7 and 8 show how to make a connection with wire and terminal; solder and tape all connections.

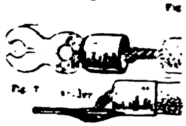

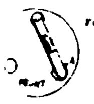

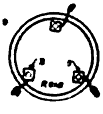

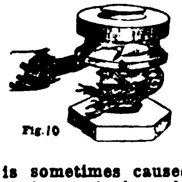

Figs. 9 and 10: Missing is sometimes caused by loose connections on the switch terminals and battery terminals. See that terminals are clean and tight.

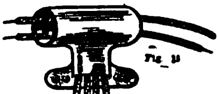

Fig. 11: A good method of protecting primary (battery) wires when they run along the frame.

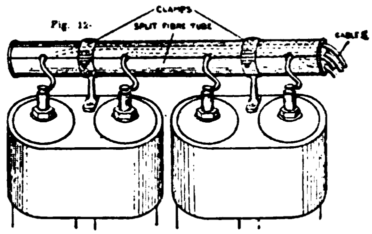

Fig. 12: Neat method of distributing the secondary or high tension cables on multi-cylinder engines. A divided fibre tube supported on brackets encloses the cables and allows of easy inspection or renewal if required. Any number of leads or cables can be distributed. The eight plug leads required for dual ignition on a four-cylinder engine can be accommodated in two-inch fibre tube.

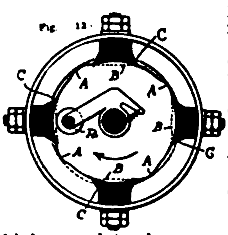

Fig. 13: Causes of commutator troubles; (1) worn metal segments (C), often cause missing by not making good contact. (2) The commutator may also become loose on the shaft and get out of time. (3) Spring weak. (4) Loose connections at binding posts. (5) Depressions worn on face of fibre on which the roller (R) travels resulting in the roller jumping (at high speeds) almost over the metal contacts (C). The roller (R) and pin; of the revolving part will also probably be found in bad shape. **To repair;** turn down in a lathe or replace with a new one. (6) Grease will coat the insulated fibre ring (C) from one segment to another and cause a short circuit. Too much oil will also cause a glazed surface over the segments (B) and good contact cannot be made between roller (R) and these metal segments.

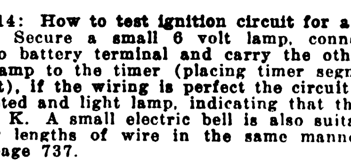

***Fig. 14: How to test ignition circuit for a broken wire:** Secure a small 6 volt lamp, connect one wire to battery terminal and carry the other wire from lamp to the timer (placing timer segment on contact), if the wiring is perfect the circuit will be completed and light lamp, indicating that the wires are O. K. A small electric bell is also suitable for testing lengths of wire in the same manner. See also, page 737.

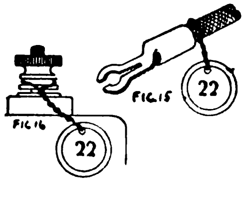

Fig. 15: Mark wires when removing, by using cheap water colors or **tag** them, thus saving a lot of time when replacing.

CHART NO. 115—Importance of Good Connections and Protection of the Wiring.

INSTRUCTION No. 19.

MODERN BATTERY AND COIL IGNITION SYSTEMS: The Timer and Interrupter. Automatic Advance of Spark. Delco, Atwater-Kent, Remy, Connecticut, Bosch, Westinghouse, Battery and Coil Ignition Systems. Storage Battery and Direct Current Generators as a Source of Electric Supply. Depolarizing Switch.

†The Modern Battery and Coil Ignition System.

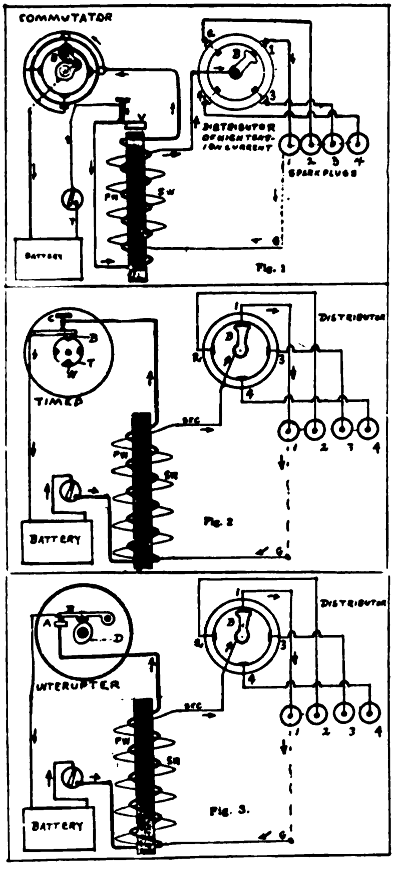

Fig. 1. A distributor and commutator using a "vibrator" type of coil as explained in chart 110, fig. 1A. This system is seldom used. Note the contacts are made by a roller. When contacts are closed, the vibrator on coil operates.

Fig. 2. A similar system but coil is "non-vibrating." When brush or blade (B) is raised by cam (T) contact is made with screw (C) current flows only when contact is thus made.

Fig. 3. This system is similar to fig. 2, except a "cam" of the type used on magnetos is employed, which "interrupts" the flow of current as the nose **of cam raises the arm (B)**, see also fig. 7, page 378.

In order to understand the modern "coil and battery" ignition systems, it was necessary that the reader study the elementary principles of the early forms or methods used for ignition; such as the low tension coil, the high tension coil, the commutator and the timer, also the distributor—all of which have been explained. It ought not therefore be difficult for the reader to grasp the principle and difference of the various makes now to be treated.

The battery and coil system is the modern ignition system, such as the Atwater-Kent, Delco, Remy and others which are supplied with a "constant" source of electric supply when used in connection with a storage battery which is kept charged by the generator.

Constant source of supply means that the ignition apparatus is not dependent upon a mechanical method of generating current, as in a magneto, but the supply of electric current is constantly supplied by a storage battery and the storage battery is constantly supplied with current (direct) by a generator.

The Timer and Distributor.

Are combined in one unit similar to the description of the distributor system shown in fig. 1A, page 230, but the principle is different.

For instance; a commutator of the "roller" or "wiping" contact is employed in fig. 1A, page 230 and fig. 1, this page, which makes a wiping contact, thereby closing the primary circuit on the coil, at which time the vibrator spring (V) fig. 1, (this page), is set in motion, thereby causing the current to be intensified in the secondary winding (SW) of coil. At the same time brush (B) on distributor makes contact with one of the spark plugs in cylinder. By tracing circuit this will be made clear. Note all of the commutator segments are connected together. The spark produced is not a "single" spark, but a "succession" of sparks. This vibration of vibrator (V) is of course, classed as the "electrically" operated vibrator.

This system with a commutator and vibrator coil is seldom used, but instead a system producing a "single" spark, which is made "mechanically" and without the use of a vibrator coil, is the modern method.

†This subject is also treated under "Electric Generators"—instructions 27 and 28, see pages 377 and 378.

†Open and Closed Circuit Principle.

The modern "interrupter," or "contact breaker," as it is called, is very similar to the interrupter on the magneto and is divided into two types; the **open circuit** and **the closed circuit.** The **open circuit** contact **maker** is termed **a timer and** closed circuit breaker an **interrupter.****

Open circuit principle; when the arm (B), fig. 2, is raised, contact is **made with** tungsten point screw (C). This closes the primary circuit but it is immediately opened again; termed the **open circuit principle,** because the points of timer are normally **open.** (see also pages 378 and 377.)

Closed circuit principle; the circuit of the primary winding on coil is normally **closed,** because points of timer are **closed** until raised by cam (D). When the "cam" or "interrupter" (D), fig. 3, raises the arm (B), circuit is momentarily **opened** but immediately closed again. This is termed **the closed circuit principle.** This action "interrupts" the flow of current suddenly, hence the term "interrupter."

Both of these systems have a "mechanical" method of making and breaking the primary circuit, instead of the "electrical" method, such as the vibrator in fig. 1. Therefore a **coil,** without a vibrator is used and a "single" spark is given at the plug gap, instead of a succession.

Both systems accomplish the same purpose, which is to interrupt the flow of current in the primary winding in order to cause induced current of a high tension, to flow in the secondary winding as previously explained.

In the open circuit principle the contact must first be made before the current flow can be interrupted. This is made very rapidly; quicker than the eye can detect.

In the closed circuit principle the current is flowing in the primary and is broken or interrupted by the contact points being separated by the cam; which runs at cam shaft speed.

***The closed circuit advocates, claim the advantage of perfect synchronism,** due to elimination of "electrical and mechanical lag," whereas the open circuit advocates claim economy.

Electrical lag means that the spark will not occur in the same position as regards piston travel at any and all engine speeds—with a very high speed the piston might have a tendency to travel past the point of ignition, before the open circuit timer made and **opened** contact, whereas with the closed circuit principle it merely **opens** the contact.

While all lag factors deal with time in seconds their effect on the engine is the number of degrees they cause the spark to occur off the point it should. Consequently a time factor of only one thousandth of a second means only a variation of 3 degrees at 500 r. p. m. yet means 12 degrees at 2000 r. p. m. and 18 degrees at 3000 r. p. m.

Mechanical lag is eliminated much for the same reason and the **quicker and simpler the mechanism to "interrupt"** the flow in the primary the quicker the spark.

For this reason **some of the systems have been additionally improved by adding an automatic advance of the spark,** by a governor arrangement placed in the timer housing, so that the timer shaft will advance with the speed of the engine and cause the spark to occur as near the proper time as possible (see page 248).

Referring to fig. 3, we have then a simplified explanation of the closed circuit principle—note the interrupter (D). At a glance it appears to resemble a magneto interrupter or contact breaker arrangement—and it is very similar, although a magneto with its "alternating" current is not used to supply the electric current, but instead, a "direct" current is used from the battery or generator. Yet the same principle; **interruption** of the current flowing through the primary winding of the coil is exactly the same.

For instance, the flow of current through the primary winding of the coil is suddenly "interrupted" by the cam raising the interrupter arm (B) from contact (A); the current is diverted to the condenser (not shown here, but a part of all coils, see fig. 5, page 228), which is charged to a fairly high voltage and which then discharges through the inductance of the primary winding of the coil; causing a rapid demagnetization of the iron core of the coil that "induces" the high tension current in the secondary winding. This high tension current is then carried from the "distributor" to the spark plugs.

The system in fig. 3, has been improved by having a cam (D) with the same number of projections as there are cylinders, thereby rendering it possible to operate the "distributor and timer or interrupter," at the same speed—see pages 378 and 377.

The open circuit principle is carried out in fig. 2, and is very much the same, although the circuit is **open** at all times except when arm (B) is in contact with (T); the spark really occurs just at the instant that timer contacts are **opened,** that is, the contact is **"made"** and **"opened" suddenly,** meaning practically the same principle as in fig. 3, where the circuit is **closed** until opened by interrupter. There are as many notches (N) in **cam** (T) as there are cylinders.

Therefore summing up the three distributor systems of the battery and coil system of ignition, we find that the old style "commutator" system, fig. 1, has been discarded and the two systems in **general** use are as per figs. 2 and 3.

The disadvantage of the "commutator" system, fig. 1, is due to the use of a "vibrator" coil. See instruction 20.

Another point to bear in mind is that both the open and closed circuit systems give a "single" spark, whereas the commutator type gives a "succession" of sparks. (see page 250.)

Another point to remember is that a coil without a vibrator is used on both the "open" and "closed" circuit battery and coil system of ignition—for previously stated a vibrator is not **necessary** with a single spark timer.

*Also claim that it allows the **maximum** amount of **contact** which permits complete saturation of coil at high engine speeds—and no doubt is a reasonable claim.
†Page 248 shows a typical open circuit type. Page 254 a popular **closed** circuit type system. See also pages 378 and 377. **We do not adhere to this rule throughout this book as the word timer is often mentioned when it is a closed circuit type.

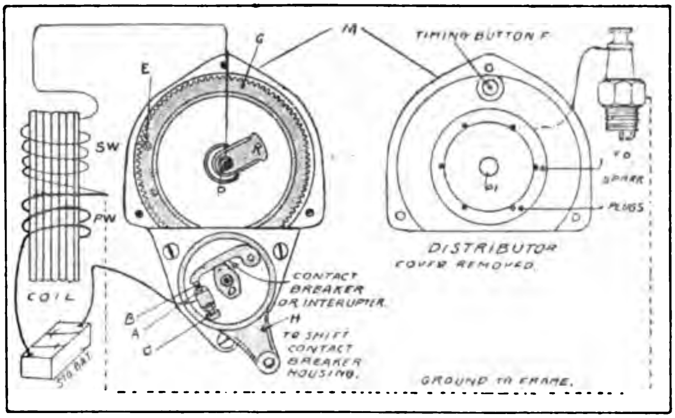

Fig. 4 The true magneto type interrupter and distributor for a six cylinder engine as used with a "coil and battery" system. Note the "interrupter" and "distributor" operate at different speeds. The interrupter cam is revolved from cam shaft but turns 1½ turns to one of crank shaft. The distributor brush (R) makes one revolution to two of the crank shaft. This is due to using a two point cam (D).

Magneto Type "Interrupter."

A first glance at the interrupter and distributor, in fig. 4, the reader would think this a "magneto" system and that is the reason for illustrating it. To show the reader the simplicity, and to bring out the difference between the "timer" fig. 2, and "interrupter" system, fig. 3, page 242.

The contact breaker or interrupter and distributor in fig. 4 are of the magneto type and the principle is practically the same as a magneto, but the "source" of electric supply is not "alternating" current taken from a magneto, but is "direct" current, taken from a storage battery or "direct" current generator if engine is running fast enough for the generator to overcome the battery voltage and recharge the battery as explained on page 387.

Here we have practically the same principle as explained in fig. 2, page 242, except that the circuit is closed until "interrupted" by movement of cam. Whereas in fig. 2, the circuit is open until contact points are closed by movement of timer.

If we applied this system, fig. 4, this page, to a four cylinder engine, it would be neccessary to revolve the cam (D) twice, during two revolutions of the crank shaft, or the same speed as crank shaft, therefore the distributor would revolve but once, during two revolutions of the crank shaft. Therefore the distributor would be geared to run half the speed of cam.

We could use a cam with four lobes instead of two, and run it at one half the speed of the crank shaft, causing it to revolve once to two revolutions of the crank shaft; then the distributor and timer would revolve at the same speed, or ½ the speed of the crank shaft.

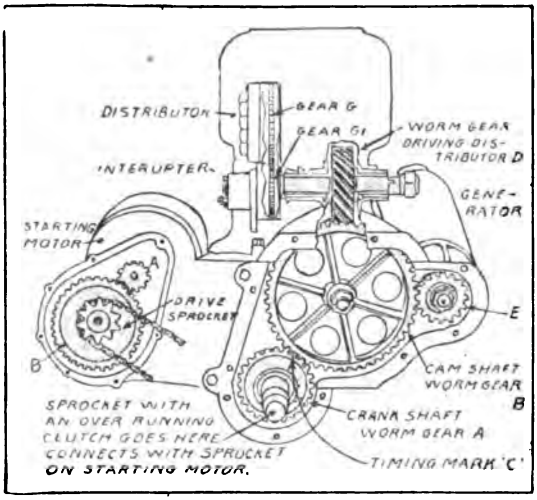

Fig. 5. Note the gear G, is driven by gear G1 which in turn is driven by a spiral worm gear from the cam gear. This system was used on the Studebaker six. See above, for relative speed of interrupter cam (D) and distributor brush (R). (Studebaker generator is now driven in a vertical position and ignition is as per pages 368, 350, 372.

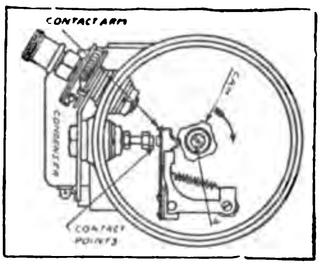

Fig. 6. The Delco timer: The contact points are open, therefore circuit is open, until closed by cam. However, the "single" spark occurs at the instant the timer contacts are opened after making contact. Both principles are similar. (see page 378.)

On a four cylinder engine this cam would turn at cam shaft speed. If there were but 2 lobes on cam, it would turn at crank shaft speed.

Six cylinder engine: Because there are but two lobes or projections on the cam (D), in fig. 4, and because it opens the circuit twice during one revolution of the cam, we would obtain two sparks during one revolution. If a six cylinder engine, we would need 3 sparks to one revolution of crank shaft, or six sparks to two revolutions, therefore the cam (D) must turn 1½ times to one turn of crank shaft.

The distributor, however, would turn but 1 time to two revolutions of crank shaft, therefore it would have to be geared to run ½ the speed of the crank shaft, or 1 turn to two of the crank, because the brush (R) must make 6 contacts during its one revolution.

A simpler plan, would be, to use a cam with 6 projections or lobes, insteao of two projections, as shown in fig. 2, page 245. This cam, with 6 projections would then run at the same speed, as distributor, or one revolution to two of the crank shaft. The Studebaker and Reo, use a system of this principle, which is the Remy system.

The coil is a single "non-vibrating" type mounted above the starting motor and to the side of the distributor and interrupter. The primary current is taken from the battery or generator, through interrupter, thence primary winding of coil. It is there transformed into a high pressure and carried from secondary winding to the distributor arm (R) and distributed to the spark plugs.

CHART NO. 116—The "Magneto type" Interrupter as applied to the Modern Battery and Coil System of Ignition. (See page 368—later Studebaker system.)

Parts of a Modern Battery and Coil System of Ignition.

The parts of this system consist of distributor, timer, ignition coil, spark plugs and storage battery—see page 254 for Connecticut, page 248 Atwater-Kent, Delco 127 and 377.

The distributor is usually placed over the timer. First note the timer shaft which is driven from the cam shaft, usually by a spiral tooth gear and at cam shaft speed.

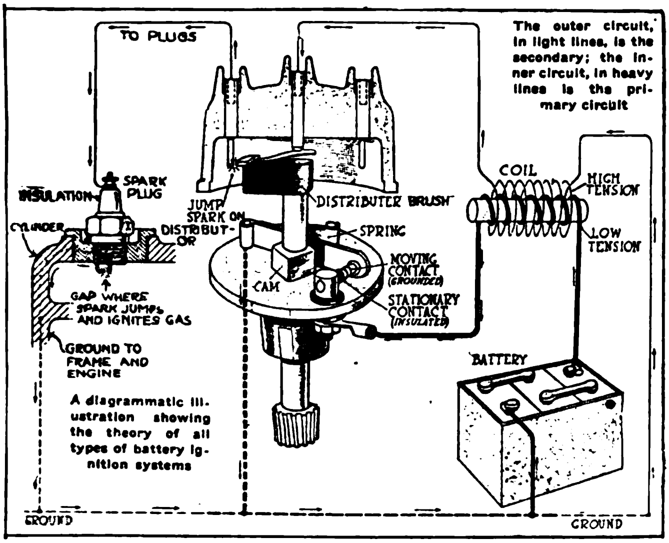

Fig. 5.—Diagram illustrating principle upon which the battery and coil ignition system operates. (Motor Age.)

††The distributor brush is connected to upper end of this shaft and as it revolves, makes contact with the spark plug terminals. Note center contact on rear of brush, connecting with secondary of coil.

Timer.

The timer is that part, containing the interrupter or contact breaker mechanism and is placed below the distributor. This mechanism simply makes and then breaks the flow of current in the primary circuit if open circuit type, and opens the circuit if closed circuit type.

The Coil.

Is the same principle of high tension coil as described on page 220, but without a vibrator. **The condenser** can be built in or on the coil but is now often placed on the timer (see page 252). The coil can be mounted on the dash, separate from the distributor and timer or adjacent to it.

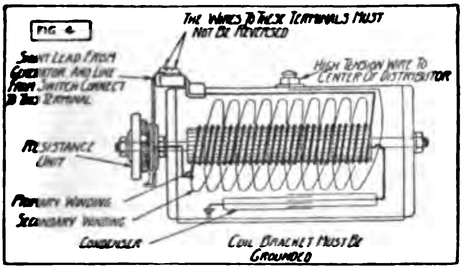

Fig. 4. Delco coil; showing winding connections, condenser and resistance unit. This coil is similar to any other high tension coil, without vibrator.

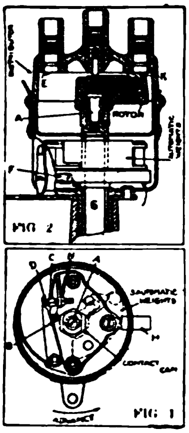
The Condenser.

For description of condenser and its purpose see pages 228 and 378.

†To test condenser: remove the distributor head and have some one crank engine. Notice if there is **excessive** sparking at the timer contact points, if so, then condenser is defective. A slight spark, however, will sometimes be observed with a good condenser.

Testing coil: The mechanic should familiarize himself with the spark obtained by removing the wire from one of the plugs and letting the spark jump to the engine (not to the spark plug). A good coil will produce a spark with a maximum jump of at least ⅛ inch, provided other conditions are normal. See pages 236, 253, 418 and 378.

**Timer Contacts.



Figs. 1 & 2.—Sectional view of Delco distributor and top **view of timer. Timer is mounted under distributor.** (see pages 377, 378 and 182.)

The timer contacts are called "interrupters" or "contact breakers" and are shown on pages 252 and 378.

The timer contacts shown at D and C (fig. 1), are two of the most important points. They are **tungsten** metal, which is extremely hard and requires a very high temperature to melt. Under normal conditions they wear or burn very slightly and will very seldom require attention but in the event of abnormal voltage, such as would be obtained by **running with the battery removed** (on generator alone); or with the ignition *resistance unit shorted out, or with a defective †condenser, these contacts burn very rapidly and in a short time will cause missing.

These contacts should be so adjusted that when the fibre block B is on top of one of the lobes of the cam the contacts are opened the thickness of the gauge on the distributor wrench (usually furnished by the manufacturer.)—see page 378.

Adjust contacts by turning contact screw C and lock with nut N. The contacts should be dressed with fine emery cloth so that they meet squarely across the entire face—see pages 377 and 378.

Referring to illustration fig. 2;—shaft which drives distributor rotor and timer. High tension current passes from distributor brush (K) to spark plug terminals. A—is screw for setting position of timer cam. Note automatic weights or governor which automatically advances the spark. Fig. 5 is not automatic. See page 377.

****To set the timer,** see pages 250 to 253, 316, 317, 390, 377, 378. *See foot note bottom page 246, and page 378. †A defective condenser such as will cause contact trouble will cause serious missing of the ignition. See also page 303, testing a magneto condenser.

††The "gap-type" distributor is one used in fig. 5, because contact is not actually made, but jumps to spark plug terminals. (see also page 247.) **A brush type distributor** is as per "Bosch," page 252.

†**To set the timer (Delco system on Buick as an example):** (1) Fully retard spark lever on steering wheel; (2) Turn engine crank until 7° mark on fly wheel is in line with center mark, which is approximately 1" from dead center mark on the fly wheel with No. 1 piston on the firing stroke. (3) Loosen screw in center of timing mechanism and locate the proper lobe of the cam. Turn until the rotor brush comes under the position which No. 1 high tension terminal on the distributor head occupies when the head is properly located. (4) Set this lobe of the cam so that when the back lash of the distributor gears is rocked forward the contacts will be open and when the back lash is rocked backward the contacts will just close. Tighten the screw and replace rotor and head. The shaft runs clockwise when viewed from the top, and the spark occurs when the contacts open. Firing order of "six" is 1, 4, 2, 6, 3, 5; of the "four," 1, 3, 4, 2.

The Electric Current.

For Delco, or in fact all of the ignition systems treated in this instruction, is taken from a storage battery to start on and to run on, under a speed of approximately 10 miles per hour. Over this speed the current is taken from the generator which will be explained further on, under the heading "Generators."

**Resistance Units.

Purpose: With the closed circuit type of ignition some method must be employed to protect winding of the coil, if the switch is left "on" accidentally when engine is not running. Resistance units and Thermostats are therefore employed.

The resistance unit used with the Delco system is for the purpose of obtaining a more uniform current. (see page 378.)

It consists of a coil of resistance wire wound on a porcelain spool as shown in fig. 4, page 245. Under ordinary conditions it remains cool and offers little resistance to the passage of current. If for any reason the ignition circuit remains closed for any considerable length of time, the current passing through the coil heats the resistance wire, increasing its resistance to a point where very little current passes and insuring against a waste of current from the battery and damage to the ignition coil and timer contacts. This unit also insures uniform current through the primary winding.

Electric Thermostat.

A thermostatic circuit breaking mechanism is used on the Connecticut closed circuit system, as explained on page 254. It is used to open the circuit in case the ignition switch is left "on." See also, p. 359, 363

The Depolarizer Switch.

Also called a pole-changing switch—used in connection with ignition systems is provided for the purpose of keeping the contact points on timer clean. See page 248.

*Automatic and Hand Advance of Spark.

The advantage of the automatic spark advance as explained on page 249 is this: With the spark lever set at the running position on the steering wheel, the "automatic" feature gives the proper spark for all speeds excepting a wide open throttle at low speeds, at which time the spark lever should be slightly retarded. When the ignition is too far advanced it causes loss of power and a knocking sound within the engine. With too late a spark there is a loss of power (which is usually not noticed excepting by an experienced driver or one very familiar with the car), and heating of the engine and excessive consumption of fuel is the result. (see page 377.)

The reason for using the manual (hand) control of spark is as follows: a heavy charge burns quicker than a light one. For this reason the engine will stand more advance with a half open throttle than with a wide open throttle. The hand control is therefore, installed in order to secure the proper timing of the ignition due to these variations and to retard the spark for "starting," "idling" and "carburetor adjusting."

Driving the Timer and Distributor.

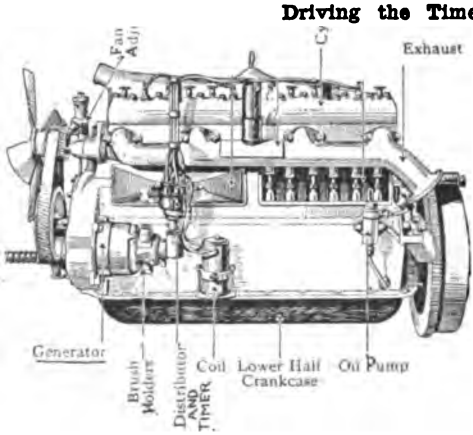


Fig. 8. Modern method of driving the timer and distributor through the generator shaft.

The modern method of driving the timer and distributor, is from the generator shaft as shown in illustration, fig. 8.

The generator shaft is driven, usually by a silent chain, encased. The timer shaft is driven from generator shaft by a spiral gear and geared so it will run distributor and timer at one half the speed of crank shaft.

Quite often the timer and distributor shaft is operated from the cam shaft—in fact there are various methods employed, but in most every instance it runs **at cam** shaft speed (½ the speed of crank shaft), made possible by placing lobes on cam, to give the desired number of sparks (see fig. 6, page 244, and pages 377 and 378.)

**It is a very easy matter to check the resistance unit (explained further on), by observing its heating when the ignition button is out and the contacts in the distributor are closed. If it is shorted out it will not heat up, and will cause missing at low speeds. See page 378.

†See pages 390, 250 to 253, 316, 317, and 132 for Delco.

*The richness of the mixture and the amount of compression are also factors in the time required for combustion to be complete—see pages 377 and 307.

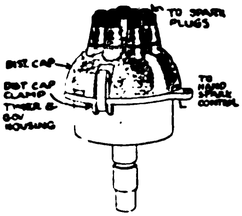
The Atwater-Kent Open Circuit Ignition System.

As an example of a modern battery and coil system of ignition, we will use the Atwater-Kent open-circuit system. (This concern also manufactures a closed-circuit system, as illustrated on page 249, 250, 252).

Parts: Consist of: (1) the distributor and timer, which is called the Unisparker; (2) the coil, which consists of a simple primary and secondary winding, sealed in an insulated cylinder. The coil has no vibrators, contacts, or other moving parts; (3) the depolarizer switch; (4) the automatic spark advance.

The function of the Atwater-Kent system is to produce a single hot spark for each power-impulse of the engine, accurately timed to occur at the right instant to produce the greatest possible power and efficiency. (See page 250).

The timer shaft is a ½ inch shaft, driven **housing**; as shown in fig. 2, page 248.



The timer shaft is a ½ inch shaft, driven usually from the cam-shaft and at **cam-shaft speed.** It is also quite often mounted on the generator and driven from it, as shown in fig. 8, page 246. It should always be installed in the coolest location available.

The contact points in the timer do not touch except during the brief instant of the spark. The ignition circuit is therefore normally open and no current flows, even though the ignition switch be left "closed." This dispenses with the use of a resistance unit, or thermostat as described on page 250, 246 and 254.

The operation of the timer. This consists of a pair of contact points, normally open, which are connected in series with a battery and the primary circuit of a simple non-vibrating induction coil.

A hardened steel **latch,** against which the trigger strikes on its recoil and which in turn operates the contact points, completes the device, see figures 1, 2, 3 and 4.

The distributor forms the upper part of the Unisparker, the high tension current from the coil is conveyed by the rotating distributor block arm (DA), fig. 2, chart 117, thence to the spark plugs in their proper order of firing.

Gap type distributor; the distributor arm (DA) does not touch contacts above it, but passes close to them (gap 1/50th in.) as it revolves and the high tension current jumps the slight gap, therefore termed a "gap-type" distributor.

Figures 1, 2, 3 and 4 show the operation of the Atwater-Kent open circuit timer clearly. It will be noted that in fig. 1 the lifter is being pulled forward by the notched shaft. When pulled forward as far as the shaft will carry it (fig. 2), the lifter is suddenly pulled back by the recoil of the lifter spring. In returning, it strikes against the latch, throwing this against the contact spring and closing the contact for a very brief instant—far too quickly for the eye to follow the movement (fig. 3).** Note that the circuit is closed only during the instant of the spark.

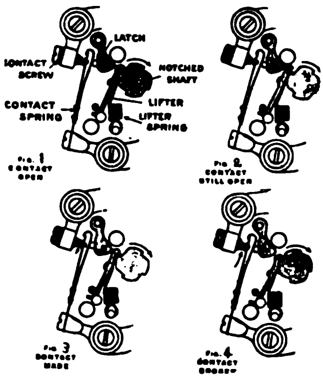


Fig. 4. Shows the lifter ready to be pulled forward by the next notch.

Adjusting AK Open-Circuit Timer.

Adjustment of gap between contact-points should be .010", when lifter (fig. 1, above) is in the notch. This adjustment can be made by placing more or less thin **shim washers** (see W fig. 8, page 248) on contact screw.

When taking up this distance between points, due from natural wear, remove both screws and dress with a very fine file, then replace and shim up to .010". **The points are made of tungsten steel** which is very hard.

Remember that when points are working properly, small particles of tungsten will be carried from one point to the other, forming a roughness and dark gray color, this however does not in any way affect the working of the points as the rough surfaces fit each other perfectly. **Spark plug gap should be .025".**

The Condenser.

The condenser instead of being in the coil, is located on the timer of both the open-circuit type, fig. 6, and on the closed-circuit type, fig. 4 and 5 and fig. 1, page 249. Note the circuit on page 249. The condenser is arranged so that it short-circuits across the timer contact-points for **reasons** stated on page 228.

To explain how the condenser is connected, see fig. 4, this is the metal cover which is placed over condenser to protect it and also to which is attached the insulated contact-point of timer.

FIG. 4

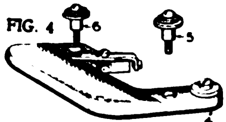

FIG. 5

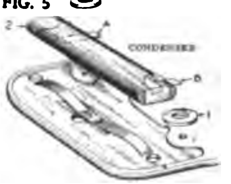

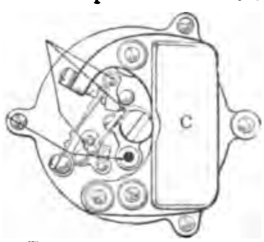

Fig. 6. C is condenser cover on open-circuit timer. **Fig. 4,** cover of closed-circuit timer.

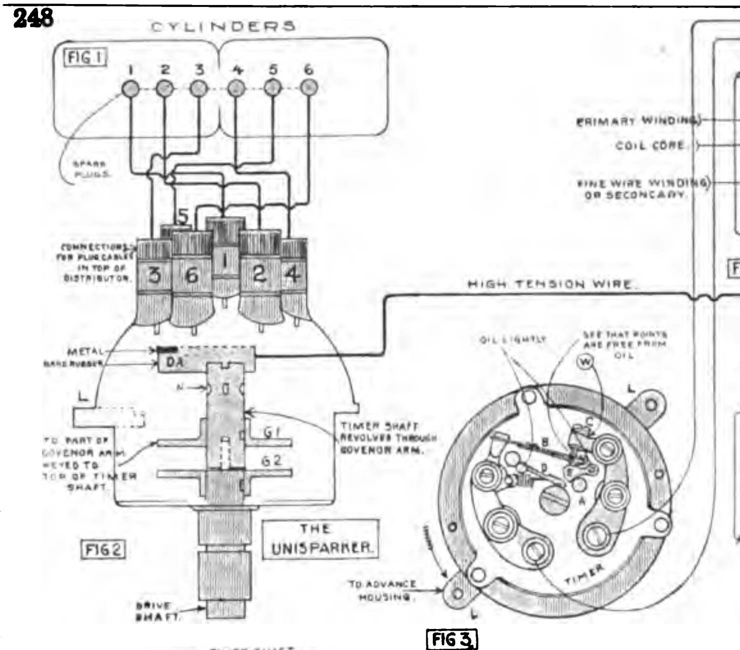
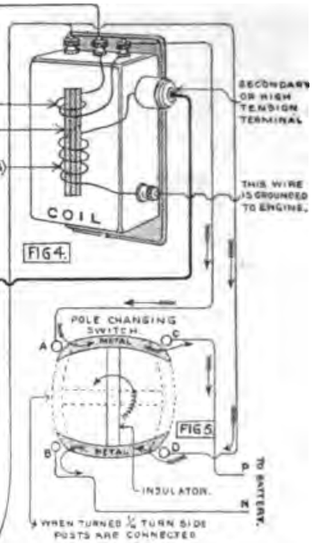
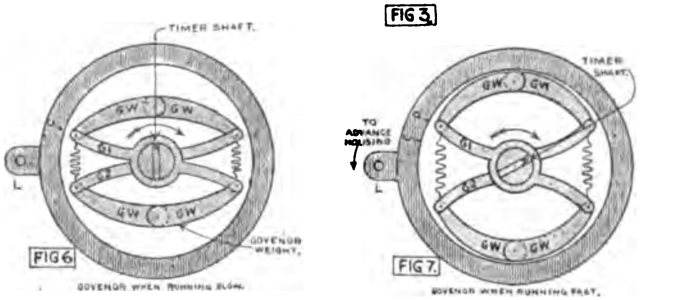
This condenser cover is insulated from base of the timer by screws 5 and 6 which have insulated washers on them.

—Continued on page 249.

****Do not think that these parts do not work properly because you cannot see their movement.** The contact maker of the Unisparker may be likened to a watch, which, because of the small size and extreme accuracy and hardness of its moving parts, is subject to very little wear. Don't change tension of spring or alter parts. **There are as many notches (fig. 1) in the timer shaft, as there are cylinders,** and as many leads from the distributor to spark plugs, as there are cylinders. See lower illustrations, page 248, for parts of the AK open-circuit timer distributor.





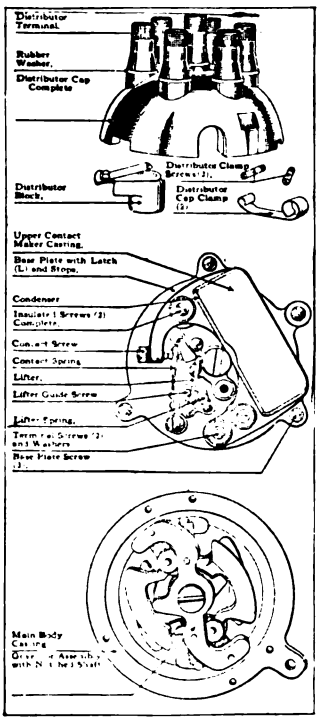


Atwater-Kent.

The distributor and timer (called the unisparker) is illustrated in fig. 2, it consists of a timer with its contact breaker or "maker," which would be more appropriate, mounted on the timer shaft, but independent of each other.

The timer is illustrated in fig. 3, and explained on page 247.

The governor, figs. 6 and 7, is mounted directly under the timer. One arm of the governor (G1), is attached to the upper part of the timer shaft which is free to advance with the action of the governor. The other arm of governor automatically advances the time of spark as the speed of engine increases, by centrifugal action of governor weights (GW), as shown. Note position of end of timer shaft (A), at retard, fig. 6, and advance, fig. 7. Note at "retard" governor arm (G1) is at (C), whereas at full speed it has advanced to (D). (Marks shown on left hand side of housing.)



The distributor, which distributes the current to the spark plugs (six in this instance), in their respective firing order of 1, 4, 2, 6, 3, 5, is mounted on the upper end of the shaft. The distributor arm (DA), revolves with timer shaft and passes the high tension current to the terminals of the distributor, as six sparks are required per revolution, there are six notches on timer cam, and the distributor points are spaced 60° apart.

The coil, is a double wound coil with a secondary and a primary winding. The primary current (6 volts), coming from the battery or generator is carried through a pole changing switch through timer contacts, where the current is opened and closed at the proper time by the contact arm (D) (fig. 3), coming in contact with notches (N, fig. 2), which raises latch (E), causing contacts (B and C), which are insulated from each other, to come in contact: thereby closing the primary circuit in the coil. This causes a secondary current to be set up in the secondary winding of high voltage. This secondary current is then distributed to the spark plugs by the distributor. (Cylindrical type coil now used—see page 249.)

There are as many notches (N), in the timer shaft as there are cylinders and as many distributor leads to spark plugs as there are cylinders.

Polarity Switch.

The polarity switch, is intended to prevent the points on (B and C) from becoming worn and pitted. "Direct" current is used which has a tendency to burn and pit the points, whereas an alternating current is much easier on the points. Therefore to alternate the flow of current from N to S and S to N or positive to negative and negative to positive—is the principle of this style switch.

As stated above, "direct" current is used with all battery systems, therefore a steady flow in one direction has a tendency to deposit the metal from one point to the other—but by changing this flow of current occasionally, the deposit will be put back to the other point again. This is similar to electro-plating.

Note the action of the polarity switch: D is now flowing negative, A is flowing positive. By turning switch one quarter turn, the poles are changed; A will become negative and D will become positive. This change is made occasionally when running and has a tendency to keep contact points clean.

CHART NO. 117—The Atwater-Kent High Tension Coil and Battery Open-Circuit Ignition System with Automatic Advance Timer and Distributor. Upper illustrations are slightly exaggerated.

*The later Atwater-Kent system is a closed circuit principle, see fig. 1, page 249 and page 252. **Condenser not shown on above system, but it is on timer, per page 247, 249.**

—continued from page 247.

Note the terminals A and B of condenser, fig. 5. Terminal (A) is grounded to base (C) of timer below it, then insulated washer (3) is placed **over** (A). The other terminal (B), has an insulated washer (1) **under** it to insulate terminal (B) from base. Cover (4) is then placed over condenser and terminal (B) makes contact with cover. We then have one terminal (A) of condenser grounded to base (C) and other terminal (B) connected with **cover** (4) **which is insulated from base.** The circuit would then be as shown in fig. 1, page 249.

It is seldom necessary to remove condenser, but if ignition fails in case timer should become water soaked, feel of coil, with switch on, it should show some heat from current passing through resistance unit in coil, you will then know current is passing through the coil allright, therefore open switch. Then remove distributor cover and condenser cover and clean all contacts and screws and replace condenser cover, also wipe water from the other parts and wires. **The ignition may also fail by these screws coming loose,** however, this seldom happens but if ignition fails, yet you know the current is passing through the coil and no spark can be obtained, then this might be investigated.

Oil. Use light machine oil at points shown by lines on open-circuit timer, fig. 6, page 247.

Testing.

If engine misses without regard to speed, test each cylinder separately by short-circuiting the plug with a screw driver, allowing a spark to jump. If all cylinders produce a good, regular spark, the trouble is not with the ignition.

If any one cylinder sparks regularly, this will indicate that the system is in working order so far as the Unisparker and coil are concerned, and the trouble is probably in the high-tension wiring between the distributor and plugs or in the plugs themselves. Examine carefully the plugs and wiring. Leaky secondary wiring is frequently the cause of missing and backfiring.

Frequently, when high-tension wires are run from the distributor to the spark plugs through metal or fibre tubing, trouble is experienced with missing and back-firing, which is due to induction between the various wires in the tube. This trouble is especially likely to happen if the main secondary wire from the coil to the center of the distributor runs through this tube with the spark plug wires.

Wherever possible, the distributor wires should be separated by at least ½ inch of space and should be supported by brackets or insulators rather than run through a tube. In no case should the main distributor wire be run through a conduit with the other wires.

If irregular sparking is noted at all plugs, examine first the battery and connections therefrom. If the trouble commences suddenly, it is probably due to a loose connection in the wiring. If gradually, the batteries may be weakening or the contact points may require attention. See that contacts are clean and bright, and also that the moving parts are not gummed with oil or rusted.

Wiring.

The wiring of the AK open-circuit system is shown on page 248.

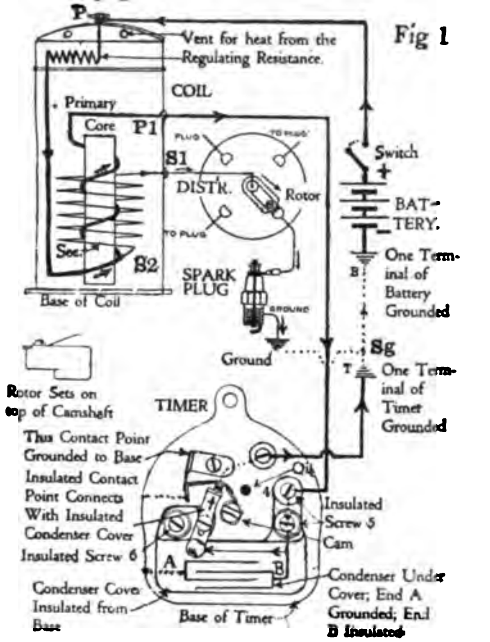


Fig 1

The wiring of the AK closed-circuit system, which is the model CC, is shown above, also page 252 and explained on page 250.

Fig. 1. Circuit of the AK closed-circuit timer. Note one wire from timer and one wire from battery is grounded, therefore it is a "single-wire" system. The open or closed-circuit system could use either a "single". or "two-wire" system.

To trace primary circuit, start at switch, follow black line to insulated terminal (4), then to insulated contact point through grounded contact point to grounded terminal, to ground (T) to ground on battery (B). (Note condenser connects across the contact points).

To trace secondary circuit start at S1, thence to distributor rotor, through spark plug to ground (Sg) through primary wire to (S2) where secondary is grounded to primary wire in the coil.

*Explanation of the Automatic Advance of Spark.

****Governor:** The Delco and Atwater-Kent systems employ a mechanical governor for advancing the spark when the engine is speeded. A governor of the centrifugal type is employed on both systems, but of slightly different construction. The purpose of the governor is to cause the timer notched shaft to turn in the direction of rotation, causing the contact to make and break earlier as the speed increases.

For instance; refer to fig. 6, page 248. Assume engine is running slow and governor is in retarded position. Note position of notch (A) in top of timer shaft. If engine is speeded up, the governor weights (GW) fly outward, causing timer shaft to turn further advance in direction of rotation—it is clear to see that the contact would be made sooner at D and E (fig. 3). The top of timer shaft is driven through the governor arm—see fig. 2.

In addition to the governor advance—the distributor housing can also be advanced by hand, the two working independent of each other (see fig. 3), L is connected with spark lever on the steering wheel.

The manual or hand control is for the purpose of securing the proper ignition control for carburetor adjusting, slow idling, retard for starting and variable conditions which cannot be held constant.

The automatic spark control is for the purpose of securing the proper control due to variations in speed alone, and all that is required for normal driving is to secure the proper spark control for slow driving from 10 to 15 miles per hour (set the spark lever about ⅔ advanced) and the automatic feature will give the proper

*The advance and retard of spark is explained under Ignition Timing—pages 305 and 307.
**Atwater-Kent supplies the Unisparker with or without governor. †Use ⅛" outside dia. of insulation for secondary wire.

spark position for all higher speeds and for all lower speeds, excepting when the throttle is wide open, at which time the spark lever should be slightly retarded.

Where the hand spark control lever is used, it should be so proportioned as to give not more than ¼ to ⅓ inch of movement, for the entire range of the spark lever on the steering wheel sector.

Range of spark advance: The high tension distributor is carried on a central shaft, which connects below the governor, so that the distributor block is not moved by the automatic advance mechanism. This permits of a wide range of spark advance without affecting the synchronism. The maximum advance is about 45 degrees, of crank shaft travel; at 2400 r. p. m.

The source of electric supply for this system, also all other systems of this kind, is from the storage battery. The storage battery, as previously explained is charged from an electric generator run from the engine.

The current consumption is very small, but the strength or pressure of current as required by the coil is necessary for a single spark system. Therefore keep the battery fully charged at all times.

In case of an emergency, dry cells can be used connected six in series. If dry cells are used, they should be insulated from each other by wood or fibre battens for if damp they will give but little service.

*The Atwater-Kent Closed Circuit Ignition System.

The closed-circuit system is similar in many respects to the open-circuit system, except the timer, or interupter is constructed differently. The points are normally **closed** instead of open. This system is termed the type "CC" per fig. 1, page 249 and page 252. When it is equipped with a governor or automatic advance it is termed the type "CA".

When using a closed-circuit timer, it is necessary to use resistance in connection with the coil, else the coil might be damaged if switch was left on when engine was not running, as the timer points are normally closed. The resistance unit also protects the coil during variations of speed of generator, which slightly increases in voltage at high speeds, when generator supplies current for ignition. At low speeds the battery (6-volt) supplies current for ignition. At medium and high speeds generator supplies current for ignition (about 8 or 9 volts). See also, page 246, "Resistance Units."

The closed-circuit timer is shown in illustration. Contacts are normally closed by spring (D). Rotation of cam (C) brings it in contact with fibre tip (T) on contact arm (A), thus separating contact-points and breaking the circuit at which instant the coil delivers the strongest current.

Adjustment of points can be made by loosening screw (S) and moving arm (B).

The gap between contact-points should be .006". Spark plug gap .025".

Timing the Atwater-Kent Ignition Systems.

Open-circuit type when hand spark control is not used (automatic advance): **First,** place piston of No. 1 cylinder on top of **compression stroke. **Second,** slowly turn unisparker backwards until a click is heard which is the exact instant of the spark. **Third,** tighten set screw on timer shaft which was loosened when starting to time. Be careful to not change position. **Fourth,** remove distributor cover and note position of distributor block or rotor. It should be on terminal for No. 1 cylinder. Then see if wires from distributor are connected properly as per firing order of cylinders, keeping in mind the direction which rotor turns.

The spark set thus, is on top-dead-center retarded and the governor action will take care of the advance as the speed increases.

Closed-circuit type when hand spark control is not used (automatic advance): The timing is the same as above, except the timer should be turned backwards until the contact-points commence to open. As it opens the spark occurs. A good way to test is to have spark plugs on top of cylinders and current on so the spark can be seen at points of plugs. If the timer with automatic advance is used in connection with the regular spark lever on steering wheel, then do not give over ⅝ or ¾" movement of timer from full retard to full advance.

Open-circuit type with hand spark control: The setting is the same, except position of spark advance lever on steering wheel should be within ½" of full retard and lug on timer should have ⅝" to ½" movement from full retard to full advance. After retarding spark lever to within ½" full retard, then with driving member loose, piston on top of compression stroke, turn backwards until a click is heard, at which point set the timer. Then see "Fourth" procedure above.

Closed-circuit type with hand spark control: Same as above except the timer is turned backwards until contact points commence to open, at which point set the timer by set screw or clamp, or if driven by a shaft on which timer can't be loosened, then the setting can be made with the advance lever shaft or drive gears loosened. The lug on timer should have ⅞" to 1" movement from full retard to full advance.

Single vs. Succession of Sparks.

An vibrator coil makes several sparks, usually starting before piston is on top of compression, and ending after top of compression. The hottest spark ignites the gas. **The spark should occur before top of compression** and ignite the gas before top is reached, so that combustion will have time to take place on the top, at the point of highest compression, and not after the top, when compression is being lowered. See page 307.

Fig. 8 represents the Remy, Delco, Westinghouse and Atwater-Kent "single spark"—a hot one at the right time, which causes gas to ignite quick without lag and consumes little current.

Fig. 9. Note the succession of sparks. This represents the sparks as they occur on the old style vibrator coil—several after top of stroke. The hottest one ignites the gas, but usually late.

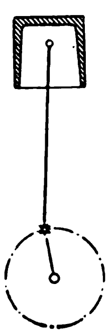

Fig. 8.

Fig. 9.

*See page 544 "Specifications of leading cars" for cars using the AK system. **See index "finding compression stroke."

**The Remy Ignition System.

The Remy ignition system consists of the combined timer-distributor unit, a coil and the switch (see chart 118). The system **operates** on the **closed-circuit** principle, and **is** distinguished by the fact that it has but two moving parts—the cam and the breaker arm. The system is made for four-, six- and eight-cylinder engines.

In operation, the rotation of the cam C brings its corners in contact with a fibre plug which is riveted to the breaker arm. The arm thus is lifted, separating the contacts. Inasmuch as the moving parts are very light and a considerable period is allowed for the saturation of the primary winding in the coil, both mechanical and electrical lag are practically eliminated.

Only **hand advance** of the breaker mechanism is provided.

Whole mechanism stationary: Another feature of the Remy unit is that the whole mechanism is stationary. Advancing or retarding the spark does not move any of the wiring. This is accomplished by mounting the breaker mechanism on a plate. The plate is attached to the advance lever and is moved with it, thus rotating the breaker mechanism partly around the cam.

The distributor mechanism consists of the usual Bakelite cover, with the terminals molded in place. There is no wiping contact, the spark jumps from the radial distributor arm to the terminals. Wear, therefore, is eliminated.

On top of the coil there is a miniature resistance coil in series with the primary winding. This is to protect this winding in the event the engine should remain idle for any length of time with the switch closed. In short, it protects the winding and also prevents excessive drain on the battery.

Remy adjustments: Under ordinary conditions the contact points, which are iridium-platinum or tungsten should not require attention more than twice a season.

They should be dressed with a fine flat file to present perfectly smooth surfaces.

The contacts should be adjusted with the wrench provided so that the maximum opening is .020 to .025 in. The rebound spring should be at least .020 in. from the breaker arm, when the contacts are at maximum opening.

For best results the **spark-plug gaps** should be .025 to .030 in.

If the engine misses when idling or at light loads; the gaps at the plugs should be wider. If the engine misses at high speed or when pulling hard the gaps should be narrower.

The oiler on the shaft should be kept filled with medium cup grease and screwed down two or three turns occasionally. On some instruments a wick oiler is used. In this case use pure vaseline instead of grease.

Manufacturers are Remy Electric Co., Anderson, Ind.

†Westinghouse Ignition System.

Battery and coil ignition system is of the **closed circuit** type (see chart 118). It is made for 4, 6 and 8 cylinder engines.

The timer-distributor unit is vertically mounted and is operated from the cam shaft or can be attached to generator, as all other systems of this type can be. Only hand operated advance is provided.

The **condenser** is mounted close to the breaker mechanism, being below the coil and distributor. Note the **condenser, coil and breaker are all in one unit.**

A metal ring can be slipped upward to **permit inspection** or adjustment of the contacts.

The distributor is the same as that used in the regular Westinghouse systems in which a circular carbon brush make contact with terminals embedded in the cover.

The standard ignition switch is of the **snap type** and combines the lighting switches in one plate which is mounted flush on the dash. Each time the ignition switch is turned the polarity of the current is reversed, therefore it would be termed a **polarity switch** (see chart 117 for principle).

Westinghouse adjustments: In **adjusting** the breaker the contacts should be dressed with a fine file and adjusted so that the maximum opening is .012 in. **Spark-plug gaps** should be .025 in.

The distributor brushes should slide freely in their holder and the spring should push the top brush out so as to extend from the holder about ¼ in. when the distributor plate is removed.

In the back of the switch plate there is what is termed a **"ballast coil"** (for same purpose as "thermostat"—chart 119). This is a small resistance in series with the final winding, and is to protect the winding and prevent excessive drain on the battery, should the engine remain idle with the switch in the "on" position. If this should be accidentally broken the ballast terminals may be temporarily short-circuited with a piece of wire or with a standard 5-amp. fuse.

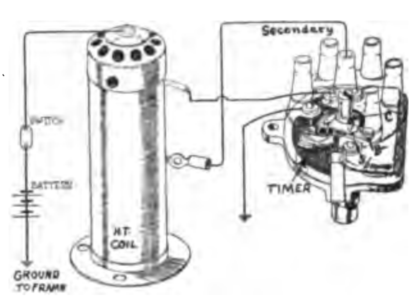
The only lubrication required will be two or three drops of oil about once a month in the oil cup provided on the side of the distributor unit.

Manufacturers are Westinghouse Electric Co., Pittsburg, Pa.

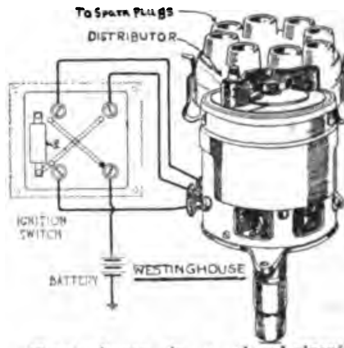
The Connecticut Ignition System.

Is a typical example of a closed circuit type and is made for 4, 6 and 8 cylinder engines. This company calls the interrupter and distributor, which is mounted in one unit—an "igniter." They also term the timer, interrupter, because it is similar to a magneto interrupter—which interrupts the flow of current—however, other systems as the Remy and other closed circuit battery and coil ignition systems also call the timer, interrupter, as it is exactly the same principle. (see pages 252, 254, 364 and 358.)

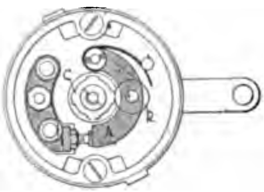
*See charts 229-234 for "Specifications of Leading Cars," for cars using these different systems.
**See page 318 for example of timing Remy ignition on Chalmers.
*See also pages 346 and 348. †See also, page 348.



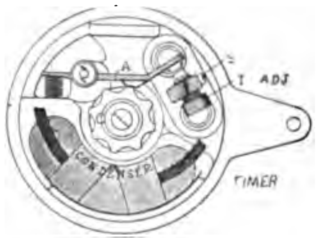
Model CC Atwater-Kent closed-circuit ignition system, see pages 250-249.



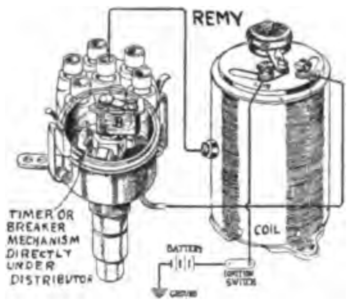
The Westinghouse is a closed-circuit **timer.** Rotation of cam C brings it in contact with **block** on arm A, thus separating the contact-points.

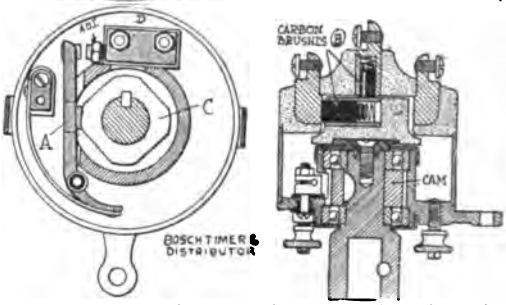


Connecticut closed-circuit timer. Rotation of cam C brings high points in contact with fibre roller R on arm A, thus opening contact-points. See pages 253, 254, 364, 358.



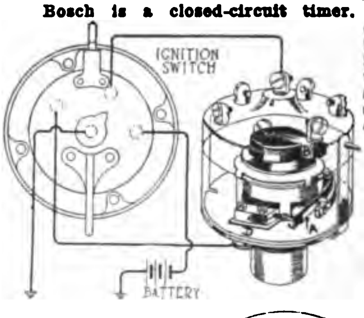
Adjustments are made by loosening clamp screw S and turning nut T. **See pages** 253, 346, 348.

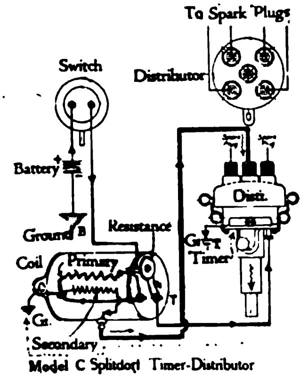




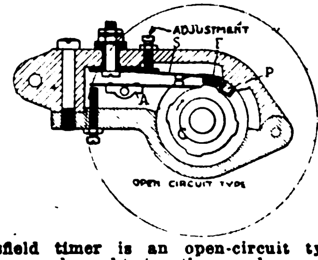
Remy is a closed-circuit timer. When cam C is rotated it touches the fibre block in contact **arm A.** thus separating the contact-points. See pages 253, 350, 924.

Bosch is a closed-circuit timer. Rotation of cam C brings it against the fibre block in the contact arm A, thus separating the contacts.





Splitdorf closed-circuit timer (type T. D. C. & T. O. C.) Points are set .015" for 4 cyl. engines; .010" for 6 cyl; .008" for 8 cyl. engines.



Pittsfield timer is an open-circuit type. The contacts are brought together and separated mechanically. When cam C is rotated its high spots first touch the lower arm A, bringing contacts forcibly together and holding them until cam rotates further against block F, thus separating contacts again. Plug P is a felt oiler.

CHART NO. 118—Examples of Coil and Battery Ignition Systems.

See page 544 for "Specifications of Leading Cars" for make of ignition systems used on leading cars. See pages 250, 254, 378, 542 for adjustments of contact points. See page 378 for Delco timers.

Test of primary circuit: When testing the primary circuit there are practically only two things to be taken into consideration, namely, the condition of the contact points in the breaker box and the wiring.

When tracing the primary circuit, first see if any of the fuses have "blown," then trace all the wiring of the ignition circuit.

Testing Ignition switch: In order to test switch and determine if current flows through it, attach a wire to the negative terminal on the storage battery and remove the wire from terminal on coil. Then push the ignition button on left end of switch in and make and break the circuit with the two wires by touching their free ends together. If a spark occurs, there is a circuit through the switch. If a spark is not obtained there is doubtless an open circuit in the interior, therefore it should be returned for repairs.

The Bosch Ignition System.

...y ignition system developed by ... Magneto Co., nearly ten years ...ot been altered greatly. It oper... the **closed-circuit** principle and is ... for two, three, four, and six... ...r engines.

...complete system consists of a com... timer and distributor and a com...ed switch and coil, the latter to be ...ounted on the dash.

The breaker mechanism is simple, rotation of the cam C (see chart 118), pressing a fibre block separates the contacts which are normally closed by a spring.

The distributor is fully as simple and is mounted directly over the breaker. Only hand operated advance of spark is provided.

The switch incorporates the vibrator attachment to facilitate starting when the engine is cold or the carburetor out of adjustment. This mechanism is controlled by the pointed button in the center of the switch plug. Under normal starting conditions momentary pressure on the button will produce a single spark at the plug. Turning the plug to the right and depressing it makes the necessary connection to provide a continuous stream of sparks at the plug. If desired the button can be locked in this position until the engine has started.

The switch provides for the use of a magneto, the engine running on the magneto with the switch in one position and on the battery with the switch in the other position.

There is only one adjustment, and this is for the gap at the contacts. With the fibre block resting on top of the cam, the contacts should be separated about .016 in. To alter the adjustment the lock nut must be released first, and carefully secured after the adjustment is made. Occasionally expansion of the fibre bushing prevents the free movement of the lever, and in this case the bore of the bushing can be slightly enlarged with a reamer. No lubrication is required.

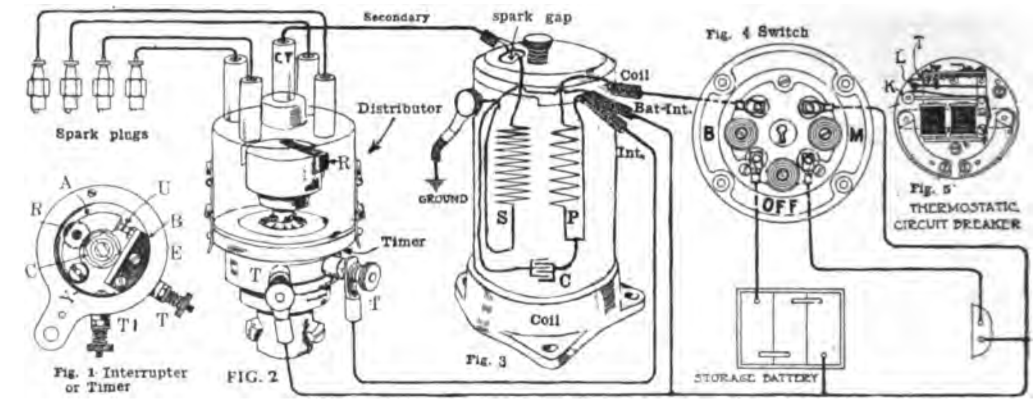
Also see chart 133, fig. 3, and instruction 21, for diagram, etc., of the Bosch battery and coil system. **Spark plug gap should be .020 to .025".**

Delco Ignition System.

The Delco coil and battery ignition system is another popular system. It is treated under instruction number 28-A, and is made in both the open and closed circuit principle—see pages 377 and 378.

*Note.—The coil and battery ignition systems treated under this instruction are also treated further on under instructions number 27 and 28.

**To suit individual requirements it may be necessary to advance the ignition slightly when timing, if greater speed is required, or to retard it slightly for very slow running. This is done by loosening set screw and turning igniter with rotation of shaft if it is found to be timed early—or against rotation if it is found to be timed late.



Connecticut Ignition.

Timer or interrupter (fig. 1, 2 above) is the model 14 and 15, where both contact points (U); one on arm A, the other on (B), are insulated from each other and two wires connect with terminals T and Tl from coil, battery and switch. R is a fibre roller and C cam, which turns at ½ the engine speed and has as many lobes as there are cylinders. Both contact-points are **normally closed** until separated by cam C.

Distributor sets above the timer, and rotor or distributor arm sets on top of cam-shaft and revolves at the same speed as timer cam. The rotor in the model 14 and 15 is of the "brush-type" contact (R), which makes a wiping contact.

The model 16 timer-distributor shown below, is very similar, except instead of having two binding-posts to timer there is one binding-post and a wire. The distributor rotor (or arm) is of the "gap-type" as explained on page 247.

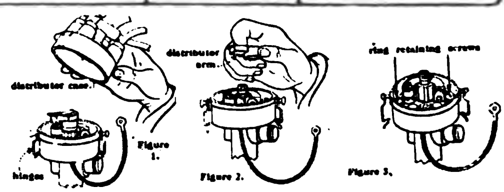
Coil is a non-vibrating type. A spark-gap is provided to protect coil from increased voltage and liability of puncture to winding insulation if spark plug or secondary wires come loose.

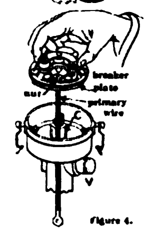
Switch on above system is the model G. When B button is pressed the storage battery supplies current for ignition. When M button is pressed the magneto supplies current for ignition. When lower button is pressed it will release either of the above, which ever may be in.

The thermostat as explained below and fig. 5 above, is contained in the back of the switch. This switch is now seldom used except where magneto ignition is employed. The switch below is the model 41Y ignition and lighting switch with thermostat. **Where a generator is on car,** it is connected with a separate cut-out, between battery and switch.

*Timer Adjustments.

Opening of contact-points should be .016" for a 6 cylinder engine and .020" for a 4 and .012" for an 8. When adjusting, roller R (fig. 1 above) should rest on point of cam (C). **Set spark-plug gap .022".**





†To Renew Interrupter Points

****A complete breaker-plate is installed. To disassemble:**

Fig. 1, Unclamp spring; remove dist. cover.

Fig. 2, Remove dist. arm.

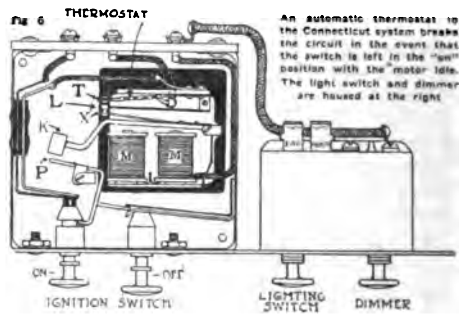
Fig. 3, Unscrew retaining screws.

Fig. 4, Lift breaker-plate and unscrew nut and loosen primary wire. Install new breaker-plate.

See also, pages 359, 365.

Ignition Thermostat.

Is enclosed in rear of switch fig. 4. See page 358 and note on the Overland it is in the "combination switch" box on steering column.



Purpose is to open the circuit, should switch be left on when engine is not running, per page 358.

The thermostat consists of blade—T, (see figs. 5 and 6), which **heats** when current passes through it for from 30 seconds to 4 minutes without interruption and causes it to bend to contact with L.

This completes an electrical circuit which energizes the magnets (M), causing releasing hammer (K), to operate like the clapper in an electric bell. This arm strikes against a plate (P) which releases whichever of the two ignition switch buttons in switch may be depressed or "on." Thermostat can be set to act from ½ to 4 min.

Adjusting screw (fig. 5), is provided directly over thermostat spring (T) which regulates the time. If thermostat was made to disconnect in less than 30 seconds it would probably "kick-off" when putting on ignition, before engine could be started.

CHART NO. 119—Connecticut Coil and Battery Ignition System. Example of Closed-circuit Interrupter (Conn. Telephone and Electric Co., Meriden, Conn.). See also, pages 359, 365.

*See page 253 for timing the Connecticut ignition. **Illustrations show model 16 interrupter. Similar method is used on model 15. †After installing new breaker-plate reassemble and **adjust**, per page 253.

INSTRUCTION No. 20.

A BRIEF REVIEW OF THE VARIOUS COIL IGNITION SYSTEMS: Advantages and Disadvantages.

We have now mastered the various methods of producing an electric spark for igniting the gas with a "primary" or low tension coil and a "secondary" or high tension coil. Before proceeding with the subject of magneto ignition ("alternating" mechanical source of electric supply), we will summarize the various systems.

Low tension coil systems; disadvantage of the "make and break" is its lack of "flexibility" and slow spark. It would be considered fairly good for a slow running constant speed stationary or marine engine.

****Coil with vibrator**; disadvantage of a vibrator coil is its tendency to miss; if battery is weak, vibrator will not operate—If too strong, points on vibrator will weld together and stick, causing missing. Spark is not fast enough. Consumption of current rather heavy. See page 250 for "succession of sparks and single spark."

Master vibrator coil—(chart 110). Where a system is already equipped with a multiple of vibrator coils, this would be an excellent method to improve it. Disadvantage—sticking vibrator—all work on one vibrator—succession of sparks.

Dry battery as source of electric supply—disadvantage is unreliability. A battery of 5 or 6 dry cells will do fairly good work when fresh for short periods of time—provided two sets are used and the use alternated from one to the other. It gets weaker as used, however, and is unreliable. Intended for "intermittent" work—as ringing door bells, etc., where used only for a few seconds at a time (see fig. 3, page 214).

Storage batteries — are better, as they maintain their pressure until exhausted. Contain greater quantity of current and are far more satisfactory—disadvantage—must be recharged when exhausted and operator must watch it for fear of running down.

Battery, coil and magneto—the battery and coil ignition, using dry cells or a storage battery, could be used for starting engine and the magneto used for ignition after starting—**disadvantage**—would be that dry cells would soon get weak and the storage battery would require charging in time. **If a generator or dynamo (direct current) was connected to engine to charge the battery,** this would be an improvement but would add another piece of machinery. The magneto generates "alternating" current, therefore is not suitable for charging a battery and can only be used independently for ignition.

High tension magneto alone—the magneto generates a very hot and voluminous spark which is desirable, as the time between ignition and actual combustion, as explained on page 307, is less, with result that more power is obtained (similar reason as "double" and "two-spark" ignition is an advantage, page 277). The **disadvantage** is that the magneto must be turned fast enough to generate current when starting and this can not always be relied upon when cranking by hand, therefore some form of starter must be employed. The popular type of magneto starter is the "impulse starter" as explained on page 832. It is used extensively on truck and tractor engines as explained on page 277. This overcomes the starting disadvantage, but is not altogether desirable for pleasure cars.

The Electric System in General Use.

Battery, coil, generator and electric starting motor—a very satisfactory system and one which is now generally used for pleasure cars is an ignition system using a high tension coil without a vibrator and a "closed circuit," "single spark" timer. The source of the electric supply for ignition and starting motor being taken from the storage battery when starting engine and after engine is up to speed the "direct current" generator charges the battery and supplies current for ignition and lights. **Advantages** of this system would be a **constant** source of electric supply, a hot spark regardless of the speed of the engine, ease of starting engine and a constant source of electric current for lights when car was idle or running. See pages 248 to 254 and page 378 for this ignition system and page 334 and 410 for a diagram explaining this system.

The question then arises, why use only a magneto on a truck and this system on a pleasure car. The answer is as follows; to avoid complication. The driver of a truck seldom runs the truck after dark and seldom at a high rate of speed. A truck must be operated on an efficient basis, therefore the added complication of battery and starter is eliminated—see page 277.

On the other hand, the pleasure car is driven considerably at night and quite often at a high rate of speed, therefore strong lights are essential. The pleasure car driver also demands an easy method of starting. Inasmuch as a starting motor and strong lights consume a great deal of current, then it is necessary that a generator be supplied to continually charge the battery while running, therefore, if a battery is required, and a generator to charge the battery, then by adding a timer, distributor and non-vibrating high tension coil we have added an ideal ignition system, thus combining all the desirable features and eliminating entirely the magneto.

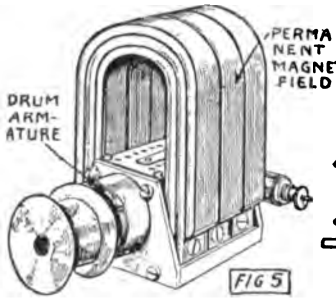
Disadvantage of the battery, coil, generator and electric starting motor system would appear to be (1) the probabilities of the dynamo at high speed burning out the ignition coil, as the voltage increases with speed of dynamo—or (2) when running slow, the connection being between the storage battery and field coils—current would flow from battery into generator. This, however, is all taken care of (1) by "regulation" of the dynamo field windings so the output remains constant at low or high speeds (2) by a "cut out" arrangement—which is explained on page 334.

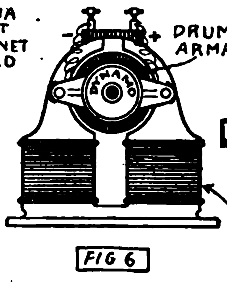
The greatest source of trouble with this system is the storage battery, as it requires careful watching, but by having the battery tested about every two weeks and seeing that generator is charging the battery while running, which is a simple operation, battery troubles can be eliminated.

Dual and Double Ignition.

See page 277.

*See "Specifications of Leading Cars," pages 543 to 546 for ignition systems used on leading cars.
**See page 243; and note a vibrator coil would have an "electrical and mechanical lag."





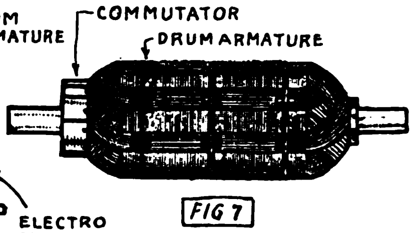


Fig. 5. A dynamo or mechanical generator of "direct" current. Note this type of generator can have either "permanent" or "electro" magnets, but the armature is always DRUM wound with a commutator on end of armature shaft.—see pages 323, 325, 332 for drum armatures.

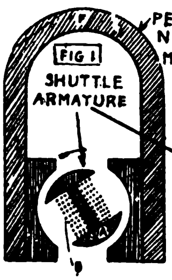
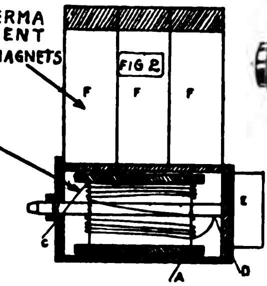
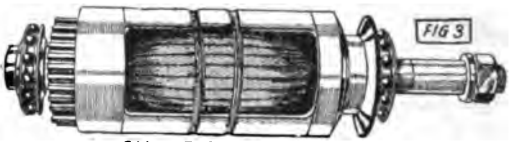
Permanent magnets are of the horse shoe type and are permanently magnetized. They are called the "field" magnets.

Electro field magnets are wound with copper wire and are electrically magnetized and remain magnetized only when armature revolves between the field magnet poles. This type of dynamo or generator, generates a steady "direct" current, usually of 6 or 8 volts and will light electric lamps and recharge a storage battery and supply current for ignition. It is usually run in connection with a starting and lighting system, and in smaller models, is used for ignition on stationary and marine engines to a considerable extent.







SHUTTLE TYPE ARMATURE WITH ONE WINDING - LOW TENSION

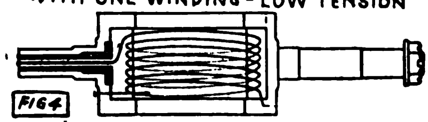


Fig. 1. The magneto is also a mechanical generator, but the current generated is "alternating," that is, the current is not a steady flow, but alternates continuously. The field magnets are always of the permanent magnet type. The armature for generating alternating current is of two types; the "shuttle" type as shown in figs. 3 and 4 or the "inductor" type as shown in fig. 8.

The shuttle or "armature" type of armature (see page 274) has a primary wire winding of copper wire, one end grounded to armature core and other end insulated. If there is but one winding on the armature it is called a "primary" winding and is of low voltage; about 6 volts. Therefore it is called a "low-tension" magneto. If there are two windings on armature it is called a "high-tension" magneto.

Fig. 8: the "inductor" type of armature: The wire is stationary and the inductors or "rotors" revolve, whereas on the "shuttle" type the armature and wire revolve. The latter type is more generally used.

***The K. W. magneto** is a leading magneto of the inductor type. **Construction;** magnets, permanent type; pole-pieces placed above armature 90° apart; rotors set 90° apart. There are two rotors with 4 ends. Fig. 8 illustrates the arrangement of rotors on armature shaft. This gives the same effect as if two shuttle armatures were placed cross wise—which would be 4 impulses per rev. (fig. 10) instead of 2 in the shuttle type (fig. 9). If we continued adding we would soon have the alternations so close together we could light an electric lamp—in fact, the K. W. low tension magneto at high speeds will accomplish this.

The coil on the K. W. is stationary and rotors revolve. With a single primary winding on coil core it is a low-tension magneto. With two windings, per page 288, fig. 6, is then a high-tension magneto.

Fig. 8A, shows lines of force passing **down** through rotor wing from N pole, then centrally through core over which coil is placed, up rotor to S pole.

Fig. 8B, shows rotors moved in position where lines of force are now passing in reverse direction, which causes a complete reversal of polarity through coil winding. This is **maximum position** and where contact points (P) should separate—see page 296, which is a high-tension type.

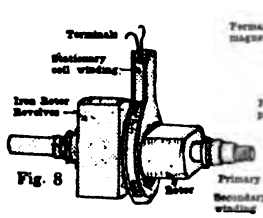

Fig. 8

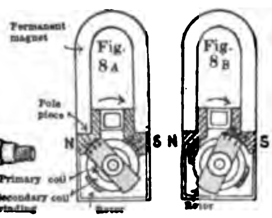

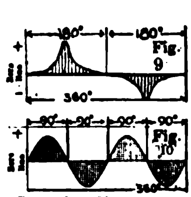

Impulse diagram.

Fig. 9: Shuttle, or "armature" type magneto (see page 274); produces 2 impulses or waves of current of maximum intensity per rev. (360°). Note direction is changed each ½ rev. or 180° (see pages 266, 267).

Fig. 10. The K. W. inductor type armature produces 4 impulses or waves per rev. Note direction of flow of current is changed 4 times or at each ¼ rev. or 90°.

CHART NO. 120—Mechanical Electrical Generators of "Direct" and "Alternating" Current.

*See also pages 264, 288, 296 and 332.

INSTRUCTION No. 21.

*LOW TENSION MAGNETOS: Construction. Parts. Principle. Magneto Action. Explanation of Impulse and Waves of Current. Low Tension Ignition Systems. Inductor Type Low Tension Magneto. Ford Magneto Principle.

We will now take up the "mechanical" source of electric supply for the different ignition systems.

A device for generating electricity mechanically is called a dynamo or magneto. The kind of current the dynamo generates is "direct" current and the magneto generates "alternating" current.

The direct current dynamo generator is usually called a "direct current generator or dynamo" and is usually applied to generators run from the engine which supply current for charging the storage battery, for lighting, also for ignition.

This type of generator can have either "permanent" magnets or "electro magnets" for the magnetic field, but in every instance, the armature is a "drum" wound armature. This type of generator generates a low tension or voltage, usually 6 volts.

The alternating current generator is always called a "magneto," because the field magnets are of the permanent magnet type and the armature is either a "shuttle" or "inductor" type. This type of generator generates nothing but an "alternating" current, suitable only for ignition. Alternating current will not charge a storage battery.

Alternating current generators are divided into two classes; the "low tension magneto" and the "high tension magneto."

We will take up the construction of the low tension magneto first, because the high tension is really a low tension magneto, but with a double winding on the armature. Therefore, starting with the low tension magneto first, it will then be easier to master the principle of the high tension magneto later.

Magneto Construction—Low Tension.

The principle of a low tension magneto is similar in many respects to a low tension coil as described on pages 215 and 214. In a magneto the armature on which the primary wire is wound is called upon to produce its own electric supply, whereas in a primary or low tension coil the electric supply is from another source. See fig. 1, page 260.

Field magnets: Therefore, permanent magnets (1a), called the "field magnets" are provided as shown in fig. 1, chart 121. The pole pieces (11a) provide a magnetic field for the shuttle type armature (fig. 4) to revolve in. End plates with ball bearings are attached to screw holes in pole pieces (11a, fig. 1). There is very little clearance between the armature and the poles, therefore accurate fitting is necessary.

The magnets; usually two, four, or six, are placed over the pole pieces; all north poles on one side and all south poles on the other side. The base (12a, chart 121), is usually made of brass or aluminum, as neither will become magnetized.

The armature is explained in fig. 6, chart 121. This has a single winding of coarse wire (usually about No. 18, insulated), called a "primary" winding similar to the primary winding on a coil.

On a high tension coil system, one end of the primary wire leads to a commutator or timer, and the other end to a battery. When the circuit is closed and suddenly broken the current is "induced" in the secondary winding as previously explained.

On a magneto, the primary winding is closed, and the sudden opening or "interruption" of the flow of current in the primary winding at certain times (see page 267) intensifies the current.

This interruption of current can be accomplished in two ways; by "breaking" the current with an "igniter" suddenly, as in fig. 1, page 260.

Or by "interrupting" the current with a "contact breaker or interrupter" as per fig. 3. Therefore, we have two methods of intensifying the low tension current of a low tension magneto.

The first method is similar in action to snapping two wires together as explained in fig. 6, page 214 and illustrated in fig. 1, page 260. The interruption is made by an igniter, operated by a cam on cam shaft.

The second method is similar in action and is explained in fig. 3, page 260.

It must be borne in mind that the time the interruption takes place is when the armature is in a vertical position, for at that time the strongest current will be available. (explained further on.)

The armature is in a vertical position twice during one revolution, therefore we can make two interruptions during one revolution, by having a "two point" cam raise the interrupter arm at the right time.

If a single cylinder engine, only one nose on cam is needed.

If a four cylinder, four cycle, we need 4 sparks during two revolutions of crank shaft, therefore the cam would have a double nose and would run at the same speed as engine crank shaft.

*This system is now seldom used, but must first be understood before reader can properly understand the high tension magneto.

**All low tension magnetos are not driven at fixed speed. See K. W., page 265.

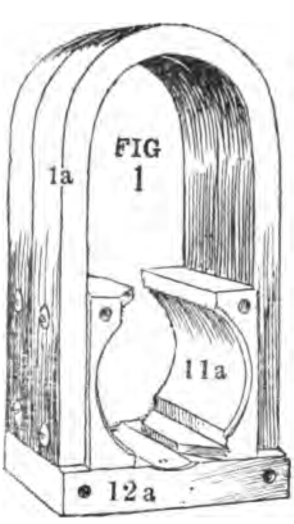

Fig. 1—Permanent magnets (1a); pole pieces (11a); base of brass or aluminum (12a).

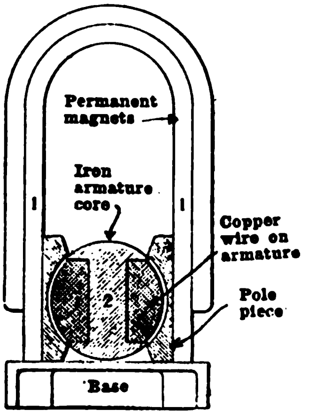

Fig. 2—View of a low tension magneto with the end plate off and armature shown in section.

1—Permanent magnets (magnetized at all times).

2—The armature, revolved by a gear connected with engine shaft.

Note that a single winding of insulated copper wire is wound on the armature.

Fig. 3—The low tension magneto complete. View shows the drive end of the armature, which is driven at a fixed speed from crank shaft of engine, by gear or chains.

The armature has one winding.

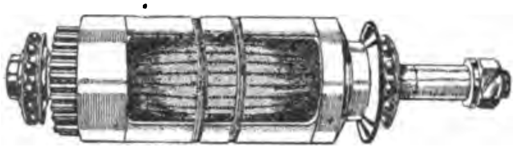

Fig. 4—The low tension magneto armature with a single winding, called the primary winding. The armature revolves between the poles 11a. This type of armature is called a "shuttle" type, also called "armature" type, see page 274.

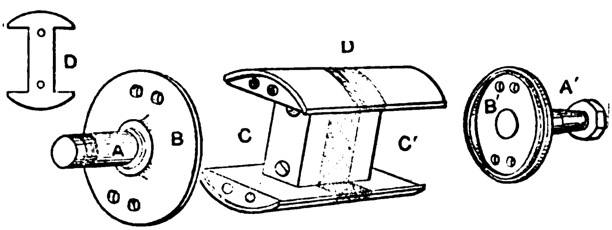

Fig. 6—Parts of the low tension magneto shuttle type armature.

This type of armature is called a "shuttle" or "H" type. Bronze heads (B B') are screwed to the armature core (C and C').

Shafts (AA) are driven and riveted to bronze heads. Wire is wrapped around space (C C'), called the core.

It will be seen that the core is not a solid casting; rather it is a pair of castings between which is clamped a group of soft iron stampings (D), having the form shown in the detail sketch. The object of thus laminating the core, as it is called, is to retard the circulation of "eddy currents" in the core due to induction. The same forces of induction which are at play in the windings, operate also in the iron core itself, and if unchecked would both consume power and heat the armature unduly. As the voltage of these currents is very low, even the slight obstruction of the laminations is sufficient to retard them.

The laminated section of the armature is shown at (D). Laminated means that instead of the castings (C) being solid there are several layers of flat sheet iron placed together, between the cores (C), as shown at (D).

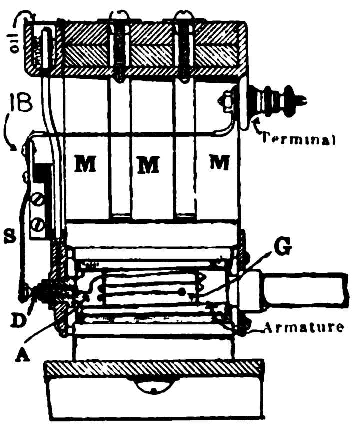

Fig. 5.—Sectional view of a low tension magneto, showing one method of conducting the low tension current from armature; one end of **primary** winding, which is heavy, **coarse wire** is grounded to armature core at (G). The other end (A), is insulated and passes through the hollow end of armature shaft and makes contact with a point (D), (see also fig. 4, page 256).

As the armature revolves, the spring (S), which is mounted on an insulated block (IB), conducts the current through a wire connected with it, to terminal. ("Collector rings," similar to one on the high tension magneto, fig. 1, O and P, page 268, are, also often used.)

From the terminal the current is carried to the "igniter," as per fig. 1, page 260.

It will be noted that a separate low tension coil is not necessary in this instance, as the winding on armature takes its place.

If the low tension magneto is used with a separate high tension coil, as per fig. 3, page 260, then this wire A from armature would go to the primary winding of coil.

CHART NO. 121—Construction of a Low Tension Magneto.

Low Tension Magneto Supplying Current for a "Make and Break" Ignition System.

...ge 217, this system is explained. ...however, was not explained, ...the reader will refer to page ...will principle of the low tension be made clear.

...well to bear in mind that a low tension magneto "used in connection with make and break" system, in fig. 1, page 260, does not require a low tension coil, because the action of intensifying the current as explained in fig. 6 page 214, is obtained by the snapping of the "igniter" points (M), fig. 1, page 260, by action of a cam, and the winding on armature of the low tension magneto takes the place of the low tension coil. By referring to page 257 and fig. 1, 260, other details which are simple, will be made clear.

Low Tension Magneto and High Tension Coil.

The low tension magneto can be used in connection with a high tension coil and produce a "jump-spark" or high tension spark at points of a spark plug in cylinder, by using the low tension magneto to produce the current, and a separate high tension coil (without vibrator) to intensify the low tension current to a high pressure, so that it will jump gap of spark plug.

We would need for this system a high tension coil, a distributor on the magneto to distribute the high tension current to the spark plugs (if a multiple cylinder engine, which in this instance, we will say, is a 4 cycle, 4 cylinder) and an interrupter to break the low tension current at the proper time.

Coil—the double wound high tension coil, similar to the coil explained on page 220, fig. 1, but **without a vibrator** can be used. The interrupter will take the place of the vibrator, therefore we would have a single spark instead of a succession of sparks.

When the contact points separate, as explained under "interrupter," the low tension magneto current is intensified, and "induced" current is set up in the secondary winding as explained on page 220. This coil can be placed separate from magneto as per fig. 3, page 260.

†**Distributor**: this "induced" or high tension current is then distributed to the spark plugs in correct firing order, by distributor rotor and brush per figs. 1, 2, this page.

The distributor is driven at one half the speed of armature (see page 261).

***The interrupter**, see fig. 2, above, and fig. 3, page 260, is mounted on the front end of magneto armature shaft. The housing on which interrupter parts are mounted, can be shifted, by means of a rod (SL) fig. 2. This rod connects with spark lever on steering wheel—see page 294.

Therefore the time for the spark to occur can be made early or "advanced," or late or "retarded." The usual range of advance on a magneto being from 22° to 35°.

Attached to the housing and moving with it, is the interrupter arm (A) and the insulated terminal (B).

On the end of the interrupter arm (A) is a platinum point (P). There is also another platinum point (P) on terminal (B).

Platinum is used because there is more or less sparking occurring at the points and platinum being hard, it stands the spark with less pitting than other metals (see "polarity switch," page 248).

‡The condenser in the coil (explained in fig. 5, page 228), takes up excess sparking to a great exent. Condenser can be placed in the coil box per pages 262, 263, or in the magneto if magneto is a high tension type—per (J), page 268. See also pages 274, 278.

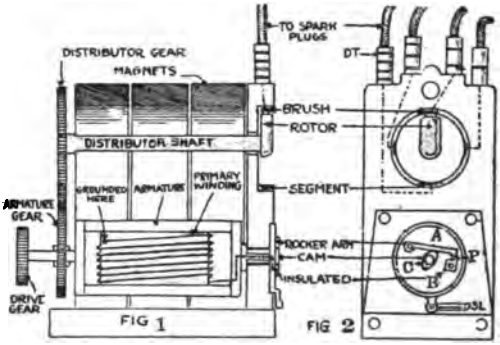

Fig. 1—Note how distributor shaft is driven by gear on armature. Fig. 2—Front view of distributor and interrupter.

The cam (C) is attached to the front end of the armature and revolves with it (see figs. 1 and 2, and fig. 3, page 260).

When the nose of cam (C) raises the interrupter arm (A), the current is interrupted in the primary winding causing the high tension current to be set up in the secondary winding of the coil.

The cam has two lobes, therefore it will raise the interrupter arm twice during one revolution, or four times during two revolutions of armature. Armature would then run at same speed as engine crank shaft. (see page 261). As it is attached to the armature it must revolve with it.

**The cam is set on the armature, so that the nose will raise the interrupter just as the armature passes vertical position.

If the cam raises the interrupter arm (A) when armature is in this position and the interrupter housing is at full retard position, this will then allow for advancing of the spark full 35 degrees or less according to range of magneto. (see page 309.)

The primary circuit on the armature of the low tension magneto consists of a winding of several layers of coarse wire B, fig. 3, page 260. One end is grounded to the armature core and the other end is insulated, and connects with primary winding of coil.

*There are many types of interrupters. One used in this example is simplified to explain the principle. (see page 298.) ‡A condenser, although not shown, is always connected around interrupter points. If low tension magneto, it is in the coil per pages 262, 263. If high tension magneto, it is in the magneto, per pages 268, 274, 278—yet it serves same purpose.

**See also, instruction 24, Ignition Timing. †—by referring to page 262, fig. 23, method of conducting current from a separate coil to distributor arm or rotor, on magneto is shown clearly.

"Make and Break" Low Tension Ignition System; Using a Low Tension Magneto To Supply Electric Current.

Low tension magneto to supply current for the "igniter" as shown in fig. 1 and explained on page 259.

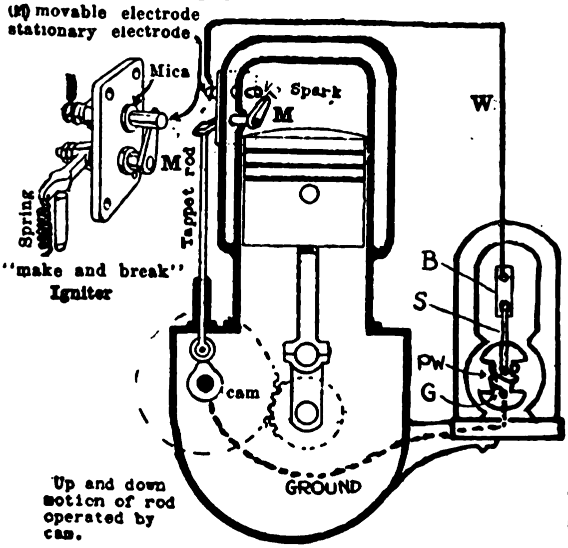

Fig. 1.—One method for intensifying the current from the low tension magneto is to suddenly break the flow of current as explained in fig. 6, page 214. Instead of breaking the flow by hand, however, the make and break type of "igniter" is used. A low tension coil is not used with above system as the winding on magneto takes its place. (see fig. 5, page 258, for names of parts of magneto.)

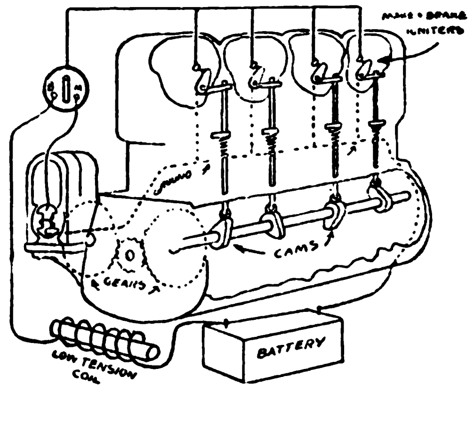

Fig. 2.—The low tension magneto ignition on a multiple cylinder engine. Battery for starting. Magneto armature revolves same speed as crank shaft of engine.

Note that a low tension or single wound coil must be used in the circuit if the battery is used, whereas if magneto is switched on instead of the battery, the winding on the armature acts as a coil instead. Note a cam shaft operates the "make and break" igniters, which govern the time of spark, causing four sparks during one revolution of cam shaft, or two revolutions of crank shaft.

On above system, armature is driven at a fixed speed, because it is of the "shuttle type." The cam snaps the igniter arm (M) when piston is on top of compression stroke. Therefore armature must be in a vertical position, just leaving the pole (see pages 266, 267 and 309). See also pages 257, 259, 261 for relation of speed.

Note—all low tension magnetos are not driven at fixed speed—see K. W., pages 264 and 265.

A "High Tension" Ignition System Using a Low Tension Magneto to Supply Electric Current.

This system is fully explained on page 259. It is similar in many respects to the battery and coil system described under Instruction 19, except a low tension magneto supplies the current instead of a battery, and the *interrupter and distributor are mounted on the magneto instead of being driven separate. The objection to this system is explained on page 261. Also see pages 261 and 259 for relation of speed of armature, distributor and engine crank shaft.

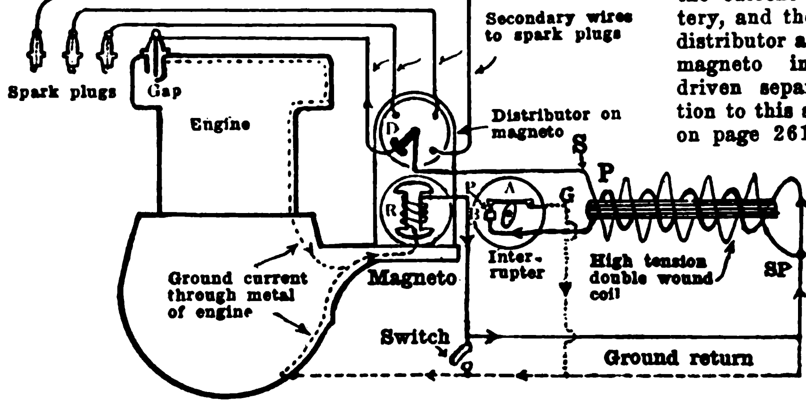

Fig. 3.—Another method for intensifying the current from a low tension magneto, is to use an *interrupter mounted on end of armature shaft and connected with a separate high tension coil, without vibrator. In this instance a high tension current would be provided in secondary winding (S) of coil by current produced from the low tension magneto when primary circuit is interrupted at maximum position of armature.

This system is slightly different from the one shown at bottom of page 268, where the interrupter or contact breaker is shunted across the primary circuit. With above system it is in series.

CHART NO. 122—Two Simplified Methods of Using a Low Tension Magneto. Note in fig. 3, method of short circuiting magneto; switch is closed to cut off magneto.

*The word "interrupter" and "contact-breaker" mean the same.

The armature revolves, therefore the end of the armature primary winding (R), from which the low tension current is taken, is carried through end of armature shaft (insulated), similar to D, fig. 5, page 258, but where an interrupter is on armature it is arranged similar to K, fig. 2. page 270, but not connecting with any other part than the wire from armature. This spring contact conveys the low tension current from armature, which revolves, to primary coil winding P, fig. 3, page 260.

Note arrangement of interrupter on page 270. It is a different construction from fig. 3, page 260. The interrupter on page 270 is more modern. The one used in fig. 3, page 260 is simplified.

The current is then carried through primary winding P, to insulated terminal B, through interrupter points P (which open when armature is in maximum position), to arm A to ground G, back to magneto ground. This completes the primary circuit of magneto and high tension coil.

Trace arrow points from upper primary wire from magneto armature, back to magneto ground for the primary circuit.

The secondary current (fig. 3, page 260), starts at distributor brush (D) to insulated part of spark plug, jumps the gap, thence returns from metal shell of spark plug, to "ground" connection on engine to secondary and primary connection on coil (S-P) through secondary winding (S) back to distributor brush (D).

Magneto switch (fig. 3, page 260) is open when the magneto is working, but to stop the magneto from generating current, the switch is closed or "short circuited." A glance at the illustration will show how the armature is short circuited, therefore "interruption" of current cannot take place—see also page 275.

The magneto must be driven at a fixed speed because the interrupter and position of armature govern the time of spark. Therefore, the magneto is either driven by a chain or a gear from the cam shaft but not by belt, see page 295, "magneto speed."

Magneto Distributor Parts.

***The purpose of the "high tension" distributor** is to distribute the high tension current to the spark plugs. The distributor brush (D) ought to be making contact with one of the spark plug leads just as the interrupter points are breaking. See page 296 explaining connections to distributor.

Distributor is usually attached to the magneto—when operated with a magneto, either of the low or high tension type.

The distributor is usually made of hard rubber insulation material with metal segments (see page 268). The rotor with brush revolves by means of a gear wheel twice the size of gear wheel on armature. (fig. 1, page 259.)

Armature for a four cylinder magneto, would revolve at engine crank shaft speed and make 4 sparks during the two revolutions of the crank shaft.

The distributor however would revolve once and make 4 contacts during two revolutions of the crank shaft—hence reason for larger gear on distributor.

On a six cylinder engine the armature revolves 1½ times to one revolution of crank, but distributor is geared to turn one-half the speed of crank shaft, or one complete revolution to 2 revolutions of engine crank shaft. (see pages 306, 295 and 294.)

There are two kinds of contact arrangements on a distributor; the "gap-type" as explained on pages 247, 245, 312, and the "brush type" as per fig. 2, page 259.

It must be remembered that while we are referring to the magneto distributor of the true "high tension type magneto"—to show the parts of a "high tension distributor"—the distributor used with the low tension magneto and separate coil (page 260, fig. 3), differs only—in that on a true **high tension magneto**—there are two windings on armature which takes the place of the separate coil.

Low Tension Magneto and High Tension Coil With a Battery to Start on.

The system described in chart 122, fig. 3, which uses a low tension magneto in connection with a high tension coil, interrupter and distributor, would not be satisfactory—for the following reasons:

The magneto is a mechanical source of electric supply. In order to produce electric current, it is necessary to revolve the armature. When the armature revolves, current is generated, but if revolved slowly the current is weak. Therefore it is natural to assume that by merely cranking the engine by hand very little current will be generated. For this reason, a battery is provided to start on, as the source of supply is then constant, no matter if engine is cranked slow or fast.

After engine is started, then the switch is placed on the magneto side and the magneto supplies the current to the high tension coil.

This system would then be called a "dual" system. Meaning a dual or second ignition system is added, but using the same set of spark plugs.

There are two ways of using a battery to start on, in connection with a low tension magneto; one method would be to have a separate high tension "vibrator" coil, commutator and battery, as per chart 124.

Another method would be to merely add the battery as per chart 123.

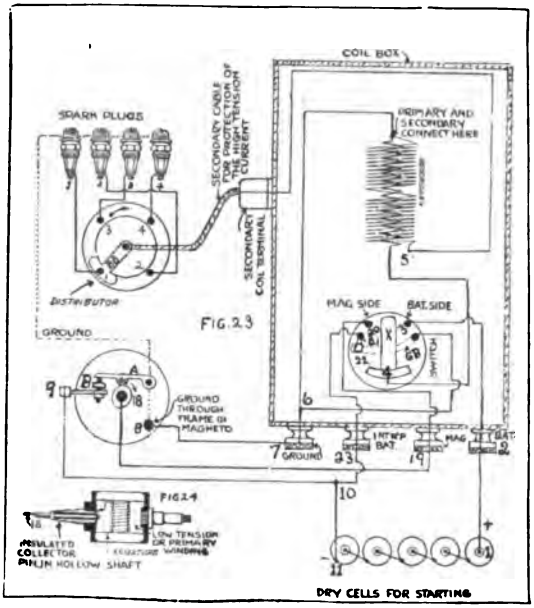
With this latter system, there is but one high tension coil. The only addition to our system first described in fig. 3, chart 122, would merely be a battery.

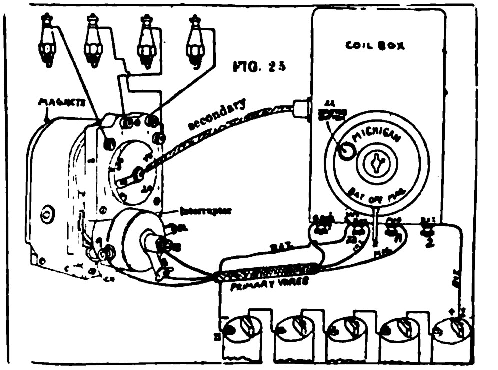
This, of course, would require special connections and be rather complicated, but will be made perfectly clear if reader will refer to chart 123 and study it carefully.

The system described in chart 124, is in reality a true "dual" system, because there are two separate and independent ignition systems, but only one set of spark plugs.

The system shown in chart 123, however, is simpler and was formerly extensively used.

*Note term—"high tension" distributor—although in this instance it is placed on a "low tension" magneto it is used for the same purpose as used on a high tension magneto—page 268—In both instances to distribute high tension current to the spark plugs.





Michigan Low Tension Magneto and High Tension Coil.

The purpose of these illustrations is to show how the interrupter on the magneto can also perform this function for the battery, which has been added to the system. Note that the current from the magneto is connected to contact (19) of the coil box.

We will now briefly outline the path of the current from both sources, and trace them from starting point, all the way through and return, fig. 23.

Battery circuit: When switch blade (X) on coil box is on the battery side, the path of current would be; from the + side of battery, to terminal (2)—then to contact (3) through switch to (4)—then through primary winding (5) to ground connection (6)—thence to ground terminal on coil box (7). From here it leads to wherever the coil is grounded (in the illustration it is shown directly on the magneto, at 8). Now as the interrupter arm (A) is grounded also, it follows that current will flow to it, then through breaker points, then to B, 9, 10 and on to negative terminal (11) of battery.

Magneto circuit: After engine is started the switch is thrown over to magneto side, this cuts out the battery, and current will then be taken from magneto, which is a low tension type.

Beginning at the terminal (18) on magneto, the path leads to terminal (19) on coil box—thence to contact (20-21) through switch (X) to (4) and then follows the same route as the previous current up to ground connection (8). Now since one end of armature coil is grounded, current will flow through it and to starting point.

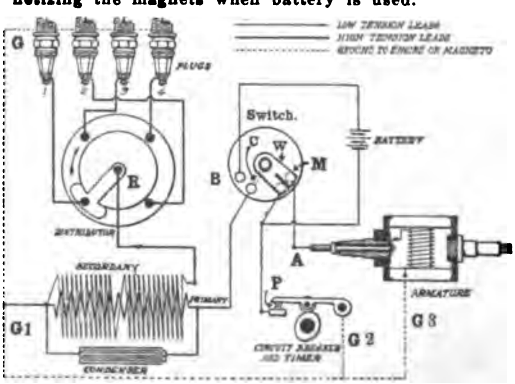
It yet remains to be explained, how the interrupter performs its duty. Notice another contact (21) close to contact (20). Switch lever (X) connects these two contacts and thus opened another path whereby current reaches contact (23) thence through circuit, to (9)—then to contact (B) and breaker points, to (A) whenever the cam is in such position as will allow points to be in contact.

Starting on ignition: Sometimes, the engine can be started by pressing a button on "starter switch," (see fig. 25) a few times in rapid succession. This button is represented in the diagram as (22) and is mounted on a spring tongue, which, when pressed in, makes contact with (GB). The switch will have to be on battery side of course, and current will be made and broken by the pressing in and releasing the starter button. One of the pistons must be in the right position and ready to fire, and most usually is; about seven out of ten times. A charge of gas must also be in that cylinder. A charge of gas, or part of a charge will remain in a cylinder quite a long time if rings are tight and precaution taken to draw in a full charge by opening throttle and speeding engine just before it stops.

The high tension circuit from secondary winding of coil is shown in figs. 23, 25. Condenser, not shown, is connected around interrupter points per page 274, but is in the coil, per below.

Splitdorf Model D Low Tension Magneto and Coil System.

Splitdorf dual system—using a low tension magneto and high tension coil with battery to start on and magneto to run on: The contact breaker on magneto is utilized for either battery or magneto system. The primary circuit through armature however, must be opened to prevent battery from de-magnetizing the magnets when battery is used.



Magneto circuit: from A to switch blade (W), through connection (O) to primary wire of coil, through ground G1 and G3, to armature. The breaker points (P) it will be noted are connected or shunted across the magneto primary circuit. The circuit proper, is through armature and circuit breaker and the coil primary winding receives only the kick of the armature (extra current) when contact points open. It will be noted battery circuit is open at switch.

Battery circuit: switch blade (W) should now be on B side connecting the two terminals, and magneto terminals on (M) side are open. Current travels from top of battery to switch point, to primary winding of coil, to ground G1 to G2, thence through interrupter points (P) to (lower connection) battery. Note armature is cut out entirely but not interrupter.

High tension current is distributed from secondary winding on coil to brush (R) on distributor, thence to spark plug center electrode, thence through spark gap to plug shell ground (G) of engine and frame back to coil where primary and secondary connect.

Condenser, although located in coil, if circuit is traced it will be observed that it "bridges" the points of contact-breaker just the same as on page 274. See page 273 for principle of magneto condenser.

CHART NO. 123—A Low Tension Magneto with a High Tension Coil—with the Addition of a Battery to Supply Current to Start with. After engine is started the magneto supplies the current. (Michigan System formerly used on Regal). **Splitdorf Dual System.**

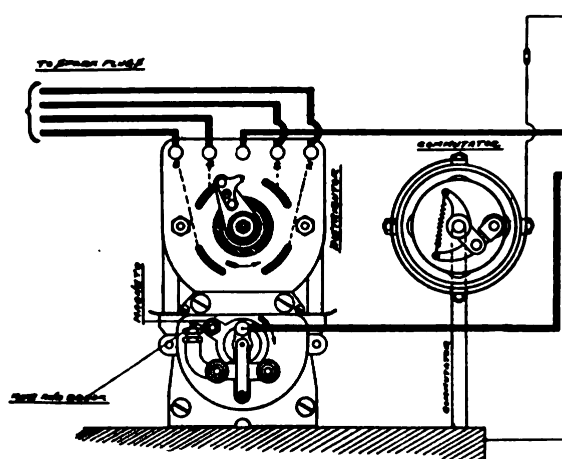


Fig. 1. "Shuttle" type magneto, with a single "primary" winding or low tension armature. Distributor, distributes current for the "coil system" and "magneto system" independently. Note magneto base is grounded to frame.

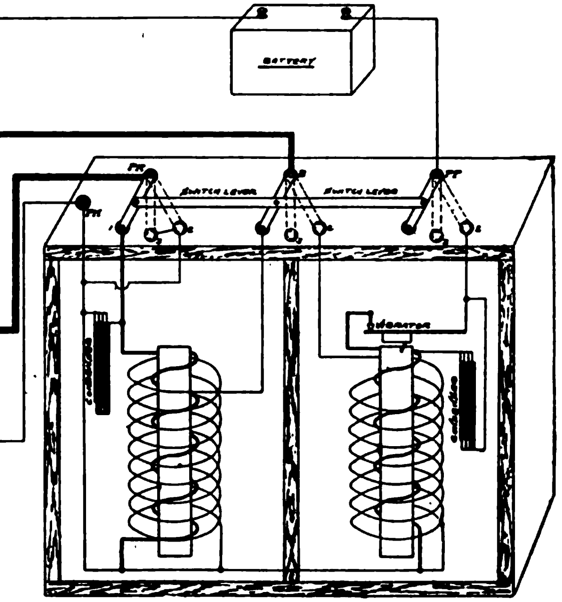

Fig. 2. High tension coil without vibrator, used with the "magneto system."

Fig. 3. High tension coil, with vibrator, used with the "coil and battery" system. Note the commutator is used with this system, but not with the magneto.

This system, the title which is given under this chart, is the system formerly used on older models of the Packard. Although it is out of date, we show same as an example of how a low tension magneto is used in connection with a high tension coil for one system and a high tension coil and battery is used for the second system, thereby forming a "dual system of ignition."

The low tension current from the magneto enters the primary winding of the magneto coil fig. 2, at the post P. R., and leaves it at post P. M., returning to the magneto through the "ground" You will readily see what an important part the wire connecting post P. M. with the screw on the rear cylinder has to perform. It is the common path for all of the current of both systems.

The high tension current thus induced in the secondary winding of the magneto coil (fig. 2), follows exactly the same path as described in connection with the high tension battery current from post "B" through the distributor arm and plate of the magneto to the respective spark plugs, and back again to the magneto coil through the "ground" and post P. M.

Whenever the engine is running, the magneto is developing current. It only passes through the magneto coil, however, when the switch is thrown to magneto side. With the switch in any other position the current is grounded without passing through the primary winding.

The interrupter mechanism of the magneto is located at the end of the armature shaft (lettered "make and break") ought to have been lettered "interrupter," as it interrupts the flow of current.

The coil box in the center of the dash contains two coils. Each coil is a complete unit in itself. The right hand coil, fig. 3, is for battery current, and is fitted with a single vibrator. The left hand coil is for magneto current, and has no vibrator.

The switch has three positions. Turn to the right for battery, turn to the left for magneto current, and turn to a vertical position for neutral (no current). On the upper side of coil box are four binding posts:
P. P. brings low tension current from the battery.
P. R. brings low tension current from the magneto.
B. transmits high tension current from both systems.
P. M. is a common ground wire for both kinds of current from both systems.

The low tension current from both the battery and **magneto**, though of good amperage (volume), is low in voltage (pressure). The two coils receive from the battery r magneto their respective low tension currents and deliver currents of high tension.

The battery and coil system: is used for starting the engine, and for reserve. There is a storage battery, which also provides a low tension "direct" current.

The battery current passes through the battery coil, fig. 3, and the contact for this battery and coil is made by a "commutator," operated from the cam shaft. This practically makes two systems of ignition using but one set of spark plugs; therefore, it is called a "dual" system ignition.

The battery and coil primary current; starts at the positive pole of the battery, the current follows the connecting wire to the post on the coil marked P. P. At this point it enters and passes through the primary winding of the battery vibrator coil, fig. 3, coming out again at post marked P. M. and along the connecting wire to the ground connection on engine frame. The only path by which it can return to the battery is through the contact shaft, and roller to one of the binding posts, and by means of the metal connecting strap to the wire running to the negative terminal, the circuit being complete at each time the roller in the contact box passes over one of the metal contact pieces.

The high tension current: Whenever this low tension circuit from the battery is completed, as above described, a high tension circuit is induced in the secondary winding of the battery coil. The high tension current leaves the coil at post "B" to the central post at the top of the distributing plate on the magneto, thence to the distributor brush, which revolves to the left (see fig. 1).

The current then travels through the **distributor** brush to segments, thence to spark plug connected with segment on which the distributor brush makes contact. The secondary current returns from metal shell of spark plug to "ground" and back again through engine frame to post P. M., thence to the battery coil, fig. 3.

The battery current is generated by chemical action, and is ready to flow the instant the circuit is completed. It is, therefore, particularly useful for "starting on." It is only necessary to break the circuit to stop the flow of the current.

The vibrator operates only when the low tension current is passing through the primary winding of the battery coil.

Condenser in coil fig. 2, protects interrupter points of magneto and in fig. 3, protects coil vibrator points, or both.

CHART NO. 124—Example of a "Dual" Ignition System; employing a "vibrator" coil with battery to start on and coil "without vibrator" and low tension "magneto" to run on. The one distributor on magneto distributes the high tension current to the spark plugs.

Note—chart 125 omitted (error in numbering)

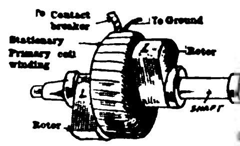

Fig. 1 Inductor Type of Armature.

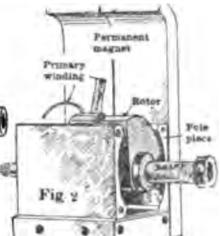

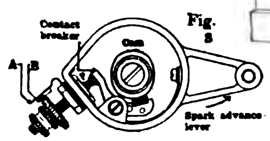

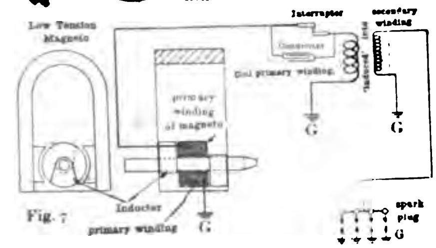

Illustration showing how a high tension coil is used in connection with Remy low tension magneto. (G—ground.)

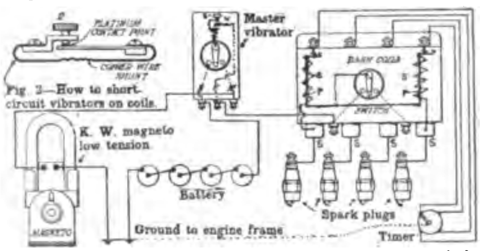

Fig. 4: The K. W. low-tension magneto used in connection with a master-vibrator coil.

The Remy Low-Tension Inductor Type Magneto (Model R L).

The principle is similar to the K. W. fig. 8, page 256, except the Remy rotor is a half-rotor, whereas the K. W., both ends of rotor are utilized. The Remy produces 2 impulses per rev. and the K. W. 4 per rev.

Fig. 1: Remy rotors (L) which revolve and the stationary single primary winding.

Fig. 2: Remy inductor or rotor in maximum position, similar position as fig. 8B, page 256.

Fig. 3: Remy contact-breaker. The points (P) should have a clean surface. Dirt and grease should not be allowed to accumulate.

If engine misses with spark retarded at slow speed, adjust the contact screw (B) out a few notches.

If engine misses with spark advanced at high speed, adjust the contact screw in a few notches.

On above magneto igniton system adjust spark plug points .025".

The contact-breaker is used on this magneto just the same as on a shuttle type magneto armature; to interrupt the flow of current in the primary winding.

To time the armature, place rotors just the same as a shuttle type armature.

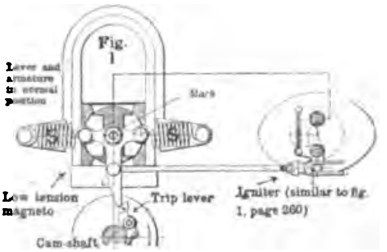
The K. W. Low-Tension Inductor Type Magneto and Master-Vibrator.

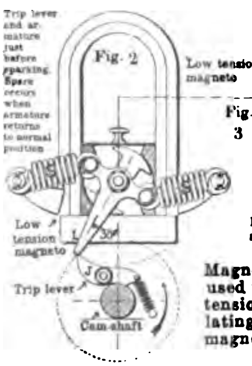
Fig. 4: The K. W. inductor type of low tension magneto, used with a master-vibrator. Dry cells as a source of supply for starting when switch lever is on the left, or (B) side. Magneto is used when switch is on (M) side. See page 280 for "master-vibrator." Also page 256, fig. 8, for inductor type of armature used on this magneto. Notє the vibrators on dash coil are short circuited, per fig. 2, and are not used on the multiple dash coil to the right, as the one vibrator on the master-vibrator coil does the vibrating for the 4 coils—see pages 280 and 265.

The Oscillating Type Magneto.

Figs. 1 & 2: This type is a regular shuttle or armature type magneto and is the original magneto principle, designed for slow speed engines. The armature does not revolve but oscillates back-and-forth from position 1, to 2 (30°).

It can be used with an igniter arangement, fig. 1, which is similar to fig. 1, page 260—except the igniter rod is actuated by lever (L) on magneto, which is tripped by trip (J). It can also be used with a magnetic plug as shown in fig. 2.





Magnetic plug used with low-tension oscillating type magneto.

The Magnetic Plug.

Fig. 5: The principal parts of the magnetic plug are, magnetic coil 5, pole-piece 2, interrupter 20 and contact piece on plug shell 21. Plug is screwed into cylinder. Principle; owing to sudden flow of current through coil (5), the upper portion of hammer bar (1), called the armature, is attracted to pole-piece (2), which effects a quick separation of contacts 20 and 21 producing a spark at these points.

Fig. 4: Illustrates how the magnetic plug is used in connection with a low-tension magneto (type "K4" Bosch) with a revolving armature, with a main and auxiliary winding, one being a continuation of the other, and a distributor for connections to the magneto plugs. This system is termed the Honold system and is for 2, 3, 4, 6 and 8 cylinder engines.

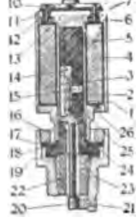


Fig. 5.

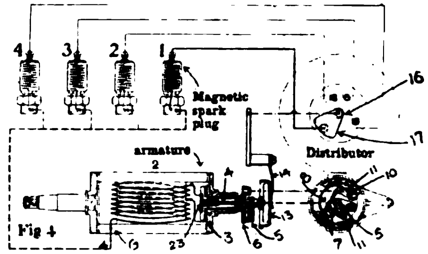

CHART NO. 126—Inductor Type of Low Tension Magnetos; one giving two impulses per revolution, **the other (fig. 4)** giving four impulses per revolution. **The Oscillating Type Magneto. Magnetic Plug.** See page 924 for Remy magneto circuits.

Note—Charts 125, 127 and 128 omitted (error in numbering).

*Low Tension Magneto with "Inductor" Type of Armature.

In the foregoing matter we have dealt entirely with the low tension magneto using a "shuttle" type of armature with its primary winding, all of which revolves between the magnet poles.

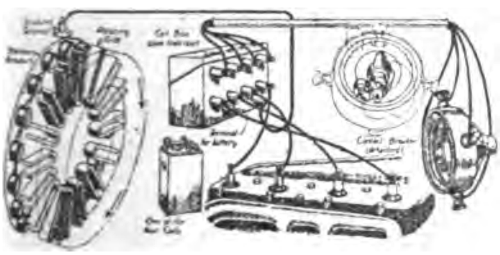
There is another type of armature called the "inductor" type. This armature differs, in that the primary winding, fig. 1, chart 126, remains stationary, whereas, the inductors (L) revolve; principle is explained in chart. This type of armature generates "alternating" current of low tension, and must be connected with an interrupter, when used with a coil. In fact, the same principle is used as with the shuttle type armature. **It gives two impulses per revolution.** The voltage is of low tension or about 6 volts.

Another type of "inductor" armature to that shown in fig. 1, chart 126, is used in the K. W. low tension magnetos. This armature is illustrated in fig. 8, page 256. Note the inductors are similar to the Remy shown in fig. 1, chart 126—except the K. W. uses both ends of rotors, whereas Remy one end, but rotors 180° apart. Instead of the inductors or rotors on the K. W. being placed so that two impulses are given per revolution; note the position and method the inductors are arranged. With this arrangement, the inductor cheek would break from the pole of magnets every quarter revolution. Therefore, there would be four positions when the current would read maximum, or **four impulses or sparks per revolution** (figs. 9 and 10, page 256). The voltage of primary winding is about 6 or 8 volts.

This type of magneto is shown connected to a "master vibrator coil" system as per fig. 4, chart 126. The speed of this armature is about 3,000 revolutions per minute. **It is not geared at a fixed speed as the** shuttle type armature, but because it gives twice the number of impulses per revolution, and by running it at a very high rate of speed, generates an alternating current, the changes taking place so rapidly, it is almost continuous. ‡**This is one type of alternating current generator which would light lamps** and operate with a vibrator coil, but it would not recharge a storage battery. A storage battery can only be charged with a true continuous or "direct" current.

‡The Ford Magneto—an "Inductor" Type.

Another form of a low tension magneto with an "inductor" type armature is the Ford magneto. The Ford magneto generates a low voltage also, of about 6 volts or slightly more, owing to the speed.** The current generated is "alternating."



This is also called an inductor type of armature because the coils of wire called the "stationary armature," remain stationary and the inductors or magnets called the "rotating field" revolve.

Instead of there being two impulses per revolution, there are **sixteen impulses per revolution,** because there are sixteen coils and sixteen inductors or magnets.

In other words, each revolution of the fly wheel, to which the magnets are attached, means one revolution of the crank shaft. **There are 16 positions of the magneto when the current output is at its maximum height** and each of these positions is called the peak of the current wave. **There are, also, 16 positions during which no current is flowing at all.** Each of these is called the neutral position and each is half way between two peaks. Therefore, every sixteenth of a revolution of the magneto a position is reached when no current is being generated and are termed "dead points."

Each alternate peak is of an opposite polarity; that is, there are 8 positions in each revolution when the current flowing from the magneto winding to the spark coil is positive and between these positions are 8 other positions when the current is negative.

Relation of the Low Tension and High Tension Magneto.

We have now dealt with practically all of the low tension types of magnetos in general use. The true form of low tension magneto from which we will produce a high tension magneto, is the type using the "shuttle" armature. which revolves between horse shoe type, permanent magnets.

The high tension magneto which will be treated in instruction No. 22, is merely a modification of the above mentioned "shuttle" type armature magneto.

*Note—These systems are now seldom used for automobile work, but are shown in order to give the reader the information and to bring out the less understood points.

**See the Ford Supplement pages 805 and 770, for "relation of speed of Ford magneto to voltage generated." ‡The Ford inductor type magneto will light lamps and supply current for a vibrator type coil, but voltage varies considerably. The Ford magneto will not charge a storage battery, because the current generated is alternating. A rectifier is shown on page 809, which could be used with a Ford magneto, but is not altogether practical.

Magneto Principle of Operation.

As previously stated a low tension magneto can supply current for a separate high tension coil, or a low tension "make and break" ignition system.*

The low tension magneto has but one winding on the armature called the primary winding. A high tension magneto has two windings on the armature, a primary and a secondary winding, therefore when it is used, the high tension coil is dispensed with entirely. The high tension magneto is treated in the next instruction. Our explanation here, of magneto principle will be confined to the low tension magneto.

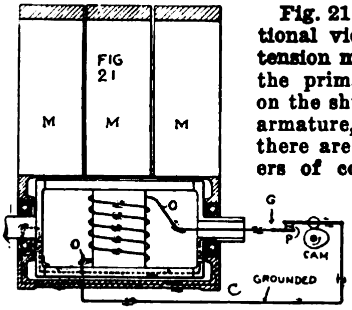


Fig. 21 shows a sectional view of a low tension magento, O is the primary winding on the shuttle type of armature, of which there are several layers of coarse copper insulated wire (only one layer shown). This wire connects with a contact-breaker P and G. This contact-breaker would be in the form of an igniter (M) per page 260, fig. 1 and inside of the cylinder—if of the "make and break" system and a true low tension ignition system and part of the circuit would be grounded.

If system consisted of a low tension magneto and high tension coil, per fig. 3, page 260, then the contact-breaker G & P above would be mounted on end of armature shaft and the circuit would be opened at the correct time, producing a spark, by a cam on end of armature shaft. The two circuits of above systems can be traced on page 260.

The circuit of a magneto system is a closed circuit, that is, the primary winding is closed and the circuit opened by the cam only at the correct time, which is just as the armature passes vertical position, at which time the greatest energy exists in the circuit, called **maximum** position.

With magneto ignition, current is generated and stored in the winding during the time it is closed. When this storage limit has been reached the interrupter opens the closed circuit and the stored energy is transmitted to igniter points or primary of high tension coil—in a similar manner as the holding a water hose closed and releasing it suddenly—the pressure is greatest just as it is opened.

In other words the spark is produced by the change from closed circuit to open circuit when the contact-breaker is opened by the cam. This break is made very quick and in order to get the hottest spark at the points of spark plugs or igniter, the opening should occur when armature is in maximum position. If the opening occurs earlier or later than maximum, then the intensity of spark is weaker (see page 309).

The correct time for the contact points to separate and open the circuit and produce the hottest spark, is when armature is just passing vertical position, or armature cheek or face has just broken away from the pole tips, as shown in e, fig. 7, page 267.

If you turn an armature by hand in direction of rotation, you would find that there is a very strong magnetic pull to armature just as the armature cheek breaks from the pole tip, or about 1/16 in., which at this instant, the contact points (P) should separate and at this time the spark is at its best or maximum strength—(see foot note bottom page 309).

Impulses.

****With the average shuttle type armature magneto the maximum position is reached twice during one revolution of armature,** which times are called †**impulses.**

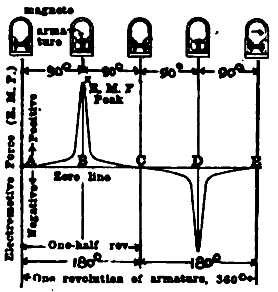

Fig. 20 Voltage Wave

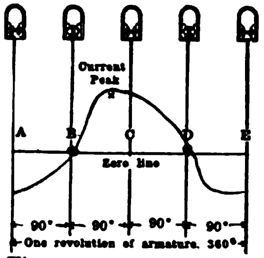

Fig. 30 Current Wave

For example, referring to fig. 20, note armature is in a horizontal position and the ‡E. M. F. (electro-motive-force) is at zero. When armature travels 90° or ¼ turn in direction of rotation, it is in a vertical position and technically this is the maximum position and where contact-breaker points should separate. Note the E. M. F. has reached its highest peak.

But owing to the fact that the circuit is a closed circuit in which current is flowing, the inductance of the coil and the armature reaction of coil combined produce a hindering effect that produces a more even change of flux and makes maximum position of armature occur a few degrees later.

The illustration fig. 20, shows the open circuit **voltage** wave under ideal conditions, whereas the **current** wave fig. 30, would be broad and flat, which allows for more **sparking range**. **The beginning of this sparking range** comes **after** the armature cheek separates from the tips of the pole pieces, therefore is strongest just as the armature cheek breaks from the pole tips.

Note voltage polarity changes at A and C, fig. 20, whereas the current polarity changes at B and D, fig. 30.

Two Sparks Per Revolution.

Alternating current is produced because, during each revolution of armature 360°, there is generated and stored in the primary winding of the armature two electrical impulses in **opposite directions.**

For instance, from horizontal position (fig. 20), to horizontal position again, armature has turned ½ revolution or 180°—the voltage (e. m. f.) polarity is in a **positive** direction. During the next 180° or ½ rev. it is in a **negative** direction. Therefore during one revolution of 360° the direction is changed twice and two maximum sparks can be produced.

*It would appear as if the "make and break" system would be the simplest, which it is, but movable contact points in cylinders exposed to intensity of the heat soon gets out of adjustment.

**On some magnetos for 8 & 12 cylinder aero engines the pole pieces are arranged so that 4 maximum positions are reached per revolution—see page 922. The K. W. magneto, page 256 also produces 4 maximum positions or sparks per revolution. ‡Refers to voltage, see page 207.

†The word impulse is also used in connection with the ignition of gas in cylinder; for instance, when the explosion takes place in cylinder the piston receives an "impulse."

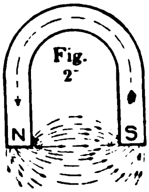
The cam: As the change takes place twice during one revolution of the armature it is necessary that a two point cam be used on the contact-breaker in order to break contact twice during one revolution—see pages 257, 259 and 261.

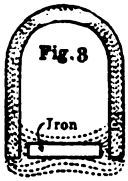
To set the magneto: As stated, the point at which the armature cheek is just breaking from the pole is the correct position to set the magneto armature—and at the same time the interrupter points should just separate—both operations should occur at the same instant. (see page 309.)

Advancing and retarding: These cams made of steel are in a casing, and by having this casing made so that it can be moved through say, the one-tenth part of a circle—the time of the interruption of current can be advanced or retarded with relation to movement of armature. This means the spark will occur early or late, relative to movement of pistons. (see page 309.)

How Current is Produced.

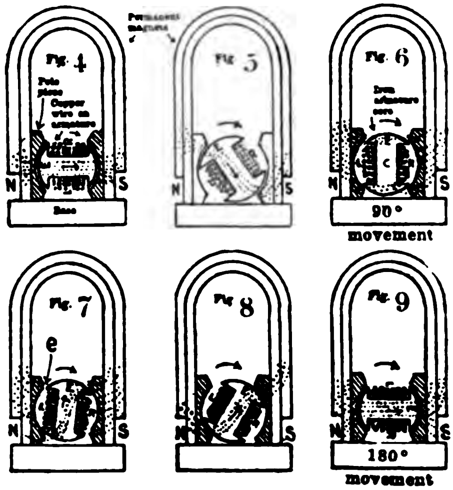
A permanent magnet is made of hard steel and retains its magnetism* Its magnetic influence extends from one pole to the other, which is called the magnetic field as shown in fig. 2.





The magnetic lines of force always flow N into S pole. If a bar of iron be placed between the poles (N&S), or in the magnetic field, fig. 3, the magnetic lines of force will travel freely through the iron, it will be an easier path, because the air gap between poles offer 280 times the resistance as does iron. The magnetic lines will also be greatly increased.

Therefore a soft iron armature core, curved, so it will revolve freely but as close as possible to the pole pieces (soft iron also), is placed between the pole pieces of the permanent magnets. A coil of insulated copper wire is then wound on the H section of armature core—see fig. 4.



Cutting Lines of Force.

If a piece of copper wire in the form of a closed loop, is moved down quickly past the pole of a magnet, it will cut the lines of force down and a momentary current is generated in the wire, flowing say, from T to S, and if connected to a galvanometer (G), needle will be deflected to one side, from zero.

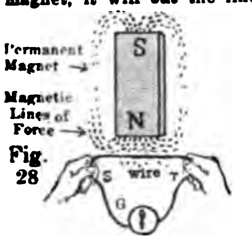


Fig. 28

If wire is moved up, cuting lines of force up, another momentary current will be generated in the wire but in an opposite direction, from S to T, and needle will be deflected to the opposite side of zero.

The momentary induced current is greatest when wire is moved so as to cut the magnetic lines of force at right angles—applying this principle to the coil of wire on magneto, the coil would be cutting the greatest number of lines of force when in position 6 to 7—or when it is moving at right angles to the lines of force.

The electric current in the wire depends upon the E. M. F. (electro-motive-force) causing it to flow—therefore E. M. F. is generated in wire when it is made to cut the lines of force, and a current flows when it is complete, due to the generated E. M. F. The faster the coil cuts the lines—greater will be the E. M. F. generated.

The generated E. M. F. also depends upon the strength or quantity of magnetic lines of force; the speed or rate of lines cut per second; the number of wires cutting the lines—therefore several layers of wire are used on the armature.

Referring to fig. 4, the coil is not cutting any of the lines of force—the lines are passing freely through armature core from N to S—therefore e. m. f. (voltage) strength is at zero.

Fig. 5: The L side of coil is starting to cut the lines of force up, and right side of coil (R) is cutting down—E. M. F. is gradually increasing in coil. Lines flowing down through core N to S.

Figs. 6, 7: In this position the coil is cutting the greatest number of lines at right angles—the lines have followed an easier path and are passing through the ends of armature core—none through center or through coil—the generation of energy has reached its maximum and is stored in the wire—the actual †flux in the core is now at zero. The thing that is most important is, not the amount of flux that is flowing through the coil at any instant that is of importance to the generation of current, but rate at which this flux is made to pass from one path to the other as it changes from out of coil into it again. Therefore from position 6, when all flux is out of core or center of coil, to position 7, when the flux starts to pass through core or coil in an opposite direction (fig. 7) represents the greatest rate of change and is the time for the contact points to open, at which time, is the practical maximum position.

Fig. 8; the lines of force (flux) are now passing through armature in a reverse direction to what it did in fig. 5, but voltage polarity is still same direction, because the L & R side of coil is still cutting lines of force in the same direction—but as coil is cutting a less number of lines, the e. m. f. weakens as it travels to zero position again.

Fig. 9: Armature has turned ½ revolution. No lines are being cut, voltage (e. m. f.) strength is at zero, but current still exists without generation—due to the storage capabilities of the armature windings. For instance, if we consider the magneto as a sort of pump and reservoir on **short circuit**, we can see why the reservoir can be full even though the pump has stopped.

The reader must bear in mind that **there are** two phenomena in connection with the magneto; one is the voltage peak or maximum voltage fig. 20, and the other is the current peak or maximum current fig. 30. These two peaks are not in unison. The current peak lags behind the voltage peak as much as 90°, when armature gets up to speed. This is the reason why there is a strong current flow even though the voltage wave is at zero. As armature moves from position fig. 9, the same cutting proceeds as before, but as the R and L side of coil will now cut lines in an opposite direction, the voltage polarity will be in opposite direction for the next half revolution.

***A permanent magnet will retain its magnetism** a long time if a keeper is kept on ends of poles—see page 303. The armature on a magneto, when in a horizontal position acts as a keeper—see page 302.

An electro magnet is a magnet consisting of an iron core around which is wrapped wire. When direct current is passed through wire the iron core becomes a magnet—if flowing in one direction. Soft iron cores are used, as it quickly loses its magnetism when current ceases flowing.

†**Magnetic flux** is the total number of lines of force flowing through a magnetic circuit.

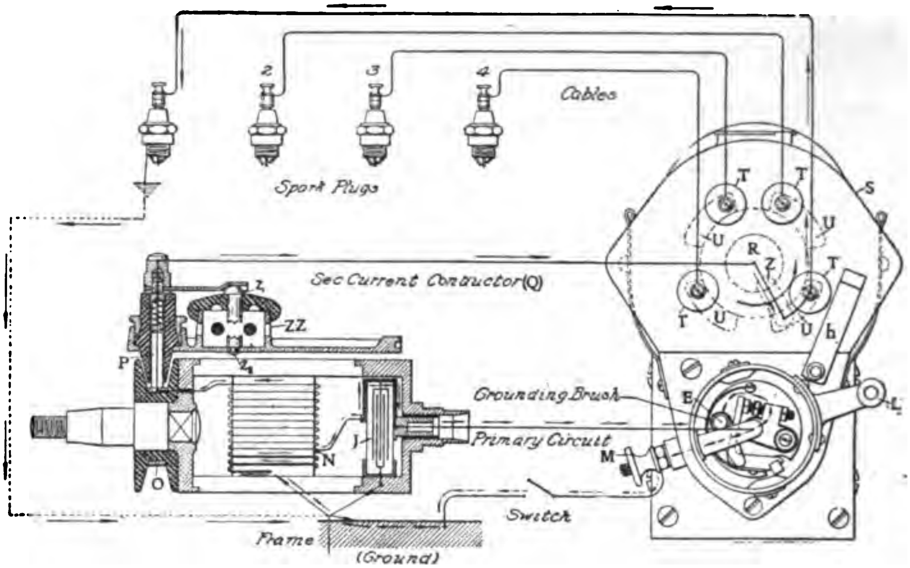

Fig. 1—Diagram of Connections of a High Tension Magneto.

Names of Principal Parts.

SW—Secondary winding of wire over the PW primary winding.

O—Collector ring. P—Brush carrying high tension current to the base of distributer (R).

The current is then distributed to the four plugs through distributer arm, (Z) to the terminals (T).

ZZ—is the spark gap. J—Condenser. S—is insulated base of distributer.

See Chart 130 for other parts, cross section of which can be seen in Fig. 2, this Chart.

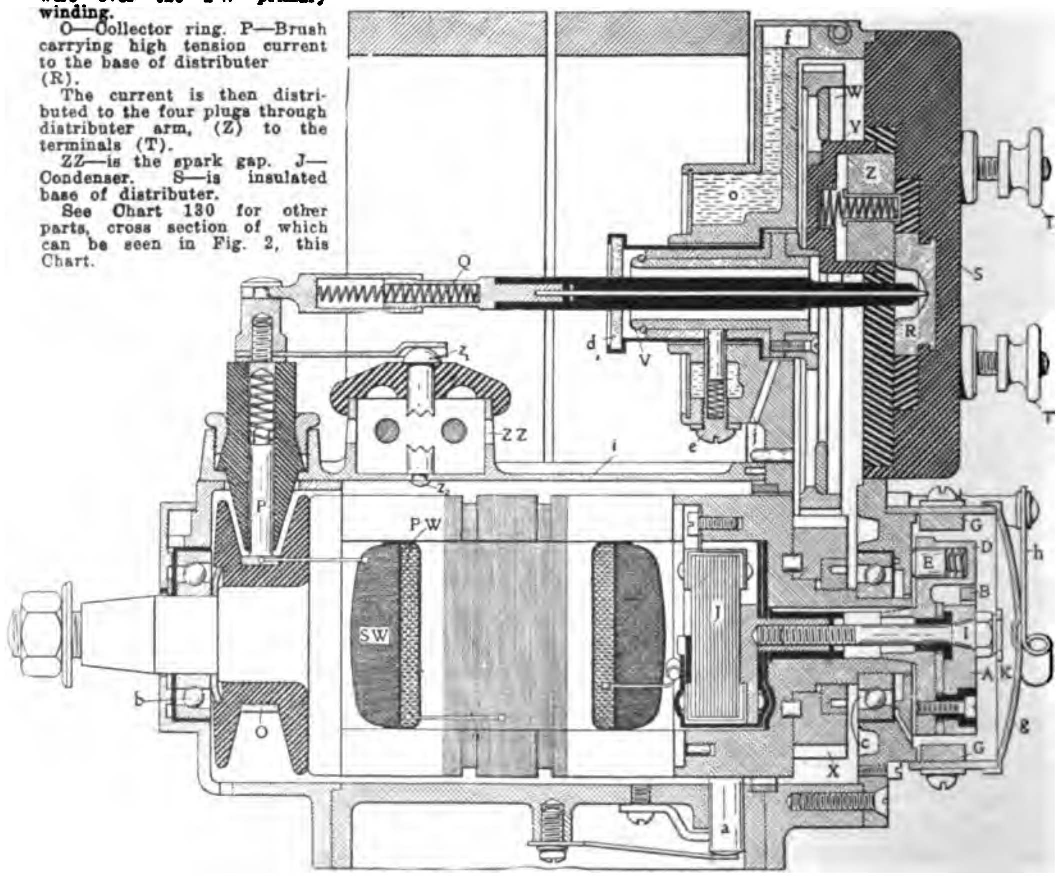

Fig. 2—Longitudinal Section Through High Tension Magneto.

CHART NO. 129—Primary and Secondary Circuit of a High Tension Magneto. Armature is known as a compound type, meaning double wound. It revolves with its wire winding.

(Note—The distributor brush (Z) is revolved by a gear (W) which is revolved by a gear (X) on armature. Type DU4 Bosch.)

Charts 127 and 128 omitted (error in numbering).

INSTRUCTION No. 22.

THE HIGH TENSION MAGNETO. Description. Construction. Parts. Combination of Dual and Double Systems. Wiring Diagrams. Leading Magnetos. Four Ignition Systems on one Engine.

Preliminary Description.

The high tension magneto is not only a mechanical generator or a substitute for the battery, but combines all the elements of a complete ignition system, except the plugs and switch.

It performs three separate essential functions as follows; generating current; transforming the current to a high pressure; distributing the high tension current to the individual cylinders. Besides these main functions, a number of minor functions have to be performed. The high tension magneto differs from the low tension magneto in only a few particulars.

Armature winding: The armature on the high tension magneto is wound with an additional winding, called the "secondary winding," whereas the low tension magneto has but one winding called the primary winding.

Instead of using a "separate" high tension coil, this second winding on the armature of the high tension magneto takes its place. (See figs. 1 and 2, chart 129.) This secondary winding is carefully insulated from the primary winding, except at one end, where both it and the primary winding are grounded. (P W) is the primary winding, and (S W) is the secondary winding (fig. 2). One end of (S W) is led, carefully insulated, to a collector ring (O) mounted on the armature shaft, and a carbon pencil or brush (P) rubbing on this collector ring takes off the secondary current and leads it to distributor brush (Z).

The other respect in which this type differs from the low tension magneto in that the condenser which is employed in connection with the interrupter is usually built into the high tension magneto (J fig. 2) whereas with the low tension magneto, the condenser is in the separate high tension coil. The condenser is usually, though not necessarily located on the armature shaft in order to get it as close to the interrupter as possible, and it is there shown in fig. 1, chart 129 (J). In some magnetos, for the sake of greater accessibility and other reasons, the condenser is located outside the armature in a stationary sealed box.

The purpose of a condenser in explained in chart 109.

Owing to the fact that the secondary coil of the high tension magneto is located on the armature itself it follows that it not only receives an induced current, due to the breakage of the primary current, but itself induces a current like that of the primary coil, but smaller in volume.

It has the same form of armature, field magnets and principle of interrupter as the low tension magneto, but varied construction. The armature-coil, however, is different, having a primary winding with a secondary winding over it.

*Construction.

The high tension collector ring (O) performs for the high tension current the same function that the spring (S) at the end of the armature shaft in fig. 5, page 258, does for a low tension current. That is, in this instance, it conducts the high tension current from armature to the distributor.

The collector ring is hard rubber with a brass ferrule (O) surrounding it, against which ferrule a heavily insulated stationary carbon pencil (P) bears. The hard rubber spool has wide flanges for the purpose of preventing the high tension current from escaping, by giving it a long path to travel from the brass contact ring to the shaft. As hard rubber is much more resistant than air, the current tends to travel over the surface of the spool instead of striking through it.

****The distributor:** It has already been explained how the high tension current is induced in the secondary or fine wire winding of the armature at the moment the current ceases in the primary winding. It remains to explain how this high tension current is distributed to the four spark plugs of a four cylinder engine in succession.

The beginning of the secondary winding (S W) (figs. 1 and 2, chart 129) is connected to the end of the primary winding at (N), and since one end of the primary winding is grounded, the secondary is also grounded through the primary. The end of the secondary winding leads to an insulated contact ring (O), fig. 2, at the driving end of the magneto.

From this ring the current is taken off by a carbon contact brush (P). From the brush

*For example of a high tension magneto, the Bosch, type DU4 as shown in charts 129 and 130 is used.

**This type of distributor is the "brush" type, as it makes a wiping contact. The "gap-type" is shown in the Berling, page 312, and explained on page 247.

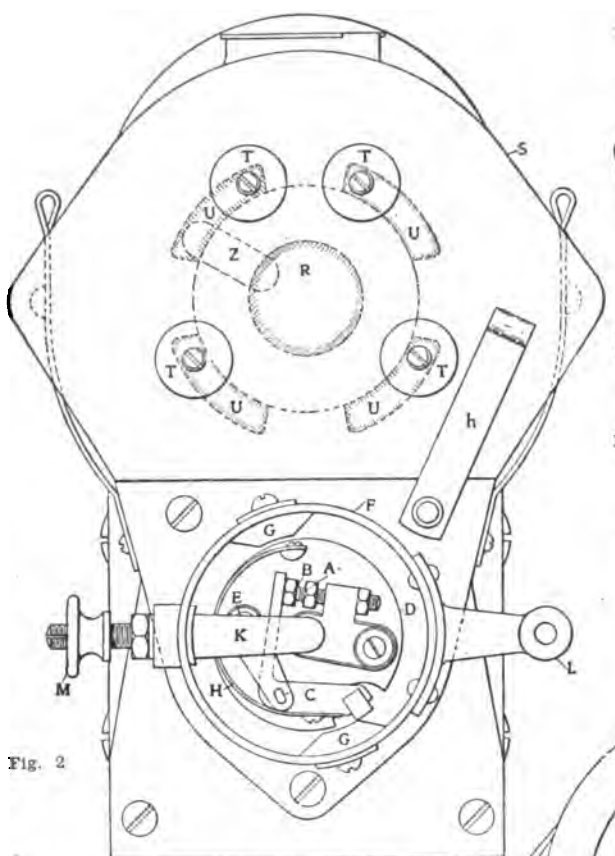

Fig. 2

Fig. 1

Fig. 1 Bosch "DU4" high-tension magneto for a 4 cyl. engine. Note single magnets. Type "DU6" is the same except for a 6 cyl. engine. Type "D4" has 3 bar magnets; Type "DR4", 2 bar magnets.

Fig. 2. Front View of Bosch "DU4" magneto.

Interrupter Parts.

A—Platinum point on insulated contact-breaker block which connects with one end of primary winding.
B—Platinum point on grounded breaker arm C.
C—Contact-breaker arm; platinum point at one end and lug at other end which comes in contact with cam G as C revolves.
D—Brass disc fastened to armature shaft and rotates with it. A, B and C are fastened to this disc and revolve with it, but A is insulated from D, while B and C are grounded to it.
E—Carbon brush grounds D to magneto frame.
F—Cylindrical breaker-box housing which can be shifted by L, to advance or retard.
G—Cam blocks which cause arm C to separate points at A and B.
H—Spring keeps points A and B closed until seperated by G.
K—Connects with A, or one end of primary and connects with terminal M (insulated).
M—Connects with switch as shown in fig. 1, page 268. Other side of switch is grounded. When switch is closed magneto is "off". See page 275 "to cut off magneto."
h—Spring for holding cover in place.

Distributor Parts.

T—Terminal to spark plugs.
Z—Distributor brush connecting with R.
R—Connects with pencil brush P on collector ring O, through contact conductor Q, as per page 268, fig. 2.
U—Segments or contact pieces connected with terminals (T) on which brush (Z) slides.

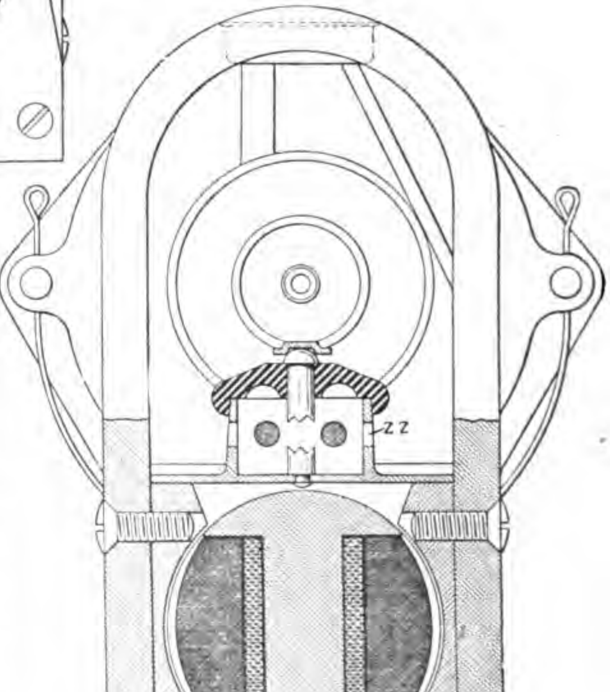

Fig. 3. Rear Sectional View. Note safety-spark-gap ZZ—see also, fig. 1 and 2, page 268. Note pole-pieces screwed to end of field magnets. The dark shaded part on armature represents secondary winding; light shading, primary winding.

CHART NO. 130—Names and Location of Parts of a High Tension Magneto. (Bosch.)

holder the current is carried through a spring contact conductor (Q) to the central distributor contact (R).

The distributor consists of a disc of insulating material (S), in which are imbedded on the inner side one central cylindrical contact-piece (R) and four annular sector-shaped contact pieces (U U U U, fig. 1, chart 129).

The distributor also comprises a shaft (V, fig. 2), which carries a gear wheel (W) meshing with a pinion (X) on the armature shaft. The gear wheel (W) has twice the number of teeth as the pinion, and the distributor shaft (V) therefore makes one turn while the armature makes two.

Distributor speed: The reason for driving the distributor at one-half the armature speed is as follows: The armature as already stated, turns at the speed of the engine crank shaft. The magneto here described is for a four cylinder, four cycle engine. In such an engine each cylinder requires a spark once in two revolutions of the crank shaft.

The distributor is therefore geared so that it makes one revolution to two revolutions of the crank shaft and establishes connection between the high tension or secondary winding of the armature and the spark plug to each cylinder once in every two revolutions of the crank shaft.

The gear wheel (W) carries a brush holder (Y) containing a carbon brush (Z), which is adapted to make contact simultaneously with the central distributor contact (R), and with one of the annular distributor contacts (U).**

The distributor sectors (U) are surrounded at the inside and outside by annular rings of a highly insulating material, since they carry the high tension current.

Each of the four annular contact segments (U) has secured to it a binding post (T) on the face of the distributor disc, and each of these binding posts is connected by a high tension (highly insulated) cable to one of the spark plugs.

There are numerous methods of taking the current from the secondary winding on the armature, but in the Bosch a carbon brush pressing on an insulated ring is adopted, thus allowing the armature to rotate freely, and also enabling the induced current to be drawn off.

The distributor is, in effect, a rotary switch, especially insulated and provided with a number of contacts equivalent to the number of cylinders on the engine.

Magnets and pole pieces: In any standard magneto made on this principle the general construction would be as follows: The field magnets consist of two—or usually three—pairs. One magnet of each pair being superimposed above the others. (See fig. 3, chart 131.)

In some few cases three magnets are placed one over the other. The magnets are set to give correct north and south polarity. All north poles on one side and all south poles on the other side.

The ends or poles embrace "pole pieces" of soft iron bored out to allow the armature to rotate quite freely, but very closely to the pole faces; in some cases the clearance is only .002 inch.

The armature: Consists of an armature core of soft iron of H-shaped cross section; also referred to as a shuttle armature. This core of soft iron serves to form a bridge for the magnetic flux between the pole shoes, and also to carry the winding in which the current is induced.

The armature is, in practically every standard type of the well-known "shuttle" type. The best class machines have the armature built up of thin stampings of soft iron, each insulated from the other by a thin film of varnish. This form of construction is known as a "laminated armature core." A laminated armature core is shown in fig. 6, chart 121, and a complete armature wound with double winding is shown in fig. 1, chart 131. It has the advantage over a solid cast-iron core in that the electrical efficiency is higher through the absence of "eddy" currents in the iron core which represent considerable waste of energy and cause heating.

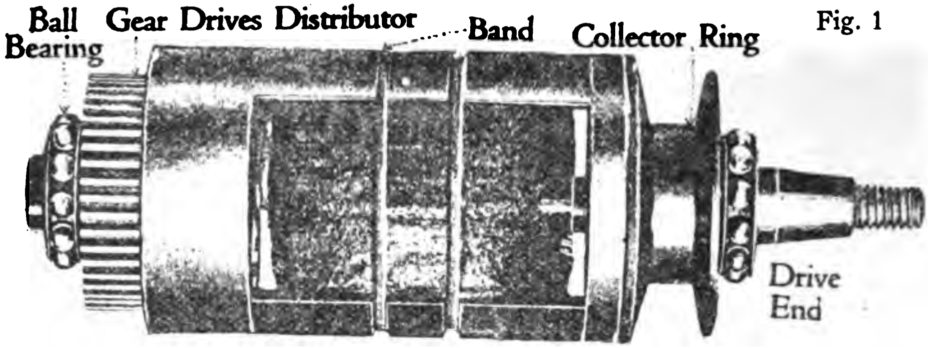
By breaking up the core into thin sections, the currents cannot circulate through the iron, (spoken of as "eddy currents.") In the case of a solid core, the iron would be annealed to render it as "soft" as possible, to obtain the best magnetic effect.

Armature winding: The armature core is first insulated with mica or similar material. Then it has several layers of heavy insulated wire wound upon it. To the end of this heavy wire is connected the beginning of a very fine wire (No. 36 or 40)* insulated with silk, which is wound on the core until the slot is filled almost to the height of the cylindrical portion, after which a wrapping of insulating cloth is applied, and bands are put around the circumference of the armature to prevent the wire and insulating material from flying out and coming in contact with the pole shoes when the armature is rotated at high speed. To the ends of the armature the steel shaft or spindle is fixed by brass end plates. (See fig. 6, chart 121.)

It will thus be noted that there are really two windings on the armature whereas the low tension magneto has but one winding —an inner winding of relatively few turns of heavy wire, and an outer winding of a large number of turns of fine wire.

*The winding of a Bosch DU-4 magneto usually consists of 8 layers of No. 21 insulated primary wire and 70 to 72 layers of No. 36 silk covered secondary wire.

**See foot note bottom of page 269.



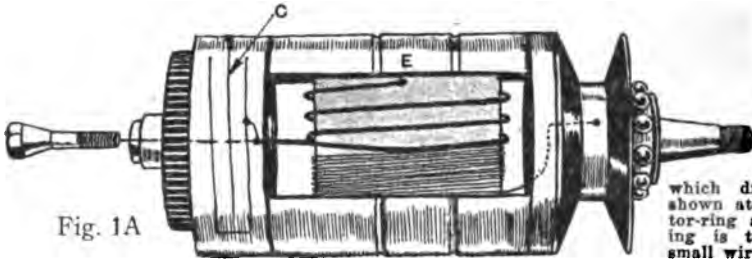


Fig. 1. Exact size of a double-wound high-tension compound armature. It is similar to the low tension armature, fig. 4, page 258, except the low tension armature is single-wound. The gear which drives the distributor is shown at one end and the collector-ring at the other end. Winding is taped and shellaced and small wire bands placed around it.

Fig. 1A. Interior view of above armature, reduced in size. E—one end of primary winding grounded. The other end of primary winding connects with condenser C (note one end of condenser is grounded, see also page 268), thence the primary winding leads to the insulated screw. This screw connects with the insulated breaker-point (A) and with switch connections (K) and (M), fig. 2, page 270. See bottom of page 278 explaining the primary circuit. One end of secondary winding connects to collector ring. Other end grounded to primary wire.

Fig. 2—Photographic view of the circuit-breaker or interrupter, on the opposite end to collector ring. Same type as shown in fig. 2, page 270, except interrupter arm above revolves clock-wise and fig. 2, page 268 revolves anti-clockwise.

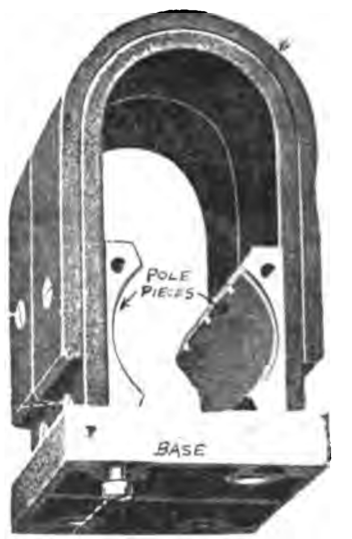

Fig. 3—The horse-shoe magnets, pole pieces, etc., are the same principle as used on a low tension magneto.

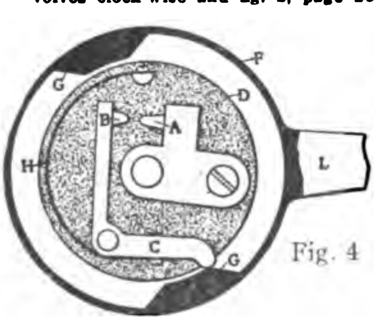

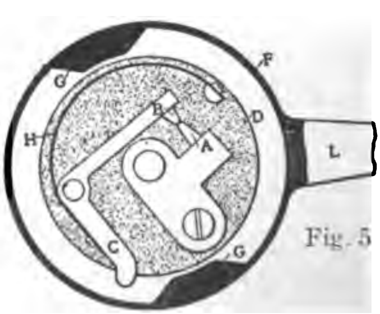

Fig. 4. Circuit open on interrupter. This is the time the spark occurs. Note C raised by cam G.

Fig. 5. Circuit closed on interrupter. Note C has passed over G. See page 273 for explanation of interrupter. A, B, C and D revolve (Anti-clockwise). F and G are stationary.

CHART NO. 131—Parts of a High Tension Magneto. Compound Wound Armature. **Magneto Interrupter or Circuit-Breaker. Magnet Structure.**

The winding of heavy wire, or primary winding, serves primarily for generating the current, and in connection with the fine wire or secondary winding, it also serves for multiplying the pressure or voltage to such an extent that it will produce a spark at the gap of the spark plug in the cylinder. **Types of armatures** are shown in chart 132.

The interrupter, also called a "contact breaker." To accomplish this breaking of the primary circuit at the proper moment and then closing it again, a device known as a circuit breaker or interrupter is used. This is carried on the armature shaft opposite the driving end.

It consists essentially of a stationary insulated contact point (A), (see fig. 4, chart 131) and a movable contact point (B) on one arm of the bell crank (C). Both of these parts are mounted on a brass disc. (D), which is securely fastened to the armature shaft and rotates with it.

The stationary contact (A) is insulated from the supporting disc (D), while the movable contact (B) is in metallic connection with it, and the disc (D) is grounded to the frame of the magneto by a carbon brush (E). (See fig. 2, chart 129.)

The circuit breaker is surrounded by a cylindrical housing (F), to the interior surface of which, at diametrically opposite points, are secured steel cam blocks (G & G.)

Ordinarily the two contact points (A and B) are kept in contact by a spring (H). As the disc (D) rotates, the outer arm of the bell crank (C) comes in contact with the cam blocks (G), whereby the contact points (A and B) are separated momentarily.* (Fig. 4, chart 131.)

As soon as the end of the bell crank (C) passes cam block (G) the spring (H) brings the two contact points (A and B) together again. (Fig. 5, chart 131.)

The stationary contact block (A) is connected with one end of the primary winding of the armature, through a screw passing through the center of the armature shaft. (See (I) fig. 2, chart 129.)

The other end of the primary winding has metallic connection with the armature core; in other words, it is grounded.

It will now be readily understood how the current flows through the primary circuit (fig. 1, chart 129). Originating in the primary winding (P W, fig. 2) on the armature, it flows through the contact breaker screw (I) to the stationary contact (A), thence across to the movable contact (B), from which it is led through the contact brush (E), into the metallic framework of the magneto, whence it returns to the beginning of the primary winding, which is also connected or grounded to the frame. (Study fig. 1, chart 129.)

****Condenser principle:** When the two contact points (A and B) are suddenly separated there is a tendency for the current to continue to flow across the gap, it possessing a property similar to the inertia of matter. This would result in a hot spark being formed between the contact points, which not only would burn the points away rapidly, but also would prevent a rapid cessation of the current, which as already explained, is necessary in order to effect a rapid change in the lines of magnetic force through the armature and a high inductive effect in the secondary winding. To obviate this effect a condenser (J, figs. 1 and 2, chart 129) is employed, which in the Bosch magneto is placed in a hollow of the armature end cover at the circuit breaker end, also see chart 132.

Condenser construction: This condenser consists of two sets of tinfoil sheets, sheets of opposite sets alternating with one another, and being separated by sheets of insulating material. All the sheets of each set are metallically connected, and one set is connected to the conductor leading from the primary winding to the stationary contact point (A), while the other set is grounded. In other words, the condenser is **shunted across the interrupter.** See fig. 1, chart 129 and fig. 5, chart 109.

Such a condenser is capable of absorbing an electrical charge, and its capacity is so proportioned that it will take up the entire charge of the extra current produced when the contact points (A and B) separate; that is, the extra current, instead of appearing in the form of a spark across the gap between A and B, passes into the condenser (J). In this way the objectional arcing or burning at the contact points is avoided and the current flow in the primary circuit is more quickly stopped.

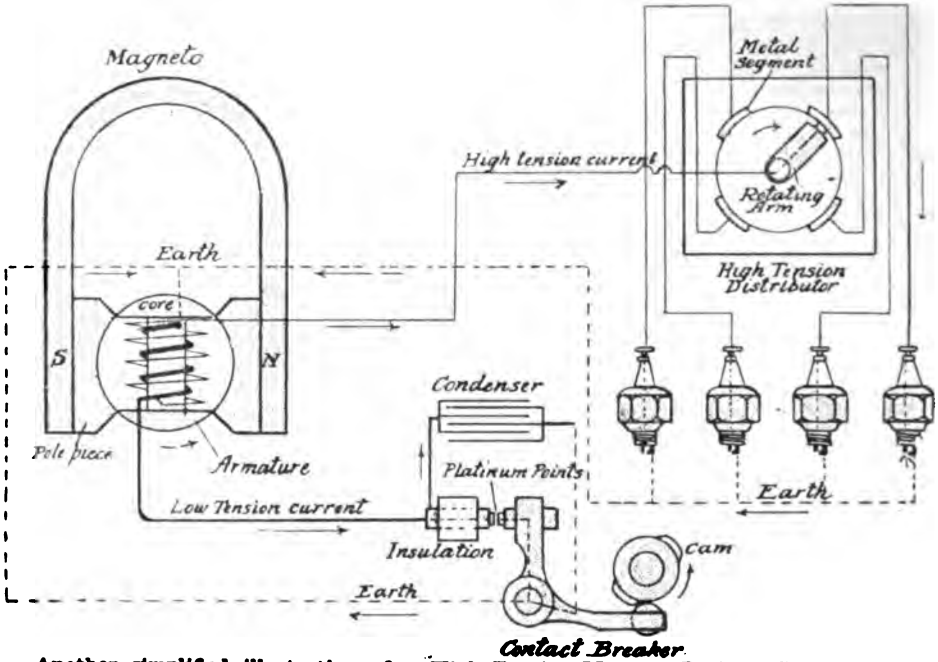
†**The safety spark gap principle:** There remains but one point to describe, and that is the safety spark gap (see Z & ZZ, fig. 2, chart 129). This is practically a safety valve for the high tension current. If, for example, a wire became detached from the sparking plug or from the distributor so that the ordinary path of high tension current was barred, there would be considerable danger of the current forcing a circuit through the insulation of the armature, and thus doing very considerable damage were it not given some easier escape as provided by the safety gap.

A magneto must be so designed that it will give a sufficiently hot spark at a comparatively low engine speed, and the ability to do this implies the ability of generating very large and hot sparks and enormously high tension at high engine speed.

The actual electro-motive force or tension produced in the secondary winding is, however, **limited by the size of the spark gap in the spark plug,** for as soon as the ten-

*The breaker points on the Bosch are usually set .016 in. gap, spark plug gap .020" to .025".

**The condenser increases the volume of spark about ten times—see also page 229. See page 303, testing a magneto condenser. †See also, pages 299, 291.



Another simplified illustration of a High Tension Magneto Ignition System, showing the circuit of the primary wire winding on the armature and its connection with the interrupter. Note the condenser is "shunted" across the interrupter. Another view shows the distributor and spark plugs and connections. Dotted lines represent the earth or ground connection to frame.

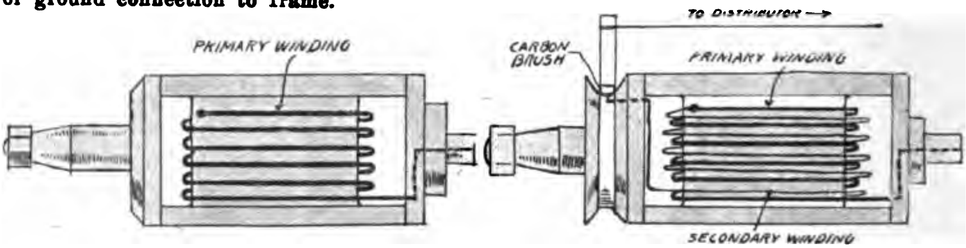


Fig. 2. Primary Armature, Single Wound. Fig. 3. Compound Armature, Double Wound.

Magneto armatures may be classified in two groups, according to the basic principles employed in the magneto field to generate the initial electrical impulses. These are known as the ARMATURE type and the INDUCTOR type.

Armature type.—Electrical current is generated in the armature type magneto by revolving several thousand feet of fine copper wire, which is wound around a soft iron core, between the pole pieces of the magneto. As the winding rotates within its narrow confines, electrical impulses are set up within the winding.

The armature type magneto may be redivided into two classes. One is called the PRIMARY ARMATURE magneto, and the other is called the COMPOUND ARMATURE type.

The primary armature type has but a SINGLE winding in the magneto field and generates a low voltage current and is described in Chart 120 as the LOW TENSION MAGNETO.

The compound armature type is the DOUBLE wound armature described previously (Chart 131) as the HIGH TENSION, DOUBLE WOUND ARMATURE TYPE OF MAGNETO.

The inductor type of armature is a little different from the armature previously described. This type consists of revolving a solid steel shaft, upon which are mounted two steel, fan-shaped inductor wings, within a stationary winding in the magneto field. (Chart 126.)

In this type the wire does not revolve or move as it does in the armature on the magnetos previously described. The fan-shaped wings and shaft revolve, while the wire remains stationary.

This type of magneto requires a separate high tension coil (transformer), which is placed separate from the magneto, as shown in Chart 123; therefore it would be called a low tension magneto with a separate high tension coil.

The type of magneto using the inductor type armature is the REMY and K. W. make.

CHART NO. 132—Another Diagram of a High Tension Magneto Circuit. Magneto Armatures.

sion reaches a point sufficient to jump this gap the discharge occurs, and there is no further increase in the electro-motive force.

*Suppose however, that the terminals of the spark plug are by chance bent unduly far apart, or that one of the high tension connections to the spark plug accidentally comes loose, then there would be no chance for the spark to pass in the ordinary way and the electro-motive force in the secondary winding might build up to such an extent as to puncture the insulation of the winding which would ruin the armature. To avoid this the safety spark gap is provided.

Safety spark gap construction: It consists of a little chamber formed on top of the armature cover plate with a top of insulating material. Into the top and bottom of this chamber, spark terminals (Z1, Z2) are set.

The spark terminal in the bottom is, of course, grounded, and that in the insulated top is connected with a high tension contact brush (P) by a strip connector.

The gap between the two terminals (Z1, Z2) is longer than the gap between the spark plugs and ordinarily no spark will pass between these terminals, but if owing to the conditions already mentioned, no spark can pass at the regular spark plug and the electro-motive force in the secondary winding attains an abnormal value, a discharge will occur at the safety spark gap, thereby preventing the secondary electro-motive force from rising still higher.

Miscellaneous Details of Construction.

Some of the mechanical details of the magneto may be seen in charts 129 and 130, which are three actual views of the Bosch model DU4. It will be observed that a spring-pressed contact brush (a, fig. 2, chart 129, extreme bottom) is placed in the base of the magneto bearing against the circumference of one armature end plate. The object of this contact brush is to make absolutely sure that the revolving metallic parts of the magneto are at all times in good metallic connection with the stationary part and the frame of the car; in this construction, therefore, the armature bearings carry no current.

The armature shaft is mounted in annular ball bearings (fig. 2, chart 129) (b and e), which are provided with oil guards so that any lubricant supplied to them will not be easily lost or reach the insulating parts. The armature tunnel is closed on top by an aluminum cover (i) and the front of the circuit breaker housing is provided with a brass cover (g), which is held in place by means of a hinged flat spring (h), so it can be removed and replaced.

The distributor shaft is mounted in a plain bronze bushed bearing, which is lubricated by means of a wick oiler (e). A felt washer (d) encloses the inner end of the bearing, while at the distributor end is provided a channel (j) for the escape of any oil working out of the bearing so it will not reach the distributor. A large size oil well (o) is provided for the wick oiler and is closed by a hinged cover (f) on top.

A number of other illustrations are also shown of the Bosch DU4 magneto, in chart 130 and 131, which may aid those not familiar with mechanical drawings to grasp the arrangement of parts.

So far as the above description of the individual parts and their functions is concerned, that applies to any true high tension magneto, that is, a magneto having both a low tension and a high tension winding on the armature.

Each of the elements here described is always present, and serves the purpose indicated, though the relative location of the parts varies somewhat.

To Out-off the Magneto Ignition—The Switch.

It is necessary to be able to stop the **magneto** from producing sparks when it is desired to stop the engine. (See fig. 2, page 270). To this end a sheet metal strip (K) is provided which contacts with the stationary contact point (A) of the circuit breaker and leads to a binding post (M) on the circuit breaker housing. From this binding post a wire is carried to a switch on the dashboard. One side of this switch is grounded.

When the switch is closed the current generated in the primary winding of the armature flows to contact point (A), thence through strip (K), binding post (M), and connecting wire to the switch, whence it passes through a wire into the framework of the car and returns to the beginning of the primary winding. The effect of this is that the primary winding is "short circuited" all the time and the opening and closing of the contact points (A and B) have no effect. In technical terms, the circuit breaker is cut out.

The flow of the primary current can easily be followed in the diagram of connections (fig. 1, page 268) where its direction when the magneto is working regularly is indicated by full arrows, and its return path when the magneto is running but not producing sparks, is indicated by dotted arrows.

*Relation of spark plug gap to engine compression: Assuming we have a 4 cylinder magneto, the "safety gap" of which is set at ⅜" corresponding to 8000 volts, which also corresponds to the voltage required to fire a spark plug having a gap .025" under a pressure of 65 lbs. If this magneto was required to fire an engine where there was a higher compression of 85 to 90 lbs., even if the mixture represented slightly lower resistance, it would probably fail to fire and instead, would jump across at the safety gap (see Z1 and Z2, figs. 1 and 2, page 268). However, a slight reduction of the distance between the spark plug points would lower the effective pressure so that it would operate in the proper manner. On the other hand, if the engine had low compression, the spark plug points should be opened up, but if too wide, this would immediately place a greater strain on the spark plug insulation and if the plug carbonized badly it would be apt to flash over. See also, pages 817, 291, 299 and 802.

Spark plug gap and compression: For high compression engines 75 to 80 lbs., set gap .020"; for medium compression engines 65 lbs., set gap .025"; for low compression engines, 55 lbs., set gap .030". See page 627 for compression.

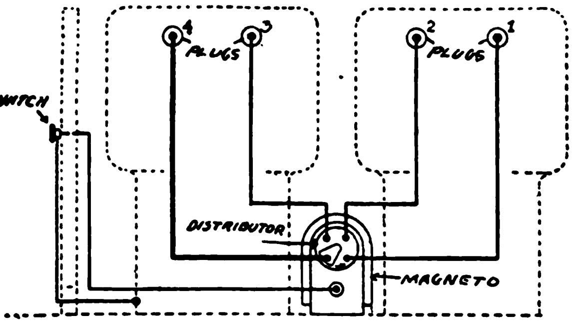

Fig. 1—A "Single" high tension magneto; Engine is started direct from magneto current. Current is distributed to plugs. The switch connects to interrupter on magneto on one end, and "ground" on the other. To stop magneto, the switch is closed, not opened.

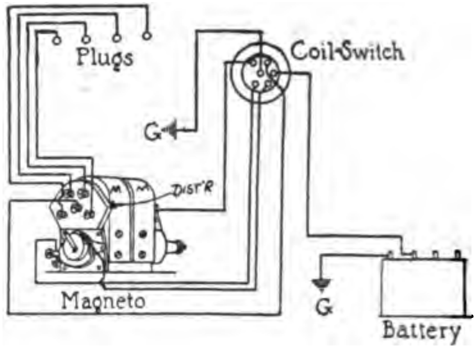

Fig. 2—A "Dual' system of ignition; Either the high tension single coil with battery (using the distributor on magneto) may be used or the high tension magneto alone, may be used. Only one set of spark plugs.

The "Double" system of ignition; high tension magneto and a separate single high tension coil with a separate timer and distributor combined, using a battery.

The positive terminal of the battery is grounded and the negative terminal led to terminal (5) of the stationary switch plate. Switch terminal (1) is then connected with the binding post located on the under side of the timer-distributor (T D). The second binding post on the timer-distributor, which is located on the under side of the timing control arm, is to be grounded.

Switch terminal (2) is connected to the grounding terminal of the magneto.

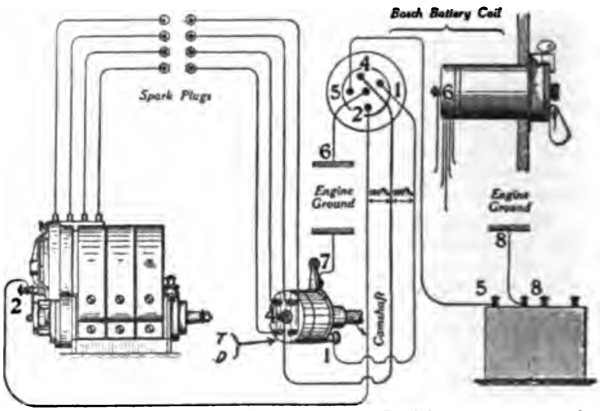

Fig. 3.—Bosch "Double" System of Ignition—two sets of Spark Plugs and two Independent Ignition Systems.

The cover of the Timer-Distributor may then be replaced, but a careful note should be made of the distributor terminal with which the distributor brush is in contact. This distributor terminal should be connected to the proper spark plug of the cylinder with which the distributor of the magneto is in circuit. The remaining distributor contacts should be connected in accordance with the firing order of the engine, and will, of course, be identical with the connections of the magneto. Switch contact (4) is then to be connected to the central contact of the timer-distributor, and this will complete the connections.

When the switch is in the off position, the battery circuit is broken and the magneto is grounded, in consequence of which no sparks will be produced when the motor is cranked.

With the switch thrown to position (B), the magneto will continue grounded, but the battery circuit will be completed, and in consequence, the breaking of the circuit by the timer-distributor will result in the production of a spark that will be transmitted to the proper cylinder by the distributor.

The same condition will exist with the switch thrown to position (MB), except that then the magneto ground circuit will be broken and that magneto sparks will be produced in addition to the battery sparks.

With the switch thrown to position (M), the magneto will operate in the normal manner, and the battery circuit will be broken.

CHART NO. 133—Magneto Wiring Diagram of a High Tension Magneto; "Single," "Dual" and "Double" Ignition System.

Note—The system fig. 3, is known as the "Bosch Battery. Coil and Timer-Distributor" system and is similar to system explained on page 253.

See foot note bottom of page 281.

Examples of Magneto Ignition.

The magneto was extensively used in the past on pleasure or passenger cars, but the high tension "coil and battery" ignition has taken its place for reasons stated on page 255.

The magneto is now extensively used on trucks and tractors for reasons stated on page 255. The truck and tractor engines are seldom equipped with electric starting motors, but are equipped with "magneto ignition" and "impulse starters." In fact, during the war very near every truck in Government use was thus equipped, which eliminated the battery and complication.

Dual Ignition.

Dual system of ignition: Where a car has two ignition systems for instance, a "coil and battery" and independent "magneto," but both systems using **one** set of **spark** plugs—this system is called a "dual" ignition system.

Dual ignition is quite common where magnetos are used, that is, before the advent of the "impulse starter." The idea being to have an auxiliary battery and coil system to start on, and the magneto to run on.

There are two general principles of dual systems, which were formerly used to a great extent; the "**low tension magneto**" and a separate "**high tension coil**" and battery—per pages 262 and 263. The coil and battery were used for starting engine; after starting, the magneto supplied the **current to the coil.**

The other method was by the use of a "**high tension magneto**" and a separate and distinct "**high tension coil**" and battery ignition system. The engine was started on the battery and coil system then switched over to the high tension magneto which was **independent of the coil.**

An example of a dual system using a high tension magneto and separate high tension coil and battery is shown in fig. 2, page 276.

High Tension Magneto Alone.

In fig. 1, page 276, note the high tension magneto supplies current to the four spark plugs on a four cylinder engine.

The armature is double wound; therefore a separate coil is not necessary. The distributor on the magneto distributes the high tension current to the spark plugs.

The disadvantage of this system is in starting, the armature on magneto must be revolved fast enough to generate current before the spark will occur at the plugs. Therefore it is necessary to "spin" the crank. This is not a very satisfactory system unless an "impulse starter" (page 832) is used as explained on page 255 and above.

When equipped with an impulse starter it is a desirable system for trucks, tractors and stationary engines.

Double Ignition.

Double system of ignition: Where two sets of spark plugs are used with two independent ignition systems—this is called a "double" system.

*See also, page 927 and Insert No. 1.

An example of a "double" ignition system using a battery, high tension coil, timer and distributor for one system and a high tension magneto for the other with two spark plugs in each cylinder, is shown on page 276, fig. 3.

Another form of Double System.

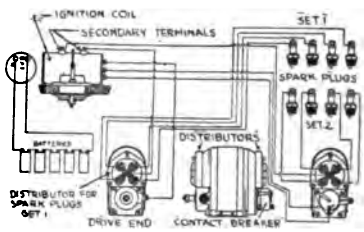
Referring to page 278, note the separate and independent high tension magneto. The coil and battery system is similar to the master vibrator system, explained on page 230. See page 278 for further explanation.

***The Pierce-Arrow engine,** from the time the system on page 278 was discontinued, up to July, 1919, used a "double" system consisting of a high tension magneto with an independent set of spark plugs and a separate coil and battery ignition with another set of spark plugs, or two spark plugs per cylinder per page 276. Either system could be used independently or together. When used together, this insured a very hot spark in the cylinder with result that more power and less gasoline is consumed, as explained below.

The late 1919 Pierce-Arrow uses a Delco battery and coil ignition system, using a "double" timer and distributor and two spark plugs to each cylinder. A generator is used to charge the battery. The magneto has been eliminated.

Two-Spark Ignition System.

The "two-spark" system used in connection with a high tension magneto is explained below on pages 283, 926. Here we have two distributors on the one magneto and two spark plugs are provided for each cylinder. The principle is similar to the "double" system except the one magneto is used.



Remy two-spark magneto.

The advantage of having two spark plugs fire at one time in each cylinder, is to increase power and speed, explained as follows: By referring to page 807 we learn that there is a difference between the time when the spark occurs and the actual time of combustion. Therefore with a weak spark, the time of spark is made to occur earlier, that is, "advanced" before piston reaches top of the compression stroke, in order that it will have time to ignite the gas, combust and expand before piston gets to far down on power stroke. With a "double" system or "two-spark" system, or a good hot spark, this advance of ignition is less, as the combustion is almost instantaneous, consequently, with less advancement of spark, there is less liability of firing back on the piston before it reaches the top of compression stroke and furthermore there is a saving of gasoline, because with a good hot spark all of the gasoline is ignited and used for power instead of part of it passing out the exhaust not fully ignited. In other words a weak spark produces slow combustion and a hot spark quick combustion.

Two-Point Ignition System.

The "two-point" system, where two sparks occur at the same time but in different cylinders, is shown on page 284.

On a four cylinder engine, the spark would occur at two spark plugs at once, but inasmuch as one of the pistons would be on exhaust stroke, this would make no difference.

This system is what would be termed a "double ignition," in that it has two sets of plugs and two independent systems of ignition, coil and magneto.

A synchronized (multiple unit) Autocoil is used in conjunction with the battery system only. The coil case contains six non-vibrator unit coils and a master vibrator. Each non-vibrator unit coil has a test key for locating troublesome plugs and each unit also has a safety gap or telltale device to indicate the accidental opening of the secondary circuit.

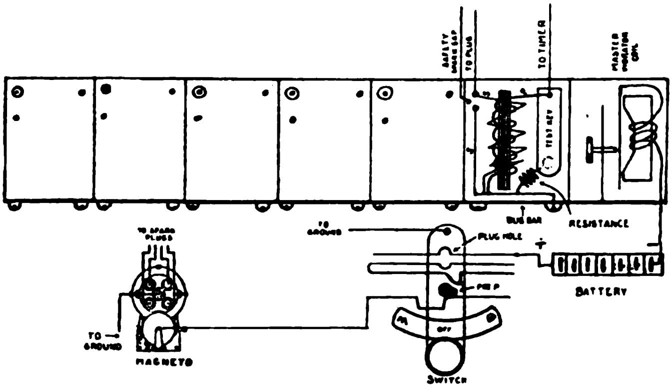


Fig. 1—Diagram of the Coil and Switch.

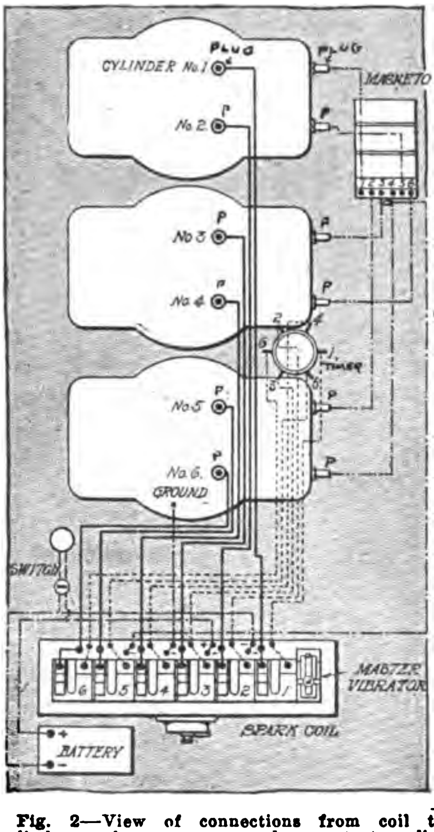

Fig. 2—View of connections from coil to cylinders and commutator, and magneto to cylinders.

When switch lever is in "off" position, magneto is grounded through pin (P) to lever and battery circuit is open. When in (B) position, magneto is still grounded and battery circuit is closed, providing plug has been inserted in switch hole. When in (M) position, magneto is not grounded and battery circuit is open on account of pin (P) being removed from spring above it.

Fig. 1 shows a complete diagrammatic circuit of the switch, master vibrator and one unit. The other five units are identical with the one shown and are connected to the common strap along the front of the case, as shown by the screws in figs. 1 and 3.

The test key is normally open until it is depressed for testing, when it causes the current to flow through the resistance (R) and through the primary. This resistance is arranged so that there is not sufficient current passing through the primary to produce a spark in the secondary circuit; hence when the key is depressed, the spark in that particular cylinder is cut out.

Spark gap—One side of the gap is connected to the high potential side of the secondary winding, the other to the low potential side of the secondary winding. This permits the spark to jump across the gap without doing damage to the internal construction of the coil, if for any reason the wire to the spark plug should become disconnected, or the points of the plug set too far apart.

The low potential (voltage) side of the magneto primary is grounded to the engine frame through the bolts which hold it in place.

The wire marked "To Ground" should run to the frame of the engine.

It is a simple matter to trace the circuit from the battery through the master vibrator, through one of the coil units to the timer, to ground, whence it returns through the ground wire to the switch lever. If it is turned in the (B) position, the magneto will be grounded and the battery circuit complete when plug is inserted in the plug hole.

The coil system being the master vibrator type similar to system explained in chart 110, fig. 1.

The magneto system above is the usual high tension type.

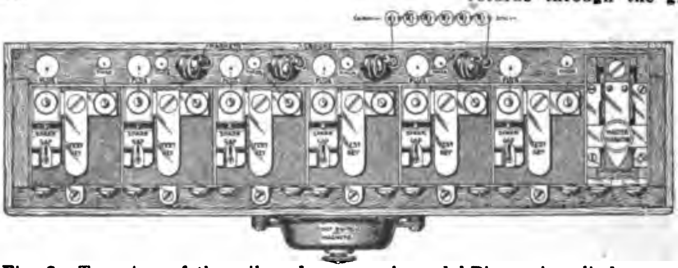

Fig. 3—Top view of the coil used on an early model Pierce six cylinder car.

CHART 133A—Example of a "Double" Ignition System Using a High Tension Magneto and a Multiple Type Coil (formerly used on **Pierce Arrow**—now obsolete—merely shown as example).

See page 349 for Pierce-Arrow electric system used after discontinuing this system, and page 277 explaining system now in use.

Bosch Vibrating Duplex System.

This system is described in chart 137. Its purpose is to assist in starting. Do not confuse this system with an electric system of starting by movement of crank shaft. The principle of this system is to supply a separate battery and vibrating coil to start engine on, doing away with a dual system. See chart 137 for further description.

To Time the Magneto.

Which is a Bosch DU4 or DU6 as an example. First place piston of No. 1 cylinder on top of compression stroke, and with magneto interrupter housing retarded set contact points just starting to break. The driving means can then be coupled up.

The timer distributor, fig. 3 chart 133, should then be revolved (in direction of rotation) until timing interrupter is in the act of breaking.

To Time the Eisemann "G" Types.

With these systems it is merely necessary to bring No. 1 piston to top dead center, rotate the magneto until the setting mark on the distributor is opposite the pointed screw at the top and couple up the drive. Use marks "R" or "L" for right or left hand rotation, respectively, as needed—rotation being judged from driving end. (see page 285.)

Instructions to the Reader.

If the reader will master the purpose and principle of the following, it will then be easy to analyze any system of ignition he may come across. For instance, learn the difference between; low tension coils, high tension coils; low tension magnetos, high tension magnetos.

Other details to classify would be; the difference between the commutator, timer and interrupter, and sources of electric supply, as direct current chemical generators; (dry cells and storage batteries). Direct current, mechanical generators; (dynamos). Alternating current, mechanical generators; (magnetos).

Methods for distributing the secondary current to the spark plugs; by a distributor as used on a magneto, or by a commutator in connection with a vibrator coil. In other worls, very nearly all of the systems compose one or more of the parts of the four principles of ignition.

Difference in Makes of Magnetos.

An inspection of the illustrations of the different leading makes of magnetos shown in chart 141 will give the reader an idea of the variance in construction. In this chart we illustrate magnetos of the low tention type and magnetos of high tension type.

As previously explained, the low tension type of magneto employs an armature wound with only one winding of wire, which is called the **primary** winding. We learned in a previous instruction that when a magneto employs a single primary wound armature, then a transformer (high tension coil) separate and distinct from the magneto, is necessary in order to step up or transform the low tension voltage, (pressure) up to a high pressure.

By referring to chart 141, we find that the Remy and Splitdorf (in the models shown) have **primary** wound armatures and need separate coils or transformers. But going a little further into detail, we find that the Splitdorf, Eisemann, Bosch, Mea and the pivoting magnetos all have armatures which **revolve with the winding** wound on the revolving part.

In the Remy and K. V. we find that the winding does not revolve, but is stationary.

"Armature" and "Inductor" Type; "Primary" and "Compound" Wound Magnetos.

The revolving type of armature, with the wire wound thereon, is called the "armature" type, and the type where the wire is stationary is called the "inductor" type.

If there is only one winding it is called a "**primary**" wound armature. **If there are two windings,** then it is called the "**compound**" **type.** (see chart 132.)

The primary wound armatures are low tension, and require separate coils.

The compound wound armatures are high tension, and do not require separate coils —only as a matter of convenience for easy starting or dual systems of ignition.

We will now go back to the "armature" and the "inductor" type. Up to the present we've shown only the Remy and K. W. with an inductor type of armature, with a single, primary winding.

By referring to the K. W. magneto, in chart 141, we find that the winding on this type is also stationary, but instead of being a single primary winding, as on the Remy, it is a double or compound wound armature like the Bosch, Eisemann and Mea —but differs from the last mentioned in that the winding **does not revolve.**

In the Bosch, Mea, and Eisemann the armature is compound wound and of the "armature" or **revolving type.** The principles of the magnetos are about the same, with some few minor differences in construction.

"Pivoting" or "Rocking" Type Magneto.

The Mea magneto differs in that the magnets can be turned from side to side (called pivoting type); they are bell-shaped, and placed horizontally; therefore, unlike the customary horse shoe type, mounted vertically. In this construction the magnets and breaker are moved simultaneously instead of the advance and retard of contact breaker alone.

—continued on page 287

The Bosch Dual Ignition System.

The parts of this system are shown in fig. 2. This system provides a coil and battery system and a high-tension magneto system, both independent. One set of spark plugs and one distributor on the magneto is used for both systems.

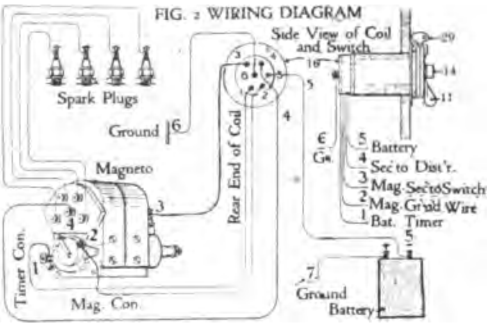

Fig. 2. Wiring diagram of the Bosch DU4 dual ignition system. The DU4 type magneto is fitted with two interrupters as shown in fig. 6a, instead of one interrupter as shown in fig. 2, page 270.

Fig. 6a. The magneto is the regular DU4 high-tension magneto fitted with a separate and independent timer or interrupter for the coil and battery system. This contact-breaker has no electrical connection with the magneto. The second alteration from that of the regular single DU4 high-tension magneto, consists of the removal of the connection (see Q, fig. 2, page 268), which on the ordinary magneto connects the high-tension collector-ring to the distributor; now that the distributor is to do duty for two ignition systems, it is necessary that the current be carried to it through the switch, via wire 4 when the battery and coil system is switched on (see fig. 7, also, fig. 2), or via wire 3 when magneto is switched on (see fig. 6).

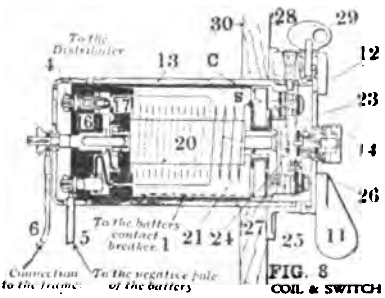

FIG. 8

Fig. 8. The coil and switch is shown above. The coil is a double wound high-tension coil. The switch and coil are mounted on the dash. The switch controls both ignition systems. Note when switch (11) is turned the coil with its core (20) and winding, and end of coil (17) turn also. Switch plate (16) is stationary.

Parts of the switch and coil are as follows: 11, switch handle (also called, kick-switch); **12,** movable switch cover; **13,** coil case; **14, starting press** button; **16,** fixed or stationary switch plate (see also, figs. 16 and 16a); **17,** movable switch plate on rear end of coil (see also, fig. 17a); **20,** iron core of coil over which primary and secondary are wound; **21,** plate carrying the starting arrangement and condenser; **C,** condenser. Note primary winding connects to it at S; **23,** contact spring; **24,** trembler blade also called vibrator blade; **25, 26,** auxiliary contact-breaker; **27,** trembler or vibrator spring; **28,** screw holding switch plate to coil; **29,** locking key; **30,** dash board or cowl.

Fig. 8A. Front view of switch. M, magneto side; B, battery side.

Fig. 8B. Side view of switch and coil case.

Fig. 17A. Rear movable switch-plate with bus-bars and connections (Z) on end of coil.

Fig. 16A. Inner side of stationary switch-plate showing connections 1, 2 3, 4, 5 and 6 which make contact with connections (Z, fig. 17A) when switch is turned to B or M side.

Fig. 16. Rear end view of switch-plate (16, fig. 8) showing terminals to which wires are connected as shown in fig. 2.

Starting Engine.

The engine is usually started by switch being placed on the B or battery side. The interrupter (1) on magneto being used for the primary winding on coil and the distributor on magneto being used to distribute the high-tension current to the spark plugs. Otherwise the magneto has no connection with the battery and coil ignition system when switch is on the B side.

In order to start engine with the starting handle (or electric starter, if one is provided) the press-button (14, fig. 2 and 8) is pressed down and then turned at right angles, a process which locks it in position for the trembler spark.

The engine can also be started on the switch or "**ignition,**" as it is often termed. The switch is turned to B side and then the brass press-button (14) is pressed down. Often times this will start engine, if cylinder has a charge of gas in it. If not, then it will be necessary to crank engine after locking press-button as explained above.

To explain this ignition starting feature, see fig. 9. The 6 volt storage battery (or 10 dry cells) is supposed to be switched on (B, side).

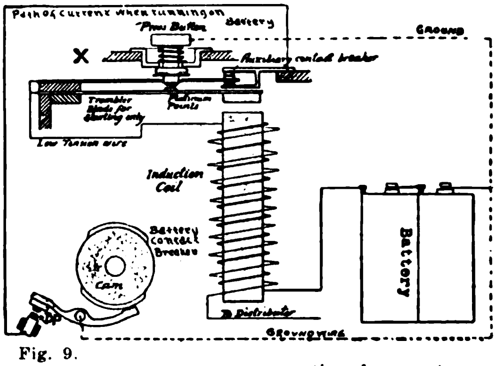

Fig. 9.

—continued on next page.

CHART NO. 134—Bosch Dual Ignition System—continued in charts 135 and 136.
Wiring connections from distributor to spark plugs are not in regular firing order. Main purpose of diagram is to show Switch Circuits.

—continued from page 280.

Starting from the left hand storage battery terminal (to make it easier to understand), the current passes through the primary winding and arrives at the end of the trembler blade and the blade above, called the auxiliary contact breaker. The current cannot travel beyond the trembler blade because, as will be seen, the platinum points are separated. Neither can it complete circuit along the auxiliary contact breaker blade because the main contact breaker (left hand lower corner) also stands open, being the position in which the contact breaker always comes to rest when the engine stops, save for the few occasions when the engine stops with the piston about dead center.

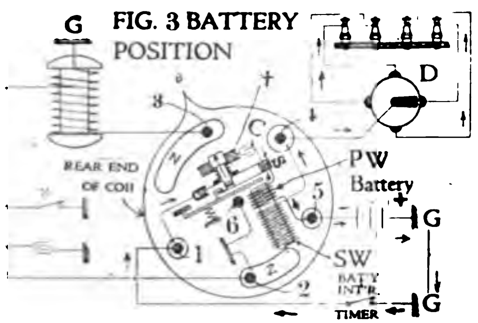
To start the engine therefore, we have only to press the button so that the upper platinum point comes into contact with the lower one, and immediately the circuit will be completed, the trembler start buzzing and a shower of sparks sent through the plug of the cylinder which is next to fire. Now the work of the trembler blade is done, the engine has started and the main contact breaker is set in motion. The current troubles no longer about the trembler blade, but follows the upper path along the auxiliary contact breaker and through the main contact breaker, the making and breaking of which does the work of the trembler and creates the high tension current. The engine may be kept running in this manner at the pleasure of the driver.

The auxiliary contact breaker, fig. 9: Now let us take the exceptional case of the engine stopping with the pistons about dead center and the main contact-breaker points (B P) closed. The current this time finds an easy circuit through the closed points, the iron core becomes magnetized, the trembler blade is held down on the core, and pressing the button as before has no effect. No spark is made because there is no break in the circuit. But if the reader will examine the diagram closely, he will observe that the act of pressing the button presses the auxiliary contact-breaker blade away from its upper platinum point and on to its lower one the momentary break thus caused in the circuit being sufficient, under the circumstances we are supposing, to create the necessary high tension current for the spark in the cylinder and so start the engine.

When the engine stops in the more usual way with the storage battery contact-breaker open, the opening and closing again of the auxiliary contact blade has no effect. The diagram, fig. 8, shows the coil as it actually exists.

Battery and Coil Position.

Fig. 3. Illustration is supposed to represent rear of coil and switch. Points 3 and 4 are not connected, consequently magneto secondary circuit is open. Note magneto primary wire is grounded at 2, therefore it is out of service.



Coil primary circuit: When switch is on B side the current in battery leaves it at the positive (+) side and travels through ground wire (G) to battery and coil timer or interrupter, which is operated by a cam on the magneto. The course is then to post 1 through mechanism in direction of arrows, to point 8.

It flows then through primary winding (PW) of coil, and as the arrows show, through point 5 back to battery, thus completing the primary circuit.

Coil secondary circuit: In passing through primary winding, a high-tension current is set up in the secondary winding (SW), when breaker-points separate.

This high-tension current flows to distributor wire at 4. Thence to magneto distributor (D). Here it is passed to the different spark plugs in order. It goes through the spark plug center terminal across gap to shell of plug to cylinder, thence to ground back to other end of secondary winding (note lower end of secondary is grounded to bus-bar Z which is grounded with 6). The coil condenser is shown at C.

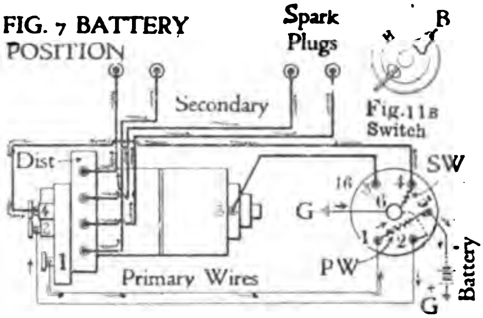


Fig. 7. Outside wiring of the battery and coil system when switch is on B side. (Note points 3 and 4 are not connected, thus opening magneto circuit). Primary current leaves battery and travels to ground (G). As 6 is grounded, current goes to 6, thence to 2 and along 2 to the magneto. Then to 1 on magneto along wire as indicated by arrows to the point 1 on switch pate (16). Here it travels through primary winding (PW) of coil then to 5 and back to battery, thus completing the primary circuit. The secondary circuit is from 4 to distributor, thence to spark plugs.

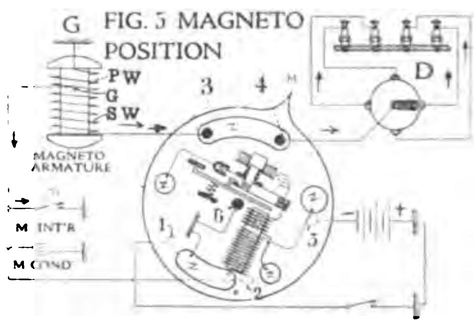
Note: when switch is turned, the rear end of coil (fig. 17A), with the bus-bars (Z) moves and connects with inner side of switch plate (16A). Therefore, when switch is thrown on B side the point 1 on switch plate (16) lines up with point 1 (one of the bus-bars Z) on rear end of coil (fig. 17A), likewise 2 and 5 line up with bus-bars on the end of coil.

Magneto Position.

Fig. 5. Note switch is now on (M) magneto side and there is but one closed circuit; it was made by connecting 3 and 4 on switch plate (16) with bus-bar (Z) on rear of coil. Note all other points of contact are open, including the magneto short circuiting or grounding wire connected with 2.



Magneto primary circuit is then from primary winding (PW) of magneto armature, to magneto interrupter (M), thence to ground. Other end of primary winding (PW) is grounded, thus completing primary circuit.

Magneto secondary circuit. One end of secondary winding (SW) goes to 3 and 4 which are now connected with bus-bar Z. From 4 it flows to distributor (D), thence to and through spark plugs. Here the current is grounded. The other end of —continued on next page.

CHART NO. 135—Bosch Dual Ignition System—continued.

In practice, connections from distributor to spark plugs are not as shown; if so, it would fire 1, 2, 3, 4, whereas it should connect to fire 1, 2, 4, 3 or 1, 3 4, 2. Main purpose of diagrams is to show Switch Circuits.

—continued from page 281.
the secondary winding (SW) is grounded also by connection with primary wire, thus completing the high-tension circuit. Note magneto condenser below magneto interrupter.

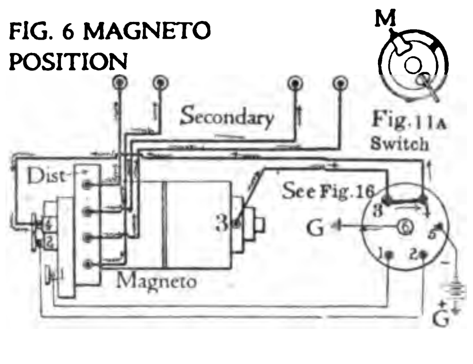


Fig. 6. Outside wiring of the magneto position. Note points 1, 2 and 5 are not connected.

The high-tension (secondary) current generated in magneto armature leaves magneto at 3, travels to 3 on switch-plate (16), thence to distributor wire 4, then to distributor where it is then distributed to spark plugs.

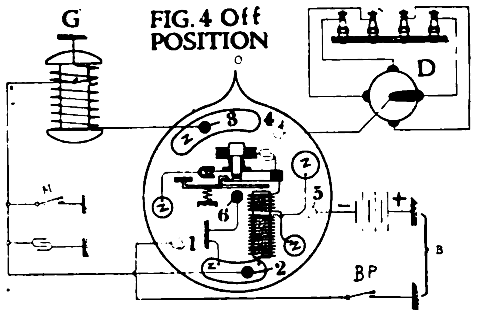

Fig. 4. Off position of switch. Note in this position there is no complete circuit, as points 1, 5 and 4 of switch-plate do not coincide with points 1, 5 and 4 of coil switch-plate, note **primary circuit** of **magneto** is short-circuited, or **grounded** at 2 on switch-plate, thus it is out of service. **Magneto secondary circuit** is open from 3 to 4.

Bosch Two-Spark or Dual Double Ignition System.

When the switch (fig. 2a) is thrown on the magneto side, without the two-point switch (fig. 2b) in the circuit, the path of the current is as follows: The low-tension current generated in the primary winding of the magneto passes through the breaker-points to ground. At the break of the points a high-tension current is set up in the secondary winding, this current leaving the magneto at 3 and passes to the point 3 on the coil, as indicated by the arrows. Then from point 3 to point 4 and thence to the distributor wire, along this wire to point 4 on the magneto. The distributor arm next receives the current which in turn is sent to the different plugs as indicated by the arrows. The current is sent to the ground after leaving the spark plugs and the high-tension or secondary winding being grounded at one end, the secondary circuit is complete.

When the two-point switch (fig. 2b) is thrown so that both sets of plugs are to come into play, both distributors of the magneto become operative. The path of the primary and secondary current to the magneto in this case is the same as before, but **when delivered to the magneto the current is passed** to two distributors instead of one. In this way two distinct electrical currents are distributed to **two** different sets of spark plugs.

The coil and battery ignition can be used independent of the magneto by switching to the B side of switch (**fig. 2a**) and one or both sets of plugs connected with two-point switch (fig. 2b). See also, page 283. (Motor Age).

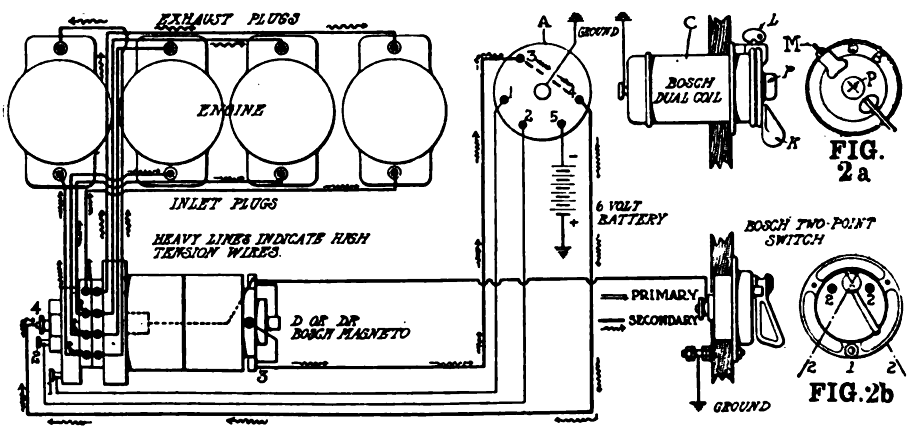

FIG. 2

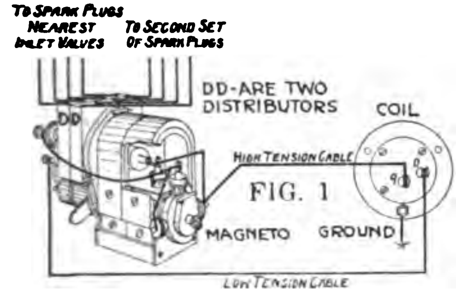
COIL LEGEND

L-KEY LOCK. K-KICK LEVER. P-PUSH BUTTON. M-MAGNETO OPERATING BOTH SETS OR ONE SET ACCORDING TO POSITION OF TWO-POINT SWITCH. B-BATTERY OPERATING INLET PLUGS.

CHART NO. 136—Bosch Dual Ignition System—continued. To time this magneto, see page 311. **Also the Bosch Two Spark or Dual-Double Ignition System.**

Bosch Two-Spark Magneto.

The purpose of the Bosch two-spark magneto (fig. 1), is to produce ignition at two plug points in each cylinder, in order to reduce the time interval between ignition and complete combustion; and, where it is possible to locate two spark plugs in each cylinder as shown on page 286 and 282. The result is to reduce the ignition advance necessary, and thus to secure an increase in the efficiency and output of the engine. See also, page 277.



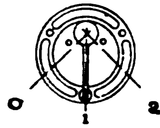


Fig. 1. Bosch two-spark magneto ignition system.

Fig. 2. Switch: 0, off; 1, one set of plugs operating; 2, both sets operating.

Fig. 2. SWITCH

The **types ZR4 and ZR6** Bosch magnetos are produced with the two-spark, independent or dual form. The noticeable difference in the two-spark magneto from the single-spark magneto is in the double distributor D D and arrangement of the safety spark-gap under the arch of the magnets.

In the single-spark magneto, the beginning of the armature secondary circuit is grounded on the armature core through the armature primary circuit, **whereas in the two-spark magneto,** the two ends of the armature secondary circuit, are connected to two sectional metal segments diametrically opposite on a single slipring. **Two slipring brushes are provided,** which are horizontally mounted in brush holders on opposite sides of the shaft and plate. During the portions of the armature rotation when high tension current is being delivered, each of the two slipring segments will be in contact with one of the brushes. One brush is connected to the **inner distributor** by means of a conducting bar similar to that used on single-spark magnetos, the second slipring brush is connected to the **outer distributor** by means of a short length of cable passing around the magnets. The rotating distributor piece is of double length and carries two brushes insulated from each other.

The four and six-cylinder types are fitted with eight and twelve distributor outlets respectively, each pair of outlets being connected to the spark plugs of the proper cylinder by the usual cables.

Path of the current is similiar to the Berling two-spark magneto, page 926 and page 282, fig. 2.

Advance and retard: The use of two-spark ignition permits the ignition lead to be cut down anywhere from 30 to 50 percent. It will be understood that if the timing is correct for two-spark ignition, and one of the series of spark plugs is cut out of action, the remaining series will operate considerably in retard of what it would if the engine were timed for single-spark ignition, therefore, if the two-spark ignition provides the full advance, the effect of retarding the spark is obtainel by cutting out one series of plugs.

The switch provided for the two-spark independent magnetos, is so arranged that ignition may be secured either with both sets of spark plugs, or with but one set. The purpose of this is to give the effect of retarding the spark, without altering the relation between the interrupter opening and the armature, as is done under normal conditions. The connections should be so made, that the system of plugs that is operative when the switch is thrown to the single position, is located near the inlet valve.

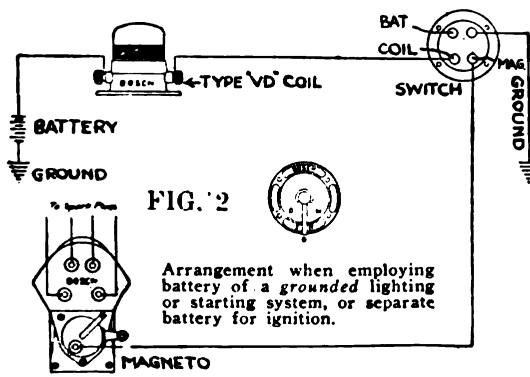
In starting—throw switch lever to "single plug" position—this gives the effect of a retarded spark.

For ordinary running, operation should be on both series of plugs; **for slow work through traffic,** or when the engine is running idle, use the single plugs, or only one set.

Timing: Time as explained for timing a single-spark magneto, at top of page 310 (interrupter retarded and piston on top of compression stroke). It will be found however that this timing will likely give two great a spark advance when interrupter is fully advanced, as the two-spark magneto should have from ⅓ to ½ the advance as that of a single-spark magneto. Therefore retime, so that the interrupter points will open slightly later. A good method to follow is as per below.

To replace a single-spark magneto with a two-spark instrument, the maximum advance for the single-spark magneto is to be marked—preferably on the flywheel—and the two-spark magneto **timed** in advanced position, so that the **interrupter opens** the circuit, at a point midway between the mark on the flywheel indicating the single-spark advance, and that indicating top dead center retarded. A more exact timing may then be secured by experiment.

The Bosch Vibrating Duplex System.



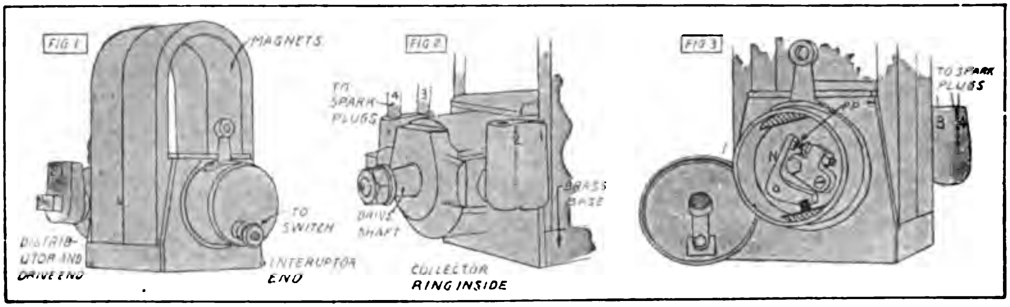
Arrangement when employing battery of a *grounded* lighting or starting system, or separate battery for ignition.

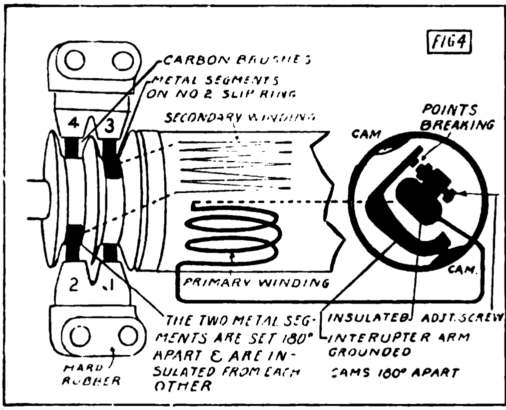
The Bosch vibrating duplex system is designed to permit easy starting on cars that are cranked by a starting motor at such a low speed that the ignition current from the ordinary magneto is insufficient to give certain ignition.

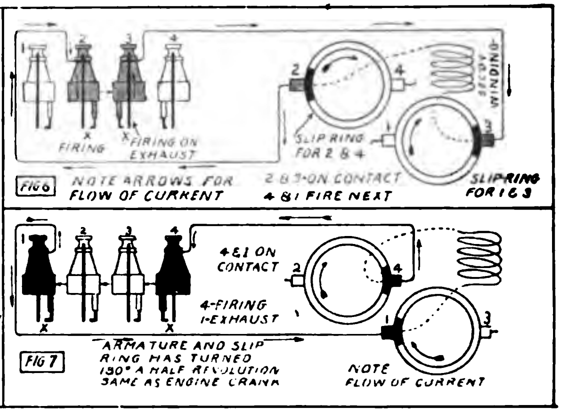
How it operates: The arrangement is such that, while the magneto circuit is absolutely independent and complete in itself, the battery circuit includes both the coil and the magneto. **With the switch in the battery position,** the battery and coil are in series with the primary winding of the magneto armature, and the current from the battery supplements that generated by the magneto. Thus there is induced in the secondary winding of the magneto armature, a very powerful sparking current, which, on account of the vibrator action of the coil, appears not as a single spark, but as a series of intense sparks that will act with certainty on any explosive mixture. The sparking current so produced is distributed in the usual way by the magneto distributor. **After engine is started, the switch is turned to M side** and coil and battery are disconnected.

CHART NO. 137—The Bosch "Two-Spark" Magneto Ignition System. Bosch Vibrating Duplex System.

The "Two-spark" system regular equipment on Stutz and Mercer. Also been used on some FIAT, Locomobile and Marmon cars. See also, page 926 for Berling two-spark magneto.







Bosch "NU4" Two-Point Magneto.

The type "NU4" Bosch magneto differs from the usual type of magneto in that the distinct gear driven distributor, common to other types, has been eliminated, and in its stead is a double slipring combining the functions of current collector and distributor. Otherwise it is about the same as any other form of magneto.

The spark occurs in two cylinders at one time with this system, but one of the cylinders in which the spark occurs is on exhaust stroke, therefore the spark does no harm.

The interrupter contacts in the full retard position should open not later than top dead center of the compression stroke; therefore the effective spark is produced in the cylinder aways toward the end of the compression stroke and the surplus spark will always occur near the end of the exhaust stroke and never during the inlet stroke. In any four-cylinder, four-cycle engine, regardless of firing order, when cylinder No. 1 is nearing the end of the compression stroke, cylinder No. 4 is nearing the end of the exhaust stroke and vice versa; similar conditions apply also to cylinder Nos. 2 and 3.

The brushes, when making contact with the metal strip in collector rings, collect the high tension current and carry it to the spark plugs. Note the connections from ring to plugs. When brushes 2 and 3 are making contact—follow the circuit in fig. 6, and note the arrow points. Now if the piston makes another stroke or 180° travel, the armature will turn 180° or half a revolution also, as it runs at engine speed in four cylinder, four cycle engine, therefore the contact on ring will turn 180° or half revolution and cylinders 4 and 1 will fire as in fig. 7. This type of magneto was used on the Overland and is now used on other cars.

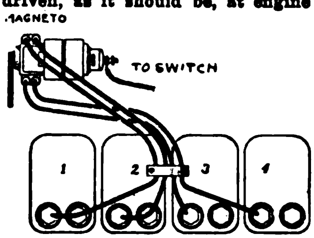
Timing.

Timing the "NU4" magneto: With the average engine, this result is obtained by connecting the magneto so that its interrupter housing is in full retard position, and the platinum interrupter screws just about to separate, when the piston of No. 1 cylinder is exactly on top dead center of the compression stroke.

At the same time the metal segments of the slip-ring should be in contact with the brush marked "1" in each of the brush holders, and this can be observed by removing one of the holders.

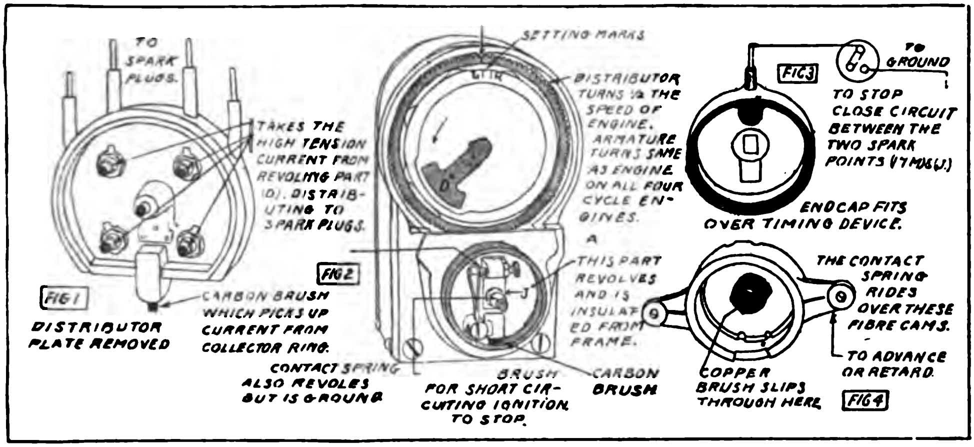
The installation is completed by connecting one of the brushes marked "1" with cylinder No. 1, and the other with cylinder No. 4, and the two remaining brushes, marked "2 and 3," with cylinders Nos. 2 and 3.

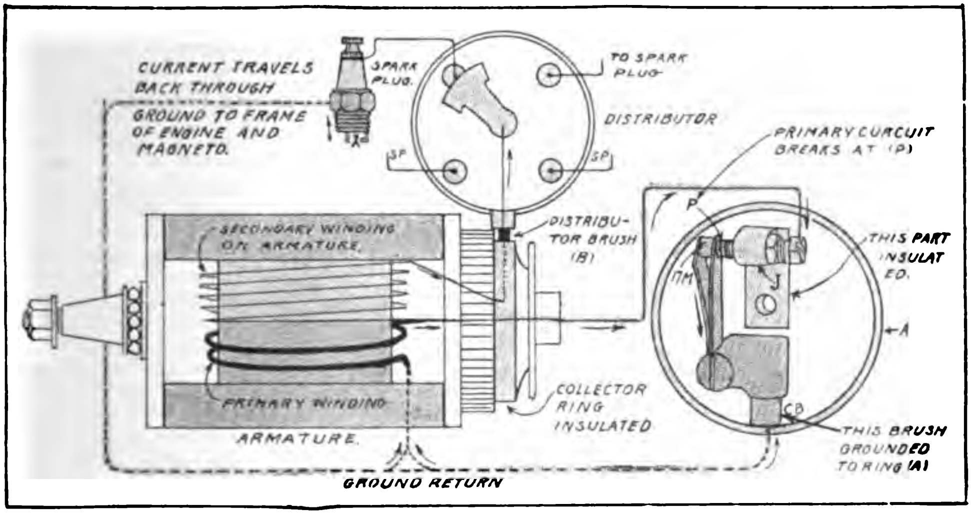
It is important to note that the type "NU4," driven, as it should be, at engine speed, produces a surplus spark in each cylinder exactly 360° behind the effective or power spark and, in coupling the magneto to the engine, it must be timed so that the surplus spark occurs during the exhaust stroke and not after the inlet valve has commenced to open.



Note connections from collector ring terminals to spark plugs.

CHART NO. 138—The Bosch Type "NU4" High Tension Magneto; a "Two-Point" System; two Sparks occurring at the same time, but in **different** cylinders.





The Eisemann "G4" type of high tension magneto differs from other Eisemann types in that the make and break or interrupter mechanism is constructed on different lines. The platinum contact springs (17M), connect with a carbon brush (CB), which revolves in a brass ring (A). Ring (A) is stationary, whereas the spring (17M) revolves with the other contact plate (J). Contact plate (J) is insulated from (17M). One end connects with primary winding on armature, therefore when contact is interrupted by (17M), and point on screw in plate (J)—the spark is given as usual. The ring (A) and (17M) are grounded.

The points of (17M) and screw on plate (J) are separated by the timing device, Fig. 4, which goes over the ring (A). Contact spring rides over the fibre cams.

The novel features of this system, besides the breaker, are—its accessible and efficient grouping of the working elements all at one end and its waterproof qualities.

To set the time of spark: Place piston of No. 1 cylinder on top of compression stroke. Set the interrupter points to break in full retarded position.

Adjustments: The breaker gaps should be set .012" and spark plugs gaps $\frac{1}{64}$" to $\frac{1}{32}$".

To stop or cut off ignition: On all magnetos the magneto is stopped generating by short circuiting the primary circuit—not by opening the circuit as in a coil system.

CHART NO. 189—Eisemann "G4" Type of High Tension Magneto, used on the Nash, Federal and other Trucks. (Eisemann Magneto Co., Bush Terminal, N. Y.) Spark plug gap is usually set .030".

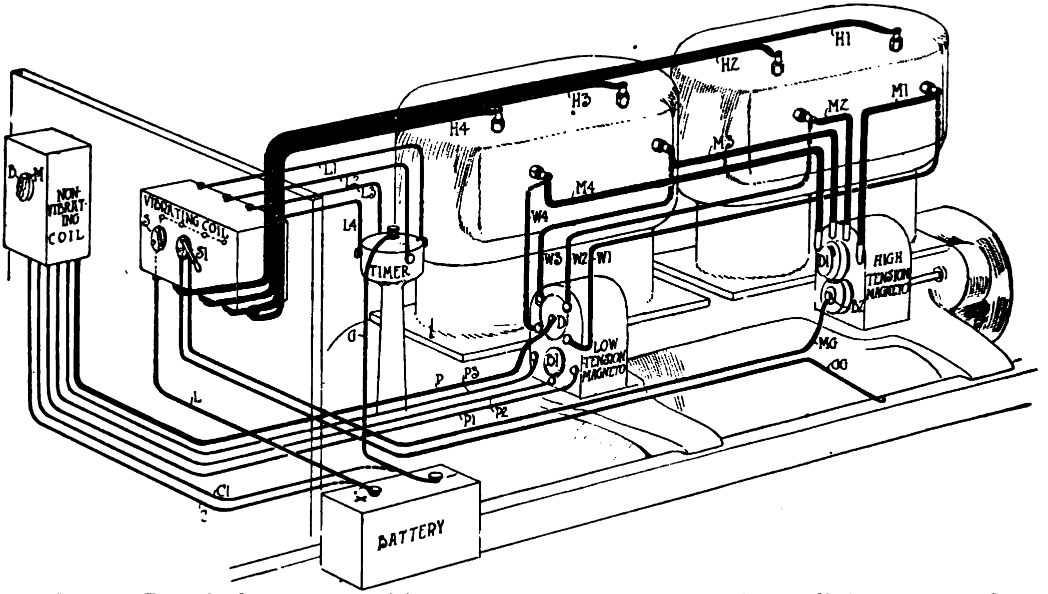


Fig. 1—Four high tension ignition systems connected to one four cylinder engine. Only two systems are usually placed on an engine, and then, only one system is used at the time. The idea is merely to show how the various systems can be combined into "Dual" or "Double" Ignition Systems, as explained on page 277.

The **vibrating coil** is seldom used. The **low-tension magneto** is seldom used. A modern "dual" and "double" system is as per pages 276, 280, 281 and 282. A modern "battery and coil" system is as per pages 342, 346, 378, 252, 250.

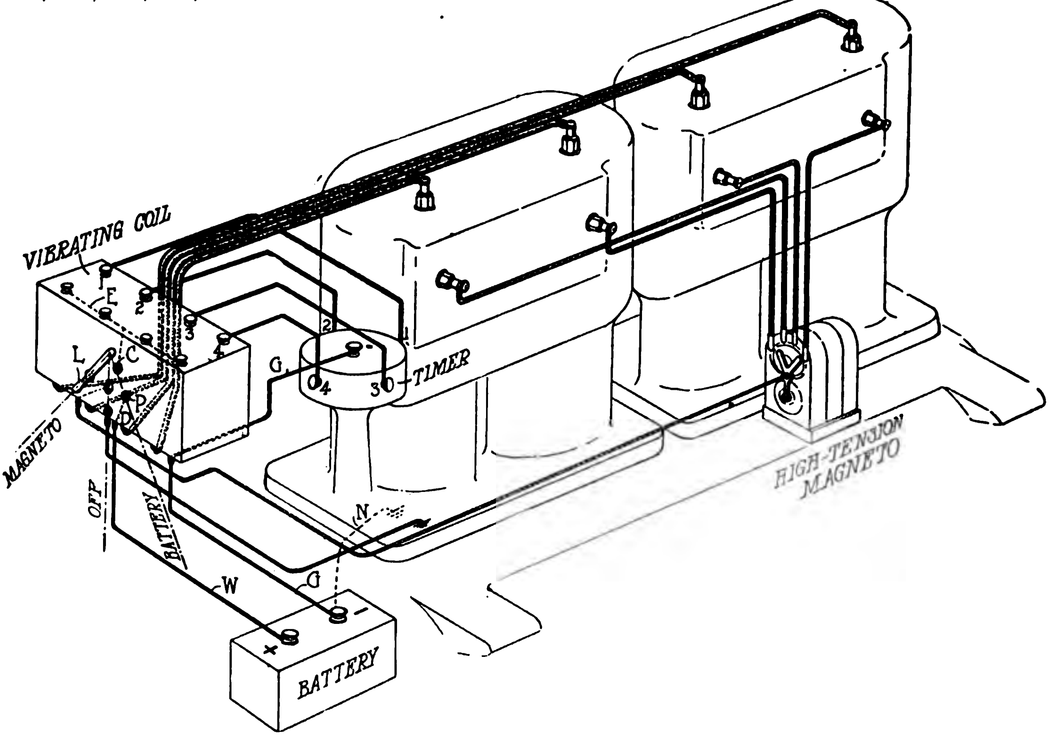

Fig. 2—Wiring diagram of a double system of ignition showing the switch arrangement; a high-tension magneto with a separate set of spark plugs. A multiple unit type of vibrator coil with commutator (marked "timer") and battery and a separate set of spark plugs.

(Trace circuits with pencil.)

CHART NO. 140—Four High Tension Ignition Systems Mounted on One Four Cylinder Engine to Explain the Combination of Systems.

See foot note bottom of page 281 which refers to fig. 1.

—continued from page 279.

This style of magneto, owing to the fact that it is rocked from side to side, gives an unlimited range of advance, and thus adds wonderfully to the flexibility of the car on which it is mounted. This great range of advance makes this instrument especially suitable for two-cycle engines, which require a much greater degree of advance and retard than the four-cycle type.

See page 289 for description.

Magneto; Automatic Advance.

The Eisemann automatic advance of spark; with all magnetos treated up to the present time, the advance and retarding of the time of spark is accomplished by hand, called "manual" advance, by means of spark lever on the steering wheel. With the Eisemann automatic advance, the same thing is accomplished by a governor arrangement automatically. This type of magneto is extensively used on commercial cars. (see chart 143 for description.)

"Combining" the High Tension Magneto and Coil and Battery System into "Dual" and "Double" Systems.

We have now explained the different leading low and high tension ignition systems for firing the charge of gas in the gasoline engine. In order to more clearly explain the four leading systems of high tension ignition, we will now place the **four ignition systems** (high tension) on one four-cylinder engine. (Fig. 1, chart 140.)

This system of using four ignition systems on one four-cylinder engine is not in actual use, but is intended to make the combination of "dual" and "double" systems clear to the reader—showing how they can be combined.

We will first explain each system separately, showing how each individual system would be connected.

FIRST: The "single" high tension magneto system—(See page 268): By referring to fig. 1, chart 140, we will put our pencil on the switch on dash coil box (S1). If this lever is thrown to the left with all other switches "off," this high tension magneto system will supply current for sparking the lower set of spark plugs (M1, M2, M3, M4). Note these wires run from the distributor on the magneto.

SECOND: The high tension coil, battery and commutator system:—See chart 140): If switch (S) is thrown to the left, the four high tension vibrating coils will spark the plugs (H1 to H4). The battery, of either storage or dry cells, usually storage, will supply the electric current in this instance. The timer, operated from one of the cam shafts through a system of bevel gears, will control the time of spark in each cylinder. (The timer is a regular type of commutator, as shown in chart 108.)

THIRD: A non-vibrating single high tension coil with battery, using the circuit breaker on the low tension magneto as the timer, and the distributor on the magneto to distribute the current to the spark plugs: —(See chart 123): If switch on the non-vibrating coil is on B, the battery will supply the electric current, passing through the primary winding of the non-vibrating coil. The circuit breaker (B1) on the low tension magneto will take the place of timer and vibrator (current does not pass through armature winding, however). The secondary current from the coil will be distributed to the spark plugs (W1 to W4), through the distributor (D) on the low tension magneto.

FOURTH: Low tension magneto and separate high tension coil:—(See charts 140 and 123): If the switch is on "M" on the non-vibrating coil, the low tension magneto will pass its current through this non-vibrating coil, increase it to high pressure and then distribute the high tension current through the distributor (D) to the spark plugs (W1 to W4), the circuit breaker opening and closing the primary circuit of magneto.

Combining into Dual Systems.

If we were to combine the last two systems, which is frequently done, we would have TWO SYSTEMS OF IGNITION using ONE set of spark plugs—but only one system sparking the plugs at the time.

The single-non-vibrating coil and battery would be used to start on by throwing the switch to (B) and after engine was started then by throwing switch to (M), the low tension magneto would take the place of the battery.

Another dual system: Vibrating coil with switch (S1), storage battery and commutator (timer), with secondary wires, H1 to H4, connected to the spark plugs, M1 to M4, in connection with the high tension magneto, connected to the same spark plugs, would give another form of dual system.

Combining into Double Systems.

The vibrating coil, timer and battery with spark plugs H1 to H4, would constitute one independent system. The high tension magneto with its spark plugs M1 to M4, would constitute the other. This would be called a double system.

Another double system, could be formed by using the low tension magneto and separate non-vibrating coil and spark plugs M1 to M4. The vibrating coil, timer and battery with spark plugs H1 to H4 would constitute the other system.

There are many methods employed to combine the different ignition systems into dual and double systems.

The Modern Battery and Coil Ignition System.

Is the system of taking the current from a storage battery, passing it through the primary winding of a high tension coil; using a combination of timer and distributor to make and break the primary current and distribute secondary current to the spark plugs. Such a system is the Delco, Connecticut, Atwater-Kent, etc. See index.

See also, page 277 for "Dual" and "Double" Ignition Systems.

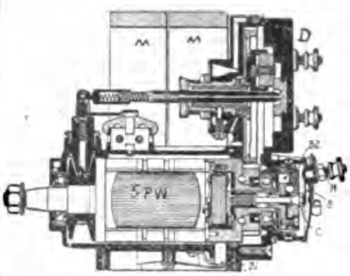

Fig. 1.—The Bosch high tension magneto. Armature revolves. The Simms, Eisemann and other types are similar.

M—magnets. D—distributor. PW—primary winding. Over this winding is (S) the secondary winding. H—is terminal which connects with switch.

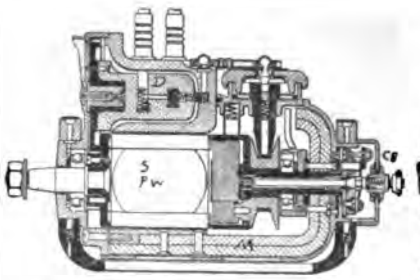

Fig. 2.—The Mea high tension magneto. Pivoting type. Revolving armature.

Note the armature is double wound, shuttle revolving type.

Instead of shifting the interrupter housing, in order to advance or retard; the field magnets are shifted.

Fig. 3.—The Eisemann high tension magneto, pivoting or rocking advance magneto. The advance and retard is obtained by rocking the magneto bodily on its cradle. Otherwise the magneto is the same as other magnetos. Armature revolves.

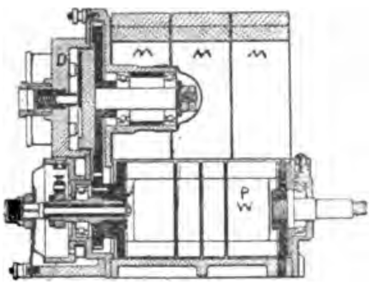

Fig. 4.—The Splitdorf low tension magneto. Armature is primary wound. Armature revolves and is of the "armature" type.

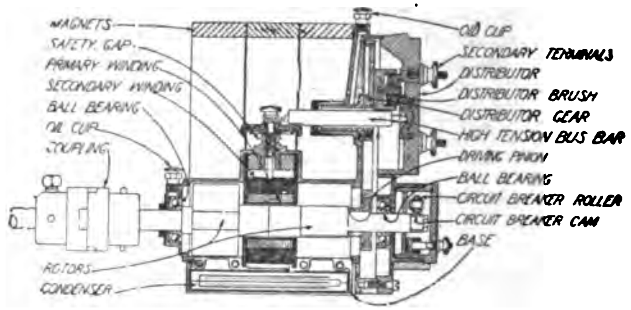
A separate high tension coil, called a transformer, must be used with this magneto.

The Splitdorf Co. also manufacture a high tension type magneto, see chart 143A and insert.



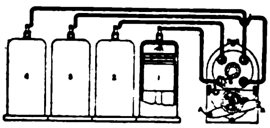


Fig. 7.—Wiring of K. W. high tension magneto.

Fig. 6.—The K. W. high tension magneto with an inductor type armature: There are two windings on this type; a primary and a secondary. The windings are stationary however, and the inductor rotors revolve. The principle of inductor type magnetos was explained in charts 120 and 126. The same principle applies here, with the exception that the two windings obviate the necessity of a separate high tension coil, as it is here provided for in the secondary winding of the stationary coil winding. By referring to index, "impulse and waves of current" and also chart 120, you will note that the K. W. gives four waves or impulses per revolution—however, either one, two, or four sparks per revolution can be obtained by using a single or a double cam.

On the K. W. there are four sparks per revolution, with a two point cam, therefore, magneto would be driven at crank shaft speed, for an 8 cylinder engine, and 1½ times crank shaft speed for a 12.

The setting of the inductor type armature is similar to the setting of any other type. The fact of its having 2 inductors, and they being placed crosswise, is a bit confusing, but in the setting, only one is taken into consideration, and is therefore as simple to set as the ordinary type. The breaker and plug gap are set to 1/64".

***See also pages 256, 296 and 332 on K. W. magnetos.**

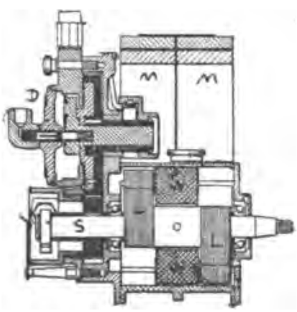

Fig. 5.—The Remy low tension magneto armature is primary wound—only one winding. Armature of the "inductor" type.

Armature does not revolve. The winding (W) is stationary and rotating magnets (L) revolve.

Separate high tension coil (called a transformer) must be used with this magneto.

The breaker gaps are set .025 in. apart.

Address of Magneto Manufacturers.

In writing, state where you saw the address.

Berling-Ericsson Mfg. Co., Buffalo, N. Y.
Bosch Magneto Co., 223 W. 46th St., New York City, N. Y..
Connecticut Telephone & Electric Co., Meriden, Conn.
Eisemann Magneto Co., The Bush Terminal, Brooklyn, New York.
Heinze Electric Co., Lowell, Mass.
K. W. Ignition Co., Cleveland, Ohio.
Mea Magneto; Marburg Bros., New York.
Motsinger Device Mfg. Co., 815 Market St., Lafayette, Indiana.
National Coil Co., Cedar St., Lansing, Michigan.
Remy Electric Co., Anderson, Indiana.
Simms Magneto Co., East Orange, New Jersey.
Splitdorf Electrical Co., Newark, New Jersey.
Westinghouse Electric & Mfg. Co., Pittsburg, Pa.

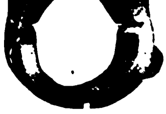

Fig. 32 — Pole structure — in which rotating poles revolve and to which the condenser and coil winding attach to its upper part. See 24-16, fig. 30, showing how connections are made to it.

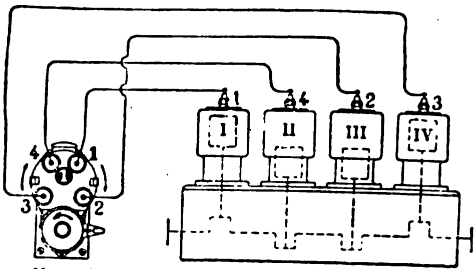
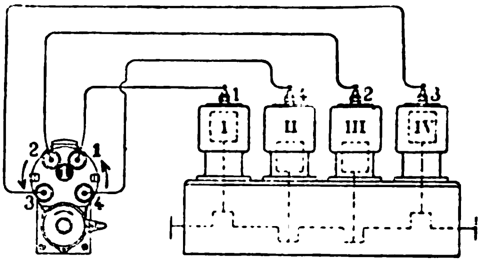
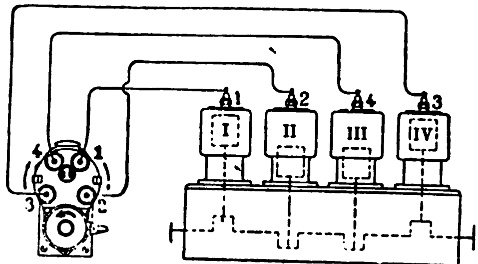
Fig. 33—Showing method of raising or lowering platinum point screw in (6) fig. 40. The usual distance to set these points are .020 or 1/50". This adjustment can be made with a screw driver. Spark plug gap is set .025.



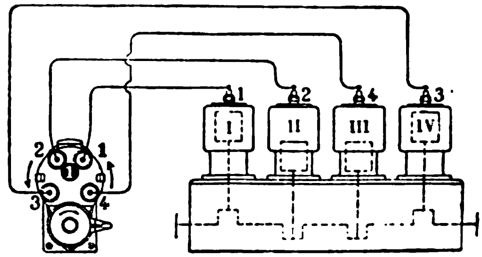
View of Distributor End — Magneto running clockwise Firing Sequence I, III, IV, II.



View of Distributor End — **Magneto running anti-clockwise** Firing Sequence I, III, IV, II.

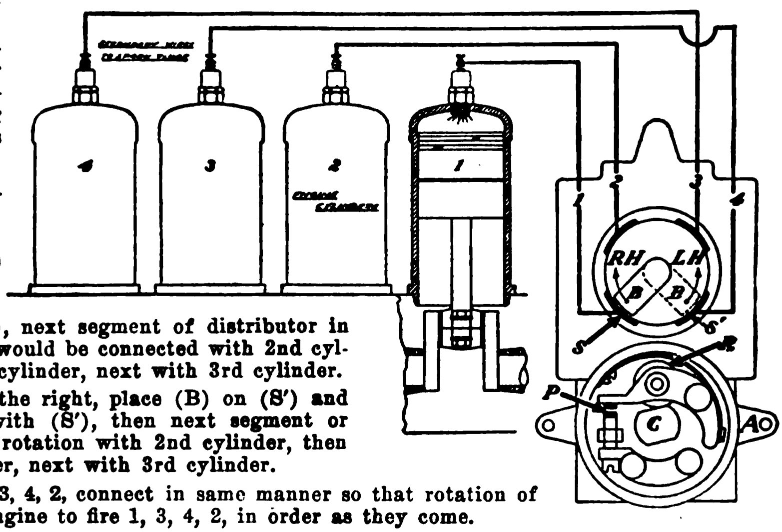


View of Distributor End — Magneto running clockwise Firing Sequence I, II, IV, III.



View of Distributor End — **Magneto running anti-clockwise** Firing Sequence I, II, IV, III.

Method of connecting the spark plugs with distributor on four-cylinder engines; when engine is firing 1, 3, 4, 2 or 1, 2, 4, 3. **Also** note the different method of connection **when** the magneto runs clockwise, and anti-clockwise. Clockwise means in the same direction as the hands of a clock move, anti-clockwise in the reverse direction. Note when armature revolves in one direction, distributor revolves in the opposite direction. This is due to the motion of the gears. In the case of a magneto the direction of rotation clockwise or **anti-clockwise,** is always stated viewing the magneto from its shaft or driving end.



Connecting distributor to cylinder: firing order 1, 2, 4, 3. If cam (C) turns to the left, set (B) on (S) and connect cylinder No. 1 with (S), next segment of distributor in direction of rotation would be connected with 2nd cylinder, next with 4th cylinder, next with 3rd cylinder.

If cam turns to the right, place (B) on (S') and connect cylinder 1 with (S'), then next segment or cable in direction of rotation with 2nd cylinder, then next with 4th cylinder, next with 3rd cylinder.

If engine fires 1, 3, 4, 2, connect in same manner so that rotation of brush B, will cause engine to fire 1, 3, 4, 2, in order as they come.

RH—abbreviation means arm (B) turns right hand, when cam (C) turns to the left; **LH**—abbreviation means arm (B) turns left hand, when cam (C) turns to the right; **P**—are platinum contact points on interrupter; **R**—is roller raised by cam (C) which causes separation of (P); **A**—is interrupter or contact breaker housing.

If cam run to left, shifting (A) **down** would "advance" and **up** would "retard."

The sooner cam separates (P)—quicker the spark—**(advance)**; the later the cam separates (P)—later the spark **(retard).**

Above illustration is that of the K. W. high tension magneto per page 288. Although the four-pole rotor is used, as explained on page 256—there are but four sparks delivered to engine during two revolutions of the crank shaft. The cam (C) being a two-point cam and revolving same speed as crank-shaft, results in two sparks per rev. or four sparks for two rev. The distributor revolves one rev. to crank-shaft two.

CHART NO. 145—Distributor Connections. Relative Rotation of Distributor to Interrupter Cam. Clockwise and Anti-Clockwise Rotation Explained. (see also page 313.)

—continued from page 295.

There is usually a peep-hole on the distributor provided on magnetos that show which contact the distributor brush is on, for instance: When the figure 1 appears through peep-hole (see fig. 2, page 310) in the distributor disk, the distributor is making contact with terminal No. 1, and this terminal should therefore be connected to the spark plug of cylinder 1. Bearing in mind that the rotation of the distributor is opposite to the direction of rotation of the armature, the next distributor contact that will be made should be connected to the spark plug of the cylinder that is next to fire. The third and fourth terminals of the distributor should be connected to the remaining spark plugs **according to the firing order.** These connections will be facilitated by a study of the wiring diagrams in chart 145.

Note the explanation of both four cylinder firing orders are given also the meaning of the term applied to magnetos running "**clockwise**" and "**anti-clockwise.**"

A study of these illustrations, especially fig. 5, chart 144, will enable the reader to also understand the connections for a six cylinder engine. It is merely a matter of connecting the cable from distributor terminal which is next on contact, to the cylinder which fires next.

Care of the Magneto.

Distributor parts: Distributor plate should be removed occasionally for inspection as to the presence of the carbon dust that wears off the carbon brushes. This dust may form a connection between the distributor segments, and in consequence cause a spark to occur in the wrong cylinder. Carbon dust that has collected on the distributor should be wiped out with a cloth, the cloth being moistened with gasoline should the carbon have become caked.

After cleaning with gasoline, the inside of the plate should be given a very light film of oil to prevent excessive wear of the brush and the distributor plate.

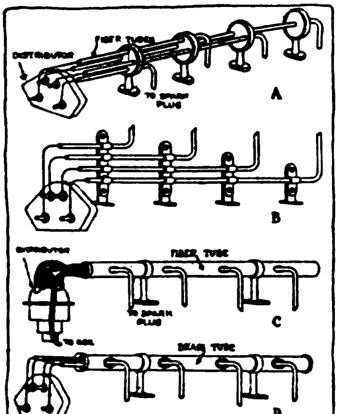


Fig. 3. A—method by which the wires can be separated from one another to avoid static effects. B—another method of separating wires to avoid static effects. C—with this arrangement static effects are sometimes felt. D—running wires through brass tubing does not avoid static effects.

****Cables.** Use only the best insulated wire for all electrical connections and especially those leading to the plugs. The wires running from the distributor to the spark plug are called **secondary cables** and should be protected from "static" electricity—see fig. 3 below. (A, B are best arrangements).

Terminals. Scrape off about 3/16 inch of the insulation from both ends of the cable, clean the copper wire and screw it into tube of terminal (it will not do to push it in only) in order to connect the two parts thoroughly. Spread out inside the tube the portion of the wire which has been stripped of its insulation and screw in the little screw supplied for the purpose.

Many a case of ignition trouble has been hard to locate due solely to one of the strands of wire short circuiting. Therefore, if special connections are provided use them, otherwise solder the ends.

*Interrupter Adjustments.

Among the most important parts of the magneto is the †interrupter (see figs. 1 and 2 illustration, chart 146); and it is advisable to inspect it from time to time. An inspection of the interrupter requires the removal of cover which is usually secured to the interrupter housing by means of a spring ring that permits it to be snapped on and off. The interrupter lever should be moved for assurance that it is free on its pivot, and a test should be made of the distance between the platinum points.

Adjustment: When the lever is depressed by one of the steel segments or cam, the distance between the platinum points should be about .015 to .020 or about 1/64 inch. This distance may usually be adjusted by the movement of a platinum pointed screw.

Should it be necessary to replace one of the platinum points or to attach a spare part, the interrupter may be more completely exposed by turning lock ring a quarter of a turn to the right or to the left and removing it and the interrupter housing. The interrupter itself may be removed by unscrewing interrupter screw.

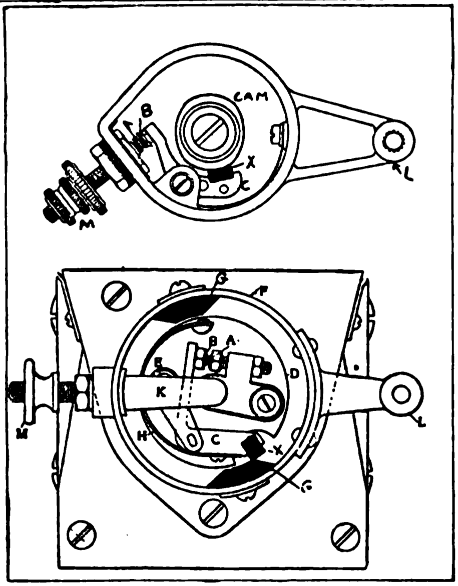
When replacing the interrupter, care must be taken that the key on the interrupter disk

Static electrical discharge means jumping of high tension current from one wire to another when together, even though insulated.

*The adjustment of the gap at the platinum contact points (see chart 146) on "contact breaker" on magneto, when separated by nose of cam, ought not to be over 1-64 of an inch, however, this is not intended for a rule to go by altogether—there is a slight variance on different makes of magnetos.

On the Bosch Z R 4 and Z R 6 magneto the space is .4 of a millimeter, as a millimeter is 1-25th part of an inch, therefore space is about .016" or 1/64 inch. On the Remy .020 to .025; the Splitdorf .020 of an inch. The average is from .020 to .025. **See pages 240 and 425.

†**Note: S. A. E. now designate the Interrupter as "Breaker-Box"**—see foot note page 298.

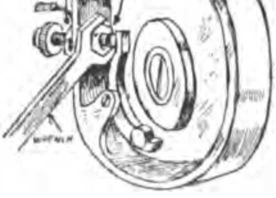


Figs. 1 and 2. Two types of interrupters.

Single spark cam. Two spark cam.

Fig. 9. On a single cylinder engine requiring but one spark during two revolutions of the crank, a single cam is used which is attached to end of armature, which revolves ½ the speed of crank shaft. The two point cam, however, is most generally used.

On a four cylinder engine the cam would open interrupter twice during one revolution, therefore it would run same speed as the engine, causing four openings during two revolutions—see chart No. 145.



The Remy interrupter.

**Magneto Interrupters.

The **interrupter is constructed in various forms. The principle, however, is about the same. The purpose of the interrupter is to open or interrupt the flow of current in the primary winding of the magneto armature just as the armature breaks from the pole cheeks (page 309).

The interrupter on four cylinder as well as the six cylinder engine magneto, must interrupt the current twice during one revolution. Therefore a cam with two projections placed 180° (half revolution) apart is provided.

If a cam is not used, then means for accomplishing the same thing must be provided.

Note the arrangement in fig. 2, here we have two cam-blocks (G) stationary to the inside of the interrupter housing (F) placed 180° apart. As the disc (D), revolves, the parts C, H, E, B, A and X revolve with it.

At the extreme end of (C) is a projection (X), when this fibre projection (X) strikes cam-block (G), the platinum point contacts (B and A) are opened. (H) is a spring provided for holding the points together at other times. (K) is a flat metal spring which connects with terminal (M) and is used to carry current to grounding switch—see fig. 1, chart 129.

†**Interrupter adjustment:** There is one adjustment on the magneto which needs watching; that of the platinum point breaker contact screw. The adjustment should be made so that the maximum break of the platinum points is about .015 to .020 inch, or about 1/64 of an inch.

***If the engine misses with the spark retarded** (and misses more at low than at high speed), the contact screw should be screwed out a notch at a time until the missing is overcome. **If the engine misses with the spark advanced** (and more at high speed than at low), the contact screw should be screwed in a notch at a time until the missing is overcome. When correct adjustment is once made, further attention should not become necessary for several months.

Note that the adjusting screw is very delicate and needs to be adjusted carefully. **If platinum points are "pitted,"** then they should be filed down flat with a very fine jewelers file. (See page 234.) **Keep oil away** from the points.

†**The spark plug gaps,** when used with magneto ignition should be about .020″ to .031″, see foot note, page 275.

Common contact-breaker troubles are; insufficient lubrication causing wear; loose breaker bar, fibre bumper worn.

THREE DIFFERENT TYPES OF MAGNETO BREAKER MECHANISMS

Bosch — In this the moving contact is carried on a bell crank which rotates with the armature shaft, the cams being inside the breaker box

Dixie — The cam revolves with the armature shaft operating a bell crank which remains stationary so adjustments can be made while running

Eisemann — This consists of two spring members separated by a fibre piece; one of the springs carries the moving contact point. The cam is stationary

CHART NO. 146—Magneto Interrupters:** Construction and Care.

***Widening the gap** causes the interrupter points to open earlier, causing spark to occur when magneto armature is at a more favorable position—giving a more intense spark. Closing of gap is just the reverse of foregoing. †Usually, a small flat wrench is provided with magneto for adjusting.

**S. A. E. now designate the Interrupter as "Breaker Box." The term "Interrupter" is used in this book owing to the fact that this matter was set up before the designation was adopted. In some instances the change will be made.

fits exactly into the keyway on the armature shaft, and care must also be exercised when replacing the interrupter housing, being sure it is placed back in exactly the position it was taken off.

The platinum points on the interrupter "pit" in time, but not so bad as the points on a vibrator coil. The alternating current of a magneto does not cause pitting of the points as much as the direct current. However in time the points are bound to become worn and new ones must be fitted, or the old ones dressed down. (See dressing platinum points, page 234.)

**The Safety Spark Gap.

In order to protect the insulation of the armature and all other parts from injury due to excessive voltage, a safety spark gap is provided to permit the passage of the current to ground without injury. The current will pass across the safety spark gap in case a high tension cable is disconnected, if the spark gap is too great, or if for any other reason the spark plug circuit is open. Discharge should not be permitted to pass through the safety spark gap for any great length of time, however. This should be particularly guarded against if the engine is operated on a second or auxiliary ignition system. When the engine is operated on such a system, the magneto should be grounded in order to prevent the production of high voltage current.

Oiling the Magneto.

The over oiling of the magneto should be guarded against in order to prevent the entrance of oil to the interrupter parts. Each of the oil holes is to be given a few drops of fine machine oil every two weeks or every 1000 miles. The interrupter is designed to work without lubrication, and the presence of oil on the platinum points will give unsatisfactory results, inasmuch as it will cause sparking at the points and possible misfiring.

Vaseline is suitable for lubricating the ball bearings, but never use oil on the interrupter whereby it will reach the platinum points.

Cutting off the Magneto Ignition.

To cut off the ignition the primary current must be "grounded," which will prevent the breaking of the circuit by the opening of the interrupter, and consequently prevent the production of the secondary current. The primary current may be grounded by making a connection between the grounding nut and the engine ground, this circuit usually including a switch. One terminal of the switch is connected to the engine or frame, the other terminal leading to grounding terminal. When the switch is open the magneto will produce a spark, but the closing of the switch will ground the primary circuit and will prevent the production of the ignition spark. (See fig. 5, chart 144 (switch is shown in lower part of figure) and fig. 1, page 268.)

Magneto Ignition Troubles.

In case of defective ignition it must be determined whether the fault is in the magneto or in the plugs. Generally when only one cylinder misses, the fault is in the plug.

Defects of Spark Plugs.

1st. Short-circuit at the spark gap, due to small metallic beads which are melted by the heat of the intense spark and form a conducting connection between the electrodes. This defect is easily ascertained and may be remedied by removing the metallic beads. (See page 237.)

2nd. If the gap between the spark plug electrodes (point) is too great, the spark will jump across the safety gap on the magneto. In such a case, when the plug is unscrewed from the cylinder the spark will jump across the electrodes of the plug, and not across the safety spark gap. This does not signify that the distance between the electrodes is correct for it must be borne in mind that open air has a lower resistance than the compressed air or gas existing in an engine cylinder. The distance between the electrodes when under compression in the cylinders must, therefore, be less than is required in the open air. The correct gap should be approximately 1/64 to 1/32", see foot note, page 275.

3rd. Fouling of the plug. If fouling should occur, the parts exposed to the burning gases may very readily be cleaned by removing the plugs from the cylinder. This exposes the plug core, and it may be cleaned with gasoline.

The spark plug used with a magneto should have the point set closer than with a battery and coil ignition, because, when the magneto runs slow the current is not as strong as when running fast. With a battery as a source of supply, the current is constant at all times.

The spark plug cables must be tested, and special attention should be paid to ascertaining that the insulation is not injured in any way. The metal terminals of the cables must not come in contact with any metal parts of the engine or with any metal parts of the magneto, except the proper binding posts.

*Diagnosing Magneto Troubles.

(1). Engine balks—no spark.
(2). Misses at low speeds.
(3). Misses at high speeds.

(1). Cause of: Broken connections, short circuit in primary circuit, or between coil and distributor brush. Timing maybe wrong or breaker points too far apart.

(2). Cause of: Spark plug gaps too far apart, or too close; breaker points too far apart; loose connections or short circuits; weak magnets.

*See also page 301. **See also, pages 273, 275, 291.

(3). Cause of: Breaker points set too close; breaker arm not working freely, loose connections or short circuit.

Ignition fails suddenly. A sudden failure of ignition indicates a short-circuit in the low tension cable, either through a defect in the cable, through a faulty connection of the switch, or through the presence of dirt or moisture. This may be tested by removing the grounding cable from binding post on the magneto and endeavoring to start the engine on the magneto. If the engine runs with this wire disconnected, but stops when the wire is connected, it may be taken for granted that there is a fault in the insulation or some other defect through which the low tension current escapes to "ground." It is also advisable to examine the carbon distributor brush to ascertain if it is in good condition. This brush may be exposed by removing distributor plate.

Irregular firing. Irregular firing is usually caused by the improper working of the interrupter, and this part should be examined. It should be seen to, that the interrupter lever moves freely on its pivot, and that the center screw is properly tightened; see also that the steel segments or cams, as well as the two platinum screws, are properly secured in position. Furthermore, the platinum points should be inspected for the correctness of their adjustment, and they should be so set that they are about 1-64 of an inch apart when the interrupter lever is depressed by one of the segments. The platinum points should be clean, flat and true to one another, and any oil, grease, or dirt that is deposited on them should be removed. If they are uneven or in bad condition—but only then—they should be trued by means of a fine flat file. If the interrupter lever does not move freely on its pivot, (as is occasionally the case, particularly with new magnetos,) the hole through the fibre bushing that forms the bearing should be reamed out. This work should be very carefully performed, however, and excessive reaming guarded against.

Starting the engine. To start engine it is sufficient to give a sudden pull to the starting handle at the moment a spark is to take place in one of the cylinders. If the engine does not start off at once this may be caused by either or all of the following:

(a) by setting not being done in a proper way; (b) by the points of the plugs being too much apart; (c) by the cables being faulty or the connections being badly made. Very often the carburetion is faulty.

In any case, care should be taken when stopping the engine to short-circuit the magneto and to cut off the supply of gasoline (by closing throttle) when the engine has ceased running. In this way the cylinders are prevented from being filled with air. If the cylinders contain gasoline, the starting of the engine is always easy. If on the contrary, the supply of gasoline (throttle) is cut off while the engine is running, the cylinders get filled with air and on restarting, it has to be driven out and replaced by gasoline.

Coil. If on turning the magneto no high tension current is produced, it may be that the coil is damaged (this applies to low tension magneto with separate coil, or the secondary winding on the high tension armature), and should be returned to the manufacturers in order to have it either repaired or replaced.

Magnets. Remagnetizing will not be necessary unless the magnets have lost their magnetism due to the fact of their having been taken off and left, for a long period, without their bases having first been bridged by a piece of iron; or else if, after having taken out the armature, no piece of iron or steel has been placed on the pole pieces. This piece of iron or steel should remain there until the armature is replaced. It often happens that on remounting the magnets, a mistake is made in placing them in the wrong order, whereby their magnetic power is completely neutralized.

When it becomes necessary to take the magneto apart you will do well to draw a chalk line across one side of all the magnets or be careful that the same marks stamped on the magnets appear all on the same side. All north poles are to be replaced on one side and all south poles on the other. See charts 148 and 149 for remagnetizing.

Difficult starting is in many cases caused by the fact, that upon stopping the engine, the supply of gasoline is cut off, while the ignition only should be stopped. In this way the cylinders are filled with air only, without any gasoline and no explosions are possible. By opening the throttle about one quarter of the way, draw in a "mixture" of air and gas then engine will start.

By cutting out the ignition only, there will be gasoline vapor in the cylinders instead of air and the engine can be set in motion by half turn of the starting handle. i. e., by a sudden pull at the moment of highest compression.

Springs. Examine from time to time whether the safety contact spring sliding in front of the cam presses sufficiently against the cam; as soon as the steel bosses are rather worn, the spring should be replaced by a new one. By putting some oil now and then upon the steel parts, too rapid wear will be prevented.

Carbon Brushes. The low tension carbon brush, as well as the high tension distributor, will wear off in the course of time and have to be replaced by new ones. i. e., in the first case as soon as the spring presses down on the metal holder of the carbon, and in the second as soon as the spring of the carbon comes out of its case.

When magneto armature rubs against pole-piece, it is likely due to worn bearings or broken ball, loose screws on armature head, or gears meshed tight causing undue wear on one end of shaft.

Synchronizing Distributor with Armature.

Synchronizing the interrupter points, cam and distributor. If magneto has been entirely dissassembled proceed as follows:

Bosch DU4 as an example: (1st) place distributor brush on segment—just starting; (2nd) place armature in direction of rotation 5/32 inch from pole shoe—just breaking (see fig. 2, page 313); (3rd) breaker to start opening advanced.

Bosch DU4, model 5: (1st) place brush in center of segment; (2nd) armature 1/16 of an inch from pole shoe; (3rd) breaker points will start to open at full retard.

Bosch dual system: (1st) place brush 1/8 inch on segment; (2nd) armature breaks from pole 1/64 inch; (3rd) breaker points will separate at full advanced position.

Magneto Trouble Indications.

Failure of magneto to give the proper spark may be due to:

Armature: weak current; open primary; open secondary; shorted primary or secondary.

Condenser: short circuited; open circuit—see page 303.

High tension circuit: brush on collector spool cracked or punctured; loose connection to collector spool; defective distributor brush.

Spark plugs: improper gap; fouled—see page 304.

Magnets: weak; reversed.

Contact breaker: points worn; points too close or too far apart; weak spring—see page 304.

Assembly: gear bearing worn or dry; armature rubbing on pole pieces and end play in armature, due to loose screws in armature head or worn bearings.

Procedure of Diagnosis.

If missing continues to occur and the cause cannot be located, then begin the diagnosis as follows; being sure that the

(1) Spark plug gaps are correct—about .020 to .031 inch gap.

(2) Magnets are not weak.

(3) Interrupter points are clean and correct distance apart—about 1/64 inch, see page 304.

(4) All connections are tight from magneto and switch.

(5) Magneto is properly set.

(6) Carburetor adjustment is correct.

(7) Armature is in perfect alignment—see page 302.

(8) Determine if missing occurs when running slow, or fast.

First Determine if the Trouble is Due to the Magneto.

By first running engine on the battery and coil system of ignition—then switch on to the magneto side—if the engine begins to miss, yet runs on battery side, this will indicate the trouble is in magneto.

Quite often, however, this test is made when engine is running slow and if engine misses only on slow speed, try setting plug points closer together and adjust interrupter or clean interrupter points, look for a loose wire or strand of wire short circuiting. If everything else, including carburetion is apparently o. k. **and engine runs on coil and battery, but misses on magneto,** then the trouble is likely due to weak magnets or punctured or short circuited insulation.

Before deciding it is the magneto winding giving the trouble, be sure magnets are strong—see test below, and **test magneto,** per pages 303, 302.

To Test Magneto on Engine.

First test which cylinders are missing, per figs. 1, 2, page 237. **If missing in all,** then trouble is likely in magneto or carburetion. **If in one regularly,** then likely due to spark plug or wiring.

Run engine slowly, advance and retard spark, note if missing, **then speed engine up** and advance and retard and notice if missing, thereby determining if missing is on low or high speed—then see page 298.

If engine is running and spark jumps 3/8 of an inch and is blue and has volume and spreads when blowing on it, then it is not likely that magneto winding is defective. If it will not jump this far regularly and is thin and yellow and cause not elsewhere, then test armature winding, per page 304.

****Note: Magneto could continue to give a weak spark, even though winding was defective,** as only part of the winding may be cut out.

Magneto Repairs.

Attaching magneto to engine: A good plan for attaching is shown in fig. 1 (upper illustration), chart 147. The base, however, should be brass, or other non-magnetic metal, unless the magneto itself is provided with a brass or aluminum base.

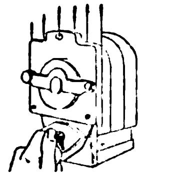
Magnetos are usually coupled to the shaft which drives it, in this case it is an easy matter to loosen the coupling and reset it. If, however, a coupling is not provided, then it will be necessary to remove the gear case cover and set by meshing the drive gear. A good type of coupling is shown in fig. 3 (upper illustration), chart 147. Another type is known as a **flexible magneto coupling,** this type permits the magneto being slightly out of line.

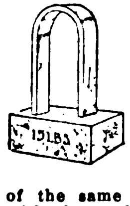
†Remagnetizing Magnets.

This subject is dealt with in chart 148.

To test if magnets need recharging. A good way to test, is to place a steel bar or pliers across the bottoms or the sides of the magnets on the magneto. If they pull fairly strong, you may know that they are in fairly good condition, and you can ascertain whether or not they are pulling fairly strong by testing some other magneto which you knew is all right. In doing this, however, turn armature so points are just separating.

Another method is to turn over the armature of the magneto by hand as shown below, and when the armature gets to a certain position resistance will be felt. This resistance is due to the breaking of the lines of force by the armature. Since weak magnets produce a weak field little resistance will be felt. The magnitude of the resistance will not be known to the repairman unless he has tried previously to turn the armature when the magnets were in good condition or unless he trys another magneto and compares the results.





Another test is to test the magnet's capacity of lifting 15 lbs. as shown. On small magnets 10 lbs. would suffice.

A good plan is to test the ability to lift of a new magnet of the same size, etc., and compare the results with those of the one just charged, or which you know is charged.

*See index for "testing coils with a test light," also pages 302, 304, 234; "testing coils."
†A. L. Dyke, St. Louis is prepared to re-magnetize and repair coils and magnetos. **See page 302.

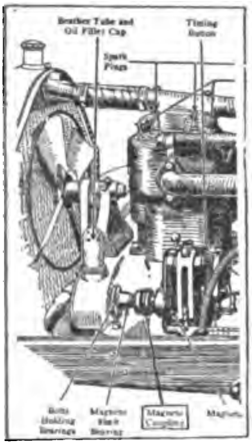


Fig. 4.—When a coupling is provided for the magneto to the driving shaft, it is a simple matter to set the magneto by uncoupling the coupling, otherwise the gears must be de-meshed.

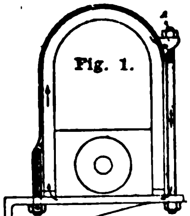
The modern coupling is one with leather between—see page 312.



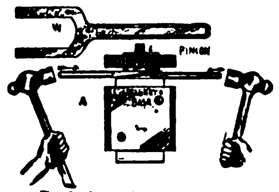


Fig. 2.—A special tool for removing gears. Especially adapted for removing magneto gears on a tapered shaft.

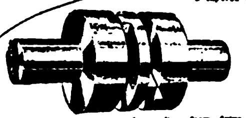

Fig. 3.—A good form of coupling from drive shaft to magneto. The Oldham used by Splitdorf.

Fitting Magneto.

Fig. 1.—One method of fitting a magneto to engine frame is by means of pins, and is held down on its base by a strap of metal passing over the magneto—this is a favorite method. The band is usually in two sections, as illustrated in fig. 1 (above), thus bringing the nut (A), which tightens or loosens the band at a point which is easily gotten at. In other instances, however, the magneto is bolted direct to its base and since the nuts are below, it is almost impossible to remove the magneto after the engine has been placed in the chassis. It might also be worth mentioning, at this point, that some magnetos are strapped down on iron or steel brackets and no precaution taken to see that brass or non-magnetic fittings are used at the point (A) where the tightening bolts joined the straps. A little thought will show that, as illustrated, **a portion of the lines of force will return by way of the bolts and base instead of through the armature.** Although the effect of this may not be noticed at ordinary speeds, it will have much to do with determining the lowest speed at which a good spark is produced. **Magnetos therefore must have brass or aluminum base.**

Testing a High Tension Coil.

Connect the low-tension circuit of the coil with a new battery of the same size as is used on the car, and provide a spark gap of suitable size on the high-tension side.

For 60 lb. compression the gap should be ¼ in. in the atmosphere and for 90 lb., ⅛ in. Fig. 2 (below), shows the conventional arrangement which may be used when the coil is not on the magneto armature.

The low-tension circuit is closed and then quickly opened, and if the coil is in good condition a spark should occur at the high-tension gap, fig. 2, also see pages 284 and 236.

There is no necessity of removing the coil box from the car to do this work if the test wires are long enough to be attached with the coil in place.

Unless the internal wiring of the coil is known, some experimenting will be required in order to connect up with the right terminal. Probably the simplest method of procedure is to note the terminals to which the low and high-tension wires are attached, and attach the test wires accordingly.

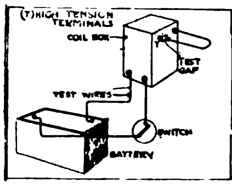

Fig. 2—A battery, switch and test wires are all that are necessary to test a coil.

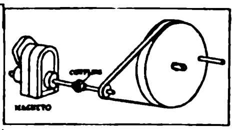

Fig. 5—Another method for determining the condition of the spark produced at high speeds.

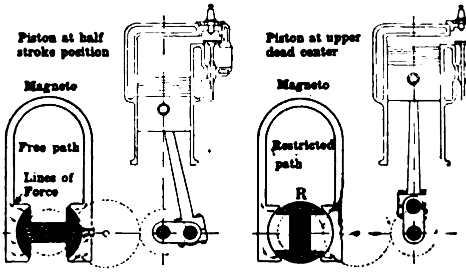
Testing a Magneto.

****Testing high tension magneto;** oil magneto; connect distributor wires to spark plugs and set points 1/16" gap; then run magneto 40 min. at 1,500 r. p. m. with interrupter full advanced and 10 min. at 3,500 r. p. m. full advance, and 10 min. 150 r. p. m. noting that it runs equally well during last run in either advanced or retarded position.

During the runs the contact points should not spark or flame excessively. There should be no excessive noise or stray sparks about magneto. The *safety gap in magneto should be 5/16" and should not spark at any of the above speeds if spark plug gaps are not over 3/16" during the test. The spark should jump the safety gap when armature revolves 60 r. p. m. with spark plug or distributor wires removed.

One method of driving a magneto on a test is by an electric motor, per page 304. Another method is shown in fig. 5. When testing magneto or coil, run until heated up.

Be careful the armature is in perfect alignment. If a ball is broken the armature shaft will be out of line and permit armature to rub against pole piece, or armature heads may become loose, or drive shaft may be worn unduly on one end of armature by the gear driving it meshing too tight.



Left, position of magneto armature with piston of engine at mid-stroke showing free path for magnetic lines of force between poles of magnet. Right, position of magnetic armature with piston at upper dead center showing restricted path of lines of force through armature

How Poor Compression Weakens Magneto Magnets.

If engine has good compression piston will stop on quarter and not dead center. Result, free path for magnetic lines of force forming virtually a complete magnetic circuit per fig. 1.

If engine has poor compression, even in one cylinder, the piston will stop on dead center. Result, the path for the magnetic lines from one pole piece to the other is very poor and consequent result is the same as when a horse shoe magnet is allowed to lay around without its keeper—the magnets will gradually lose their magnetism. (from Motor World, by Thurston W. Turner.)

One Reason Why a Magneto Fails to Spark at Times.

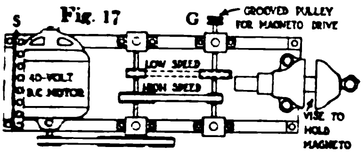
A high tension magneto secondary winding insulation in time, may become hardened and leaky from heat, caused by strain of running with too wide a spark plug and safety gap.

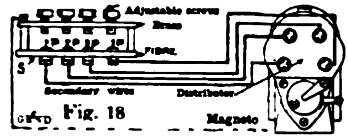
A wide open throttle increases compression and plug gap offers resistance which increases voltage in winding, with result spark jumps the insulation internally instead of plug gap.

When running on a level with almost closed throttle, compression is less, result, spark although weak may jump plug gap. This accounts for reason why a magneto armature may require rewinding, yet produce spark at times—see also page 275.

CHART NO. 147—Attaching Magneto to Engine. Couplings. Testing.

A coil tester consisting of meter and switch and instructions for testing coils can be secured of A. L. Dyke, Pub., St. Louis, Mo., price seven dollars. *See pages 273, 275, 299 for safety-gap principle. **See also pages 301, 304.





Magneto Testing Apparatus.

When considerable testing is done, a countershaft with pulleys, and used in connection with a ⅛ h. p. electric motor can be used to run the magneto at various speeds to test the length of gap and volume of spark at various speeds—see fig. 17.

An adjustable gap arrangement can easily be made as per fig. 18. Note the length of the gap can be adjusted.

To test magneto, place it in the vise. Connect secondary terminals to the stationary points P. Place a grooved pulley on the taper shaft of magneto and connect it with grooved pulley G on the second counter shaft by means of a round belt. Then run magneto and test as per page 302 and 304.

If the spark does not test out satisfactorily then disassemble magneto and test armature and condenser per page 304, 308.

To Test Condenser.

All high tension magnetos and high tension coils are provided with condensers, as explained on pages 273 and 228.

A condenser usually consists of 161 layers of mica insulation material, between which sheets of tin-foil are laid so that each layer of tin-foil is electrically insulated from its neighbor—see page 228. In some coil condensers the paraffined paper is used instead of mica which is not as efficient.

Condensers can be removed, but it is usually necessary to unsolder the primary armature winding connections to one of its terminals, the other condenser terminal being grounded to the armature frame, per fig. 1, page 268.

Usual troubles are due to the sheets of tin-foil becoming grounded, or one of the connections open. **Indication of a defective condenser** is excessive sparking at the contact-breaker points which become pitted white.

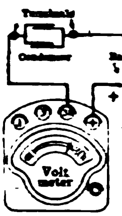


Fig. 23

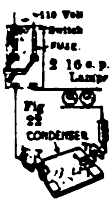


How to test: Use 110 volt direct current with one or two lamps connected as shown in fig. 22. **If condenser is properly insulated and not grounded,** the lamp will not light when switch is closed. **If it does light,** then condenser is grounded and if ground cannot be removed, a new condenser is necessary.

Another test is per fig. 23; use a 30 volt range volt meter and connect as shown (and page 414). **If condenser is good,** no indication will be obtained. **If it is grounded,** an indication will be obtained.

Magneto Magnets.

Magnets Made of Steel.

The magnets used on both low and high tension machines are of special tungsten steel made as hard as it is possible to obtain them, so hard that a sharp file cannot make any impression on the metal. Much depends on the class of steel used—a special grade known as magnet steel is now being adopted. **The retention of magnetism** by steel is a very curious and interesting property. It **resides only on the surface** of the steel, and it is found that a much stronger magnet is obtained, weight for weight, by making it in sections, one placed over the other, than in using a massive single magnet. **Magnetos** have two magnets placed side by side; some have a single large magnet—they were formerly two—superimposed.

Soft steel is easier to magnetize than hard steel, but the former loses it quickly if submitted to vibration. The hard steel magnet loses its magnetism very slowly, although the magneto has, as a matter of course, to withstand much vibration from the engine, etc.

Weak Magnets.

After magneto has been in use for **approximately two years,** the magnets may have become weakened. The length of time a magneto retains its magnetism is governed by the quality of steel used in the magnets and also, to reason explained bottom of page 302, see also page 301.

Misfiring will be the result of weak magnets. There are other conditions however, to determine before blaming the magnets, for instance the missing may occur from spark plug points not being set equal distances apart.

The best remedy for trouble from this source is obtained by having magnets of the magneto recharged; but temporary relief often may be obtained by adjusting the points of the spark plugs so that all are brought a little closer together; and all equally distant apart; that is, the gap between the points should be the same on all plugs. If the gaps are not all the same, then the plug with the widest gap generally will be the first to misfire, as a result of weak magnets.

When running a car slowly on the high-speed gear, the engine may be turning over so slowly that the magneto will not generate the required current and misfiring accompanied by a jerky action of the car will take place. When this occurs, one should either shift to a lower gear, or switch over onto the battery. The better plan is to shift to the lower gear, if in congested traffic when the car speed cannot be increased; for by so doing one speeds up the engine and magneto; more current is generated, a hotter spark and missing eliminated.

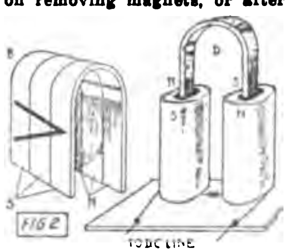
*Remagnetizing Magnets.

In charging by the use of an electro-magnet, one of which is shown at D (below), unlike poles must be placed together. That is, the north or N pole of the magnet should be in contact with the S or south pole of the electro-magnet and the south pole of the magnet with the north of the charging device. The electro-magnet has polarity because the fields are wound in opposite directions. It is determined easily whether the magnet is in its proper position even if the poles are not marked. Since like poles repel and unlike attract each other, when the magnet is placed in contact with the electro-magnet cores they should hold fast. If there is a repulsion then the magnet should be reversed.

After charging has been completed and the magnets are assembled onto the magneto it is necessary that like poles be in contact. That is, if the magneto has three magnets the north poles of these must be in contact as shown in fig. 2. Often some figure is painted upon the magnets, such as is shown, and when this figure is made by the assembly of the magnets the poles are properly facing. It is best then to determine the proper polarity by the attraction and repulsion methods; like poles repel each other and unlike poles attract each other.

Another method to find N & S pole: S pole of magnet will attract N pole of compass, see fig. 3.

Keeper: When magnets are disassembled, place an iron bar (called the "keeper") across ends to retain magnetism. This should be done instantly on removing magnets, or after remagnetizing.



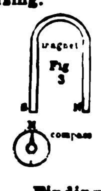


Fig. 3 — Finding polarity of a magnet with a compass.

CHART NO. 148—Condenser Tests. Magneto Magnets.

*A good magnet re-magnetizer to operate from a 6 or 12 volt battery or dry cells, price $7.50, can be secured of A. L. Dyke, Pub., St. Louis, Mo. An attachment to recharge Ford magnets, one dollar extra.

Testing The Magneto on The Bench.

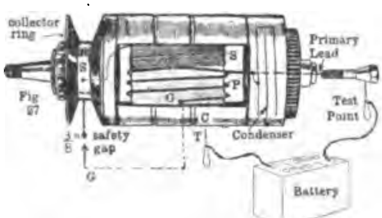
It is not advisable to take the magneto apart unless you know it is defective. Before taking apart read pages 301 and 303 carefully.

To Disassemble the Magneto.

Remove interrupter, distributor block, gear housing, magneto and bearings. This will leave armature as shown in fig. 27. Be sure and place a "keeper" on the magnets the instant they are removed, per page 303.

To Test Complete Armature.

Use a 6 volt battery and test points as shown in fig. 27. Connect one test point with primary lead and the other test point (T), touch to armature core at (O) for instant. The current then travels through **primary winding and condenser, and is induced into secondary winding.



If a spark occurs at the test point, and at the same time it jumps the secondary gap of ⅜ inch, then we know the armature has tested out o. k.

If there is no spark at all, then we know that there is an open circuit in the **primary winding.**

If there is a heavy spark at the test point when touching core, then there is a short circuit in the condenser or primary winding and it is necessary to disassemble armature. This of course, would mean a dead short circuit on the battery.

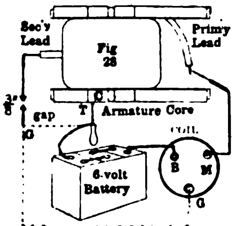
To Disassemble Armature.

Remove screws, armature heads, collector spool, etc., as shown in fig. 22.

To Test Secondary Winding

***A single wound primary coil with a vibrator and condenser fitted internally can be used for this test.** A *Pfanstiehl coil, is excellent for this purpose, or a Heinze coil unit as used on a Model N Ford, with the secondary winding short circuited, could also be used.

Only the primary winding in connection with the vibrator is necessary, as the secondary winding on armature is used instead, hence reason for shorting the secondary terminals.

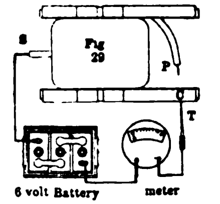


If secondary is o. k., then on touching test point (T) to armature core, fig. 28, the spark will jump the ⅜ inch gap.

If secondary is short circuited, the secondary spark on this test, will arc from secondary winding to armature core, but will not jump the gap.

If secondary is open, a spark could occur, as it could jump the open gap internally, but it would be weak.

To actually tell if a secondary winding is open, about the only plan is to put a very low reading sensitive voltmeter, connected with a 6 volt storage battery across the winding per fig. 29. If circuit is open, meter needle will not move at all. If it moves at all, then this circuit is o. k.



Note: Never run current through armature when magnets are on the magneto, it may be run through in wrong direction and tend to demagnetize them.

Magneto Spark Plug Gap.

.020 to .031" (see foot note, page 275), is correct gap. **If too wide,** starting will be hard and there is a liability of breaking down the high tension insulation of winding. **If too close,** they are more likely to become shorted, due to carbon collecting on gap points.

Compression of an engine determines type of magneto to be used. For instance if magneto is used on a high compression engine, then points must be closer than on a low compression engine. If, however, the magneto is made of sufficient capacity for the high compression engine, then the gap could be normal, or .025"—see page 275.

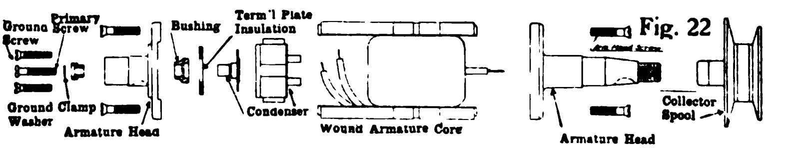
Contact Breaker.

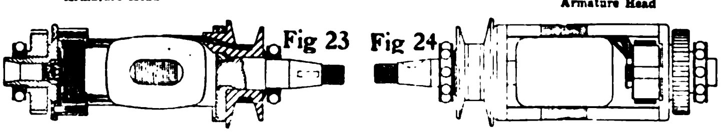
Usual troubles are dirty points; platinum worn off; arcing at points; gap too far apart or not far enough; points not genuine platinum.

To test platinum points, use nitric acid, if it eats the points, they are not genuine platinum. The best test is to use a jeweler's stone test (ask any jeweler). Platinum, or platinum-iridium is generally used for points on magnetos and Tungsten (which is very hard), for points on battery and coil system interrupters. See also page 234.

Disassembly and Assembly of the Berling Magneto.

Fig. 22 shows how the parts of the armature on the type E and F Berling magneto disassembled. The interrupter which was first removed and the magnets, distributor, etc., are not shown. On most magnetos there is but one primary connection to the condenser, the other primary terminal being grounded, also one terminal of the condenser. Here primary leads are connected to condenser and one terminal of condenser is grounded which gives the same results. The primary leads are soldered to condenser.





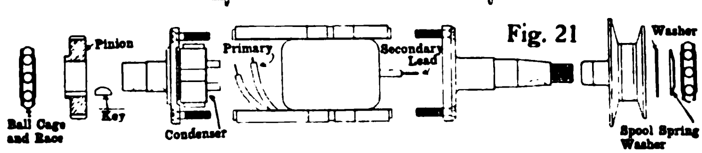


Fig. 21 shows armature parts being assembled.

Figs. 23 and 24; sectional and top view of completed armature.

CHART NO. 149—Magneto Tests. Armature Disassembly.

*This coil can be supplied by A. L. Dyke (Elect. Dept.), Granite Bldg., St. Louis—price $7.50.

**Secondary is grounded. On some magnetos it connectsto two collector rings.

INSTRUCTION No. 24.

*IGNITION TIMING: Advance and Retard of Spark. Relation of Time of Spark to Combustion. Relation of Spark to Speed. Relation Between Piston, Armature, Interrupter and Distributor. Setting the Time of Spark. Pointers in connection with Setting of Magneto. Setting Time of Spark of Vibrator Coil System. Setting Time of Spark on Engines of Leading Cars. Spark Control and Overheating. Finding Position of Piston. Conversion Table; degrees to inches.

Since in regular operation of the engine the charge is ignited just an instant before the top of the compression stroke, the **magneto** armature is so set relative to the engine crank shaft that the maximum induction effect occurs at this moment.

It is, however, necessary to be able to vary the point in the cycle at which the ignition occurs, since, when the **engine is** cranked **by hand**, the spark must occur after the end of the compression stroke, or else the engine may kick back.

If started by some form of self-starter it is then possible to start with slightly more advance than when starting by hand, because the self-starter turns the engine crank faster.

**Meaning of "Advance" and "Retard" of Spark.

The meaning of "**advance**" of spark; to cause the spark to occur **earlier**, before piston is on top of compression stroke.

The meaning of "**retard**" of spark; to cause spark to occur **later**. On engines that are cranked by hand, the spark is usually set "retarded" after top, so that there will be no danger of a kick back.

The exact position to "advance" or "retard" is determined by running as far "advanced" as possible at all times until a knock is detected, and then "retard" until the knock disappears. The driver will then soon learn the exact position where engine gives the greatest power. Remember **also**, that a retarded spark heats up the engine, see page 69 and 319.

Control of Spark.

Principle. As the spark occurs only when the primary circuit is broken by the opening of the platinum contacts, the timing of the spark can, therefore, be controlled, by having these platinum contacts open sooner or later. This latter is accomplished by the angular movement of the timing lever. This movement gives a timing range of about 35 degrees. The spark is fully retarded when the timing lever is pushed as far as possible in the direction of rotation of the armature and is advanced when pushed in the opposite direction.

Magneto spark control. In order to make it possible to vary the time of the spark on a magneto, the circuit breaker housing (F, by means of lever L, chart 130, also fig. 3, chart 150) is so arranged that it can be rocked around its axis, being provided with a lever arm for the purpose, from which connection can be made to a spark lever on the steering post.

It will readily be understood that if the armature shaft turns right-handedly, and if then the circuit breaker housing is moved through a certain angle in a right hand direction, the contact points A and B will separate later, with relation to the position of the engine crank shaft; while on the other hand, if the housing F is moved in a left hand direction the circuit breaker point will open earlier. In this way the point at which the spark occurs can be shifted through an angle of about 35 degrees.

Coil and battery system control: On the Delco and Atwater-Kent or similar systems; the advance and retard is obtained by shifting the housing surrounding the timer and distributor and also by governor action (see charts 117 and 143.)

Spark Control Methods.

There are three general principles used for control of spark: (1) by hand, to vary the spark position, which would be termed "variable spark;" (2) by a governor, which would also vary the spark according to the speed; (3) a fixed spark.

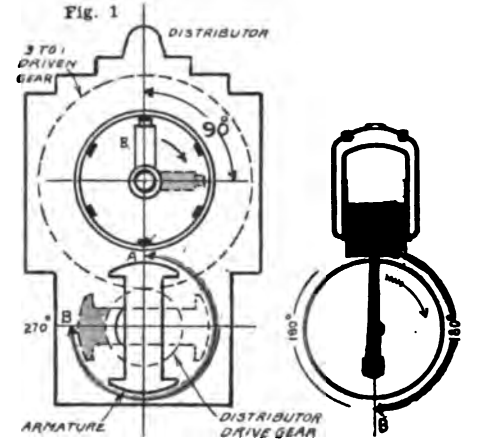
(1) By hand means the spark lever on the steering post shifts the commutator or interrupter. (see pages 222, 248, 66.)

*For ignition systems, firing orders, valve timing, etc. of motorcycle engines—see Dyke's Motor Manual.
**Also see pages 61 and 68.

Six Cylinder Magneto Speed.

Fig. 1. Note when **piston makes a full stroke,** or when **crank-shaft** travels 180° or ½ of a revolution, **armature** would turn ¾ of a revolution or 270° (A to B).

Fig. 1



Therefore if **crank** pin made 1 complete revolution, the armature would make twice ¾ or 1½ revolutions. During this 1½ revolutions it would have made 3 impulses.

When the engine crank, makes another revolution, then the magneto armature would have made 1½ revolutions more, or 3 revolutions to 2 of the crank, therefore, it would make 6 sparks during the 3 revolutions of armature, or 2 revolutions of the crank-shaft. Therefore the armature is geared to run 1½ times as fast as the crank-shaft.

The six cylinder engine crank must make 2 revolutions to complete its four cycle operation, therefore it would require 6 sparks during its 2 revolutions (720°).

The **distributor,** however, having the 6 plug connections to make during 1 revolution of its rotating brush (B), would have to be geared so it would make a connection every 60°, or 1/6th of a revolution. For instance: If crank traveled ½ of a revolution, or 180°, the distributor would travel 90°, or ¼ revolution.

If crank traveled 1 revolution, or 360°, distributor would travel 180°, or ½ revolution.

If crank traveled 2 revolutions, or 720°, distributor would travel 360° or 1 revolution.

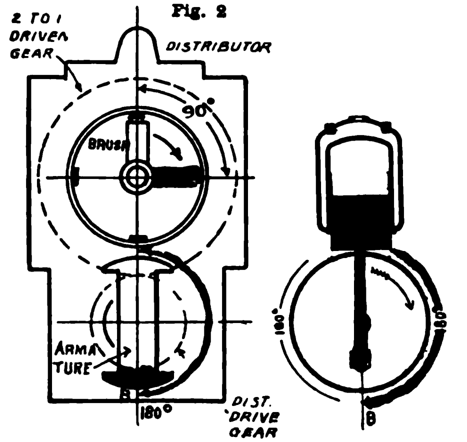
If one of the cylinders fired every 120°, or ⅓ of a revolution, (there being 6 cylinders to fire during 2 revolutions, or 720° travel of crank) then we would need 6 sparks or impulses during 720° travel of crank.

Distributor being geared one-half the speed of the crank-shaft, the segments would be placed 60° apart, therefore, when crank traveled 120° and required a spark, distributor brush (B) would travel 60°. There being 6 segments 60° apart this would give 6 sparks or impulses during 2 revolutions, or 720° travel of the crank, or 1 revolution, or 360° travel of the distributor brush (B). See also, pages 308, 309.

Four Cylinder Magneto Speed.

Fig. 2. Note if **crank** of engine travels 180°, **armature** also travels 180°. Both travel at the same speed.

Fig. 2



The four cylinder engine requires four sparks during two revolutions of the crank. The **armature** gives two sparks or impulses every revolution, therefore traveling at the same speed as the engine crank it will give four sparks during two revolutions.

The **distributor** would be geared one-half the speed. Every time the crank shaft moved 180°, or ½ revolution, distributor brush would move 90° or ¼ revolution.

The distributor always runs one-half the speed of the crank-shaft on all four-cycle engines. See also, pages 294, 295, 298, 308.

Clockwise and Anti-Clockwise Rotation of Magneto.

The illustrations show the cam and distributor as viewed from the front, or interrupter or distributor end. The rule is to view magneto from rear or drive-shaft end—and thus speak of it as "Clockwise" or "Anti-clockwise"—see pages 316, 296.

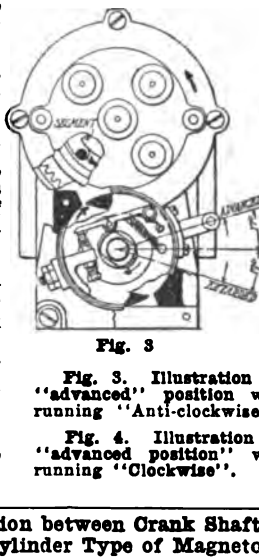


Fig. 3

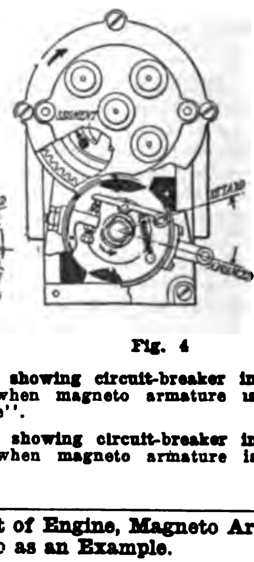

Fig. 4

Fig. 3. **Illustration showing circuit-breaker in "advanced" position when magneto armature is running "Anti-clockwise".**

Fig. 4. **Illustration showing circuit-breaker in "advanced position" when magneto armature is running "Clockwise".**

CHART NO. 150—Explanation of Speed Relation between Crank Shaft of Engine, Magneto Armature and Distributor. Six and Four Cylinder Type of Magneto as an Example.

If a magneto is used, the housing which the interrupter arm is placed on, is shifted in opposite direction of rotation to armature to "advance," or cause the spark to occur earlier, or, in the direction of rotation to cause the spark to occur later—chart 150.

When the spark is advanced or retarded by hand, it is left to the good judgment of the driver to manipulate the spark lever; except where the system is equipped with an "automatic" advance.

(2) *The automatic advance is probably the most satisfactory with battery and coil system of ignition, because the spark occurs just at the right time automatically, and there is no guessing as to just how far to advance or retard at various speeds, see pages 249 and 246.

(3) The fixed spark is sometimes used with a high tension magneto, which means, the time of spark is fixed at one position, usually advanced, and the contact breaker, breaks at one position regardless of speed. This system has not proven very satisfactory on engines where speed varies, but would be satisfactory if the speed of engine was constant and did not vary. The objection, however, would be in starting—liability of a kick—for the spark would necessarily be placed advanced for proper running. (see page 311.)

The disadvantage in one instance; suppose the car was running up hill, the charge of gas would be heavy and throttle would be open, consequently a high compression. If the spark was advanced, which it usually is with a fixed spark, the spark would occur at such a time that the combustion would take place before piston reached the top, because piston would be moving slow at ten miles an hour; the result would be, the force would be exerted on the head of piston causing the momentum of piston to buck against the force of the combustion, which would invariably cause a knock and loss of power.

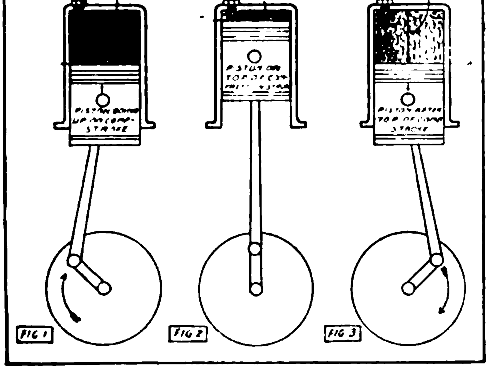
A remedy, but one that is not efficient, would be to cause the combustion to take place later, say on top or after top of compression. We could not do this by shifting the time of spark, therefore, about the only resource would be to enrich the mixture, by partly closing the air intake on carburetor. This would cause more gasoline to be taken in and the "rich" mixture would be slower to combust, and the effect would be the same as retarding the spark.

Where cars are equipped with a "fixed" spark, a rod could be fitted to the air valve lever to the dash. The fixed spark, however, is not at all advisable on variable speed engines.

**Relation Between the Time of Spark and Time of Combustion.

The combustion should take place as the piston is on top of the compression stroke, (fig. 2), because at that point the gas drawn into the cylinder has been forced up into the head of the cylinder and is at the point of greatest compression—hence more force exerted on the head of the piston when the explosion occurs.

If it occurs **after** the piston has started down, the compression it not as great. If it occurs **before** the piston reaches the top of the compression stroke, it is not as great. If running slow, the explosion occurring before the top of the stroke, the force will be exerted against the pistons travel, and will cause knock and loss of power.



An example: Fig. 1—Note the piston is going up on compression stroke, pushing or compressing the gas (which was drawn in at the previous suction stroke), into the head of cylinder. At the point piston is now, the gas is not very tightly compressed.

Fig. 2—The piston has now reached the top of compression stroke and the gas is packed tight into the head of cylinder. It is clear that if the combustion took place at this time—the force against the piston would be greater than if the combustion did not take place until piston had passed over the top and was on the way down, as in fig. 3.

Also observe that if the combustion took place before the piston reached the top of the compression stroke, as in fig. 1, especially if running slow, the power would be exerted on the up coming piston's momentum and not only cause a falling off of power, but a knock would occur, caused by the sudden reverse force.

Remember, the momentum of the fly wheel carries the piston up and down on the other three of the four strokes.

*Note—This automatic spark control takes into account variations in speed only. See pages 246 and 249. **See also, page 277, "advantage of having two spark plugs."

Time for the Spark to Occur.

There is a difference in time, between the time the "spark" is made at the spark plug, and the time the "combustion" of the gas actually takes place. If combustion took place immediately that the contact was made or broken, then the proper time to set the spark to occur would be on top of the compression stroke.

But as stated, there is a slight difference in time allowed for the gas to burst into full explosion after spark occurs; but as we desire that full explosion occur at the highest point of compression, **we will figure out just how we can make the combustion take place at the highest point of compression.**

***First: We must figure out how far in advance of the top of the compression stroke the spark must be set to occur,** in order to have combustion take place on top of the compression stroke.

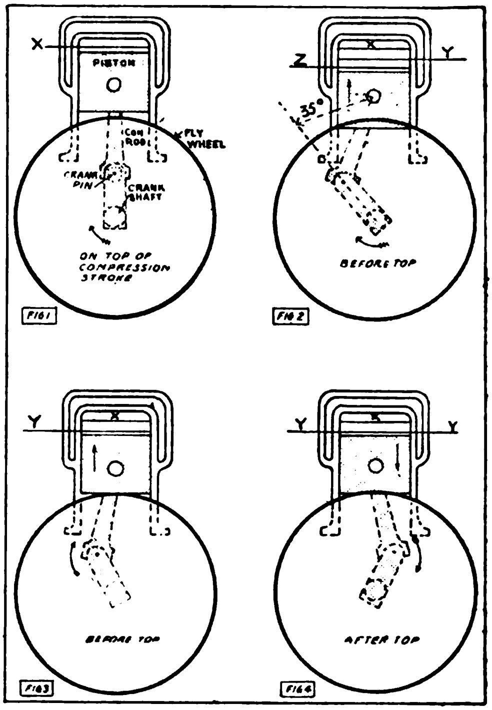
There are two main points to be considered; the system of ignition being one; if a coil and vibrator system is used, then it is natural to suppose that the time consumed in making contact on the commutator and the time of action of the vibrator, will consume more time than a single contact, as in a magneto or single spark system. Therefore if a vibrator coil system is used, we would have to set the spark to occur a longer time before the top of the compression stroke, than if a quicker single spark system of ignition was used.

The second consideration is speed; if the piston was traveling slow, the spark would be set (retarded) to occur later or nearer the top of cempression stroke—than if engine was running fast.

†Speed Relation to Time of Spark.

Suppose engine was running 500 revolutions per minute. Taking (X), fig. 3, as top of compression stroke; the distance to set spark would be, say at (Y), in order to give the combustion time to take place when piston was on top of compression stroke.

Now if the spark was fixed to occur at (Y) (fig. 3), and speed was increased to 1000 revolutions per minute, then the piston would go to the top of compression stroke at (X), (fig. 4), and pass over it and down to (Y), on the other side or down in power stroke, before the process



of combustion was completed. The result would be a loss of power during the pistons down travel between the points (X) and (Y) (fig. 4), the full force of the explosion not being exerted on the piston until the latter point (Y) was reached.

To increase this, it will be necessary to recalculate the piston speed at 1,000 r. p. m. and set the spark at a point say, (Z), fig. 2, which will allow of complete combustion by the time the piston reaches the top of compression stroke (X).

Setting the time of spark to occur before the top of compression stroke, is called advancing the spark.

In setting a magneto—the usual extreme range of advance on a magneto is 22 to 35°, therefore if you wanted to set the spark to occur 35° at full advance position so that you could have spark occur 35° before top, when running at full speed—simply place piston on top of compression stroke, set contact-breaker in "retard" position.

If you only wanted 30° advance at full speed, place piston 5° past the top of compression stroke and set breaker box housing at full retard.

**Speed Relation between Crank Shaft of Engine and Cam Shaft. Also Armature of Magneto and Distributor.

On a four cylinder, four-cycle engine, crank-shaft turns two revolutions (or 720 degrees) to complete its four-cycle operation, explained on page 58: cam-shaft turns 1 revolution; magneto armature turns 2 revolutions; magneto distributor brush, 1 revolution (see pages 294, 306).

Four sparks are necessary during the 2 revolutions of crank-shaft, therefore, as magneto armature turns 2 revolutions, same as crank-shaft, it produces 4 sparks, or a spark at every ½ revolution. **Distributor** brush is geared to turn ½ the speed of magneto armature, therefore, it will turn 1 revolution (360 degrees) to 2 revolutions of crank-shaft. As the 4 contact segments on distributor are spaced 90 degrees apart, then 1 revolution of distributor brush will make 4 contacts, producing 4 sparks 90 degrees apart during 1 revolution of distributor brush, or 180 degrees apart relative to crank-shaft, or 4 sparks to 2 revolutions of crank-shaft (see page 294 and fig. 2, page 306).

A two-point cam is used on magneto contact-breaker, which interrupts the primary circuit twice during each half revolution of armature.

On a six-cylinder, four-cycle engine, crank turns 2 revolutions to complete the four-cycle operation, just the same as the four-cylinder engine. The cam-shaft also turns the same as the four-cylinder engine, that is, 1 revolution to 2 of crank-shaft.

*See page 311. †See also page 319. **See also pages 294 and 306.

But six sparks are necessary during the two revolutions of the crank-shaft, because the crank shaft is divided into three pairs of throws (see page 122), each pair firing 120 degrees apart, or 1/3 of a circle. It is then necessary to gear magneto armature so it will turn 3 times to the crank-shaft 2, or 1 1/2 times to each revolution of crank-shaft. Armature produces 3 sparks during 1 1/2 rev., or 6 sparks during 3 revolutions (see page 306, fig. 1). Distributor brush must turn 1 revolution to crank-shaft 2, therefore, if armature turns 3 times when crank-shaft turns 2 times, then distributor is geared from armature shaft to turn 1 rev. when armature turns 3 rev., or 1/2 rev. when armature turns 1 1/2 rev.

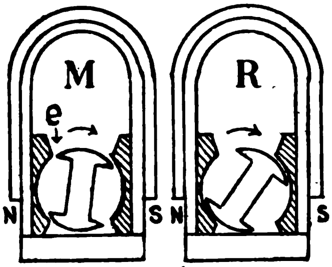
As the 6 contact segments on distributor are set 60 degrees apart, then 1 revolution of distributor brush will make 6 contacts, producing 6 sparks 60 degrees apart during 1 rev. of distributor brush, or 120 degrees apart relative to crank-shaft, or 6 sparks to 2 rev. of crank-shaft (see pages 306 and 294).

A single cylinder, four cycle engine requires only one spark every other revolution. The usual practice, therefore is to pass over one of the two "maximum" positions of the armature, simply by omitting one of the two cams, thus leaving primary winding short-circuited. Therefore as magneto is driven at cam shaft speed in this instance, a single spark is obtained.

Relation Between Position of Armature To Contact-Breaker When Advanced or Retarded.

Advanced position: Referring to (M), the armature cheek is just breaking from pole tip (e), in direction of rotation. This is the **maximum** position, or when current strength is strongest. At this time the contact-points (P), fig. 4, should separate. We learned this on pages 266, 267.

The magneto is set at the factory with armature in maximum position (M) and the contact-breaker housing fig. 4, is placed in an advanced position. That is, it is moved opposite to direction of rotation of cam (c). The cam (c) is set so that it causes points (P) to separate when contact-breaker housing is in the advanced position.



Armature in maximum position

Armature in retarded position

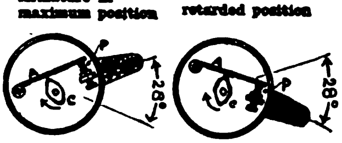


Fig. 4—Contact-breaker advanced

Fig. 6—Contact-breaker retarded

Retarded position: Suppose the contact-breaker housing is **retarded**, or moved with direction of cam rotation as far as it will go, fig. 6, (†28 degrees is average range), then points (P) of contact-breaker would not separate until armature had traveled *further in the direction of rotation, approximately the position shown in (R), at which point the armature has passed the maximum position and where the current strength is weaker. By referring to pages 266 and 267, we learned that the current strength begins to weaken the nearer armature travels to zero position after maximum position.

From the above explanation we learn that the spark is strongest at maximum position of armature (M), with contact-breaker in advanced position (fig. 4)—and that spark is weaker when contact-breaker is in retarded position (fig. 6)—because armature has passed the maximum position.

Let us see what happens when we follow out the magneto-setting given on page 310, which says: place piston on top of compression stroke, place contact-breaker in retarded positon, then turn armature in direction of rotation until contact-points just start to separate.

This would place the armature in position (R), and contact-breaker in position, fig. 6—both retarded. In this position the spark would occur when piston was on top of the stroke—but we must remember that the combustion is not instantaneous, therefore allowing for this lag, then the spark would occur when piston had moved slightly down after top—which at slow speed is desirable, but a weaker position of armature for starting engine on.

This is why spark plug points ought to set close together and why magnetos do not permit engine to throttle down as slow as a constant source of electric supply, such as a battery. The contact-breaker is usually retarded when engine is running slow and magneto armature is turning over slow, for reason stated on page 308, therefore both actions tend to weaken the spark. Always run as far advanced on magneto ignition as possible.

****As the speed of engine increases;** if contact-breaker was retarded and combustion was not instantaneous, as explained above, then the piston traveling fast, would move further down after top before spark occurred—therefore as we have a range of 28° which we can move contact-breaker housing so that spark will occur earlier, we then advance the contact-breaker more and more as the speed of engine increases, so that spark will occur before top of compression, thereby giving the combustion time to take place, when piston was on top or just starting down. The more we advance the breaker, the nearer we reach maximum or strongest position of armature. Therefore the current strength is greatest at high speeds.

When setting a magneto, the only point to consider is if breaker housing is to be retarded or advanced when interruption takes place and position of piston.

†The average advance range of armature is 22° to 35°—many magnetos actually having but 22° or 28° in which breaker moves from full advance to full retard. The Bosch Co., state that the Bosch 4 cyl. standard average speed (less than 2000 r. p. m.), has a timing range of 35° figured on magneto axis. On a timer or commutator, it is possible to get as high as 48°. For instance the Atwater-Kent timer; the timer shaft will advance automatically about 15° at high speed and the housing itself can be advanced about 33°—see page 248. **See also pages 308, 319.

*About 1/16 in. break from cheek of armature to pole-piece (e) when advanced, is the average break. The distance at full retard, would be about 22/32 in.

A 4 cylinder engine with a speed of 2000 or less, is termed average speed and gap between pole piece and armature cheek is 1/16 in. An engine with speed of 2000 to 3500 r. p. m. would be termed a high speed engine and in this case the gap opening is increased to 5/32 or 3/16 in.

Setting the High Tension Magneto "Retarded On Top."

(1)—**Place No. 1 piston on top of compression stroke.** To find compression stroke, see page 320.

(2)—**Uncouple magneto** from its drive shaft (see page 302, fig. 4). If magneto cannot be uncoupled, then time from magneto gear and gear driving it, by taking them out of mesh.

(3)—**Retard the breaker box** (also called interrupter) (F), by turning it in the direction of rotation of armature shaft, as far as it will go.

(4)—**Turn armature in direction of rotation until the distributor arm (DA) is on segment (S) of No. 1 spark plug cable connection, then turn armature, one way or the other slightly;** until interrupter arm (A), is just starting to separate the platinum point connection (P) with (K), which of course is caused by cam action as shown. In other words, just as the points start to separate, is the time to set the magneto.

(5)—**Couple magneto shaft, or mesh gears driving magneto** at this point, being careful to not move either the armature or piston—(see page 312).

(6)—**Now see that wire cables from distributor are properly connected,** as explained on page 296. In this instance, by looking at the distributor connections and noting direction DA turns, the firing order would be 1, 3, 4, 2.

The above setting is for retarded position of interrupter and piston on top—this setting would allow the spark to occur considerably **before** piston reached top of stroke when **interrupter** was **advanced,** which is usually the case with high speed engines, and the average and usual setting. Exact settings cannot be given—see page 311.

Setting Magneto "Retarded—After Top."

If instruction said, place piston say, ⅛ inch down after center of compression stroke with breaker box retarded, then this would not permit advancing spark so far ahead of stroke, and in some instances, this is done on slow speed engines and where very slow running or idling is desired, as truck and tractor engines.

NOTE—The armature turns in opposite direction to distributor, therefore always note direction distributor turns before connecting cables to plugs. To tell how an engine fires—see page 120.

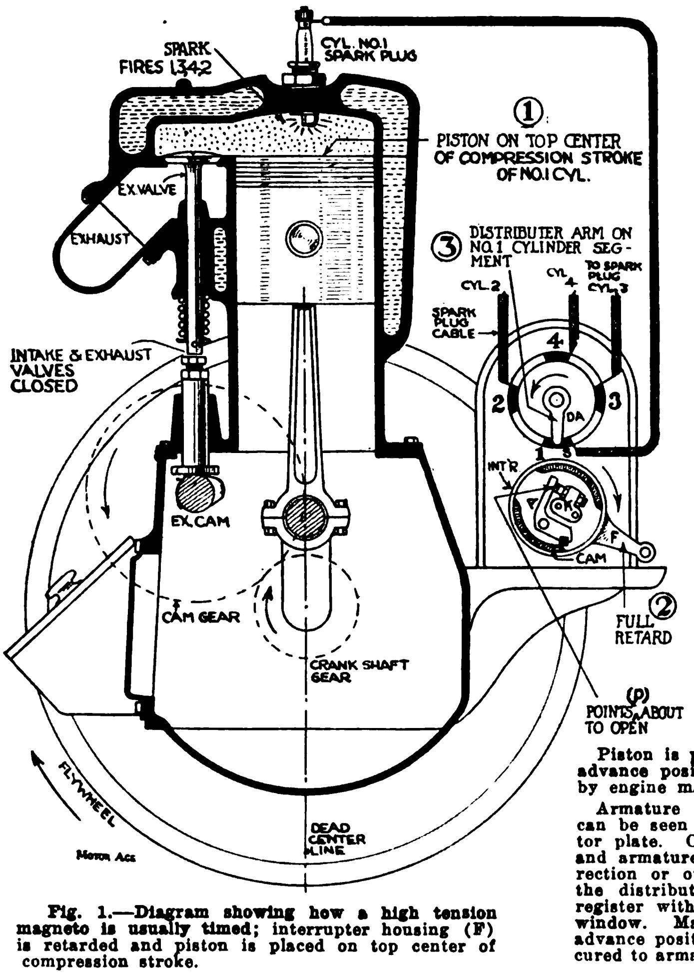

Fig. 1.—Diagram showing how a high tension magneto is usually timed; interrupter housing (F) is retarded and piston is placed on top center of compression stroke.

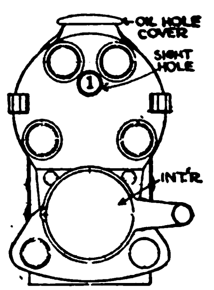
The breaker box (F) is stationary. The arm (A) and (K) revolve with armature (fig. 1).

Usually when viewing magneto from front of engine, the magneto would be facing in opposite direction—towards fly wheel, as the rear end of a magneto is usually driven from front of engine (see fig. 4, page 302 and page 312.)

When breaker points are just breaking, the armature cheek, breaking from pole (fig. 2, page 313) is in correct position, as it was set at factory. Likewise the speed of distributor to armature. See top of page 301.



Magneto Setting by Sight Hole.

Fig. 2. In some magnetos, ZR Bosch for instance, the magneto can be set by observing sight hole.

Piston is placed to firing position, for full advance position. This point is determined by engine manufacturer.

Armature is then rotated until fig. "1" can be seen in window in face of distributor plate. Cover of oil well is then raised, and armature turned few degrees in one direction or other until red mark on one of the distributor gear teeth is brought into register with red marks on the side of the window. Magneto is then turned for full advance position, and gear or coupling is secured to armature shaft. See top of page 297.

CHART NO. 150A—Setting the Time of Spark of a High Tension Magneto.

See also pages 290 and 292.

Setting Time of Spark of Magneto.

There are three general positions of piston, for setting the time for the spark to occur with the magneto:

(a) **Top** of compression stroke.
(b) **After** top of compression stroke.
(c) **Before** top of compression stroke.

A variable spark is where the breaker can be shifted to **advance** or **retard** the time of spark.

A fixed spark is where the breaker (or interrupter) is set or fixed at one position and cannot be varied. (see page 307.)

In setting a magneto of the fixed spark type, the instructions in reference to the moving of the breaker housing to the extreme advance or retard position are to be disregarded. The magneto should be set so that the spark occurs at the most advantageous point in the cylinder. This should be decided upon by the engine manufacturer, but where such information is not available, the spark should occur **at top-center.**

In setting a magneto of the variable spark type, one of three methods can be used:

(a)—by setting the piston on top of compression stroke and setting magneto breaker retarded. In this instance the most advantageous position of the piston for the spark to then occur, when breaker is fully advanced, is determined by how much advance the magneto is capable of giving. A high speed engine requires more advance than a slow speed engine. Magnetos vary from 22° to 35° or more. However, this is the average and general setting as explained on page 310. This is termed "setting piston on top and ignition retarded."

(b)—Sometimes, on truck and tractor engines and others, the spark is made to occur, when piston is down after compression stroke slightly—and breaker retarded. This would not permit advancing spark so far ahead of stroke—unless a magneto with a greater range was used, but this is done on slow speed engines and where very slow running or idling is desired.

(c)—By setting the piston before top of compression stroke and advancing the breaker would be termed "setting ignition advanced." The point to determine here, as to where to set the piston depends entirely upon where you wish spark to occur when breaker is fully retarded. For instance, suppose magneto range of advance was 35° and you wished spark to occur on top of compression stroke, simply set piston 35° before top, with magneto breaker full advanced. This would mean the same thing as setting piston on top with magneto retarded.

How The Instructions For Setting a Magneto Vary.

(1)—**set by marks on fly wheel.** Usually designated on fly wheel by a mark "C" or "F". This mark is placed in line with a punch mark on cylinder which indicates that piston No. 1 is on compression stroke and the magneto is to be set advanced or retarded as instructions may be given, at this point.

(2)—**by inches;** should the time for spark to occur be given in inches, for **example;** "time for spark to occur is full advanced position measured 3½ inches on fly wheel, before upper dead center."

These are the instructions given to set the valves on the Simplex engine, which is 4⅜ in. bore, 6¾ in. stroke and 18¾ in. fly wheel.

We would simply set spark lever or breaker on magneto at "full advance" position. Then turn fly wheel until the top center of compression stroke was reached—at this point a center mark on fly wheel is in line with a center mark on inspection hole. To have spark occur 3½ inches, as measured on fly wheel, would mean to turn fly wheel back or before top of compression stroke until this center line was 3½ inches away from center line on inspection hole. This would be the position for spark to occur.

The armature of magneto would then be uncoupled, breaker advanced, and armature turned slightly until points were just starting to separate. The coupling would then be tightened. This setting would cause spark to occur 21 degrees before top of compression stroke, with breaker housing advanced. (I found the degrees by referring to table on page 115).

(3)—**by measurement of armature from pole piece,** as per fig. 2, page 313, note (e), which is the distance the armature is to be set with piston on top and breaker points separating (see top of page 301).

(4)—**by sight hole,** per fig. 2, page 310.

(5)—**by degrees;** should the firing position be given in degrees, the movement of the piston, measured in inches corresponding with any given number of degrees of the crank shaft (where the relation of the crank shaft throw to the length of the connecting rod is as *1:5.4) may be determined by reference to diagram, page 314.

Example: suppose you were instructed to set the spark 34° before top of compression stroke— "advanced," on an engine with 5½ inch stroke.

(a) Turn to table on page 314; find 5½ inches at bottom. Next find 34° to right. Follow instructions for finding result given in chart. The distance in inches to place piston would be midway between ¼ and ⅜ of an inch from top.

(b) With this information you would then proceed to place piston, say, within 5/16 inch of top of compression stroke.

(c) The interrupter housing would then be full advanced and armature turned in direction of rotation until the cam just started to separate the interrupter points.

Timing the Bosch Dual Magneto.

This system is explained on pages 280 to 282. Note that there is a **battery interrupter** and a **magneto interrupter** (see fig. 6A, page 281). Although both are in the same housing on front of magneto—but one setting; that of **setting the magneto** **interrupter is necessary.

The **battery interrupter** is so arranged that it will then interrupt or break its circuit approximately 10 degrees later than the magneto interrupter; this feature gives the full timing range of the magneto. For instance; if timing lever is fully retarded and **magneto interrupter** set to break when piston is on top of compression stroke, the **battery interrupter**, with switch in battery position, would break slightly **after** top or 10 degrees later. Therefore set the **magneto interrupter** just the same as you would set the Bosch independent type of magneto.

Setting Bosch Independent Type.

Place piston on **top** of compression stroke and interrupter **retarded** as explained on page 310.

Magneto Drive Shaft.

Is usually tapered, therefore the coupling should be tapered to correspond. If driven by a gear, and teeth are meshed too tight, undue strain will result on bearings.

Breaker and Spark Plug Points.

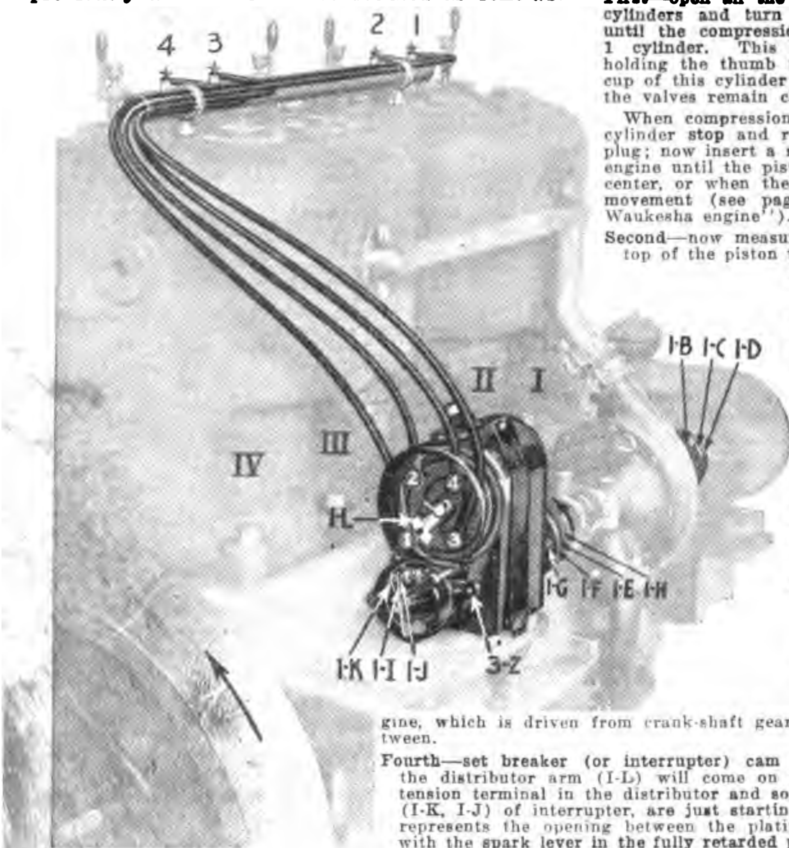
Magneto points on dual system should be adjusted to open about 0.35 millimeters or slightly under 1/64 inch, and **interrupter points** full 1/64 inch. **Spark plug points** should have a gap of about 1/64 inch to .025.

*1:4.5 is a ratio equation and means (as 1 is to 4 5/10) or in other words, the connecting rod is 4½ times longer than the crank throw. **See foot note page 298.

Example of Setting Time of Spark by Position of Piston.

Engine used in this example is the Waukesha 4 **cylinder truck and tractor engine,** per pages 833 to 838, using a high tension magneto for ignition.

In case the magneto has been removed from the engine and its connections have not been previously marked it can be retimed as follows:



First—open all the priming cups on top of cylinders and turn the engine over slowly until the compression stroke begins in No. 1 cylinder. This can be ascertained by holding the thumb tightly over the priming cup of this cylinder and observing that both the valves remain closed.

When compression stroke begins on No. 1 cylinder stop and remove the cylinder head plug; now insert a ruler and slowly turn the engine until the piston comes to upper dead center, or when the ruler ceases its upward movement (see page 836, "timing valves, Waukesha engine").

Second—now measure the distance **from the top of the piston to the top of cylinder.**

For example, let us say that the distance measures 2 inches **from the** top of the piston to the **top of the cylinder. Turn** the crank **over until** it measures **2⅛ inches.** This means that the piston has made **a drop of** ⅛ of an inch **after top, on firing or power stroke,** at which point **the spark should occur. Replace the cylinder head plug to** prevent any **obstacles** from falling **in the cylinder.**

Third—**remove the bolts (I-B) which connect the flanges (I-D and I-C)** (or **leather coupling I-G to I-H could be disconnected). Magneto is driven by a** gear in **front of engine,** which is driven from crank-shaft gear, with an **idler gear between.**

Fourth—set breaker (or interrupter) cam in such a **position that** the distributor arm (I-L) will come on the No. 1 **cylinder high** tension terminal in the distributor and so that the **contact screws** (I-K, I-J) of interrupter, are just starting to open. **Letter (I-I)** represents the opening between the platinum **contacts (I-K, I-J)** with the spark lever in the fully retarded position.

Fifth—replace the bolts (I-B) in the flanges (I-D, I-C); that is, one on either side of the coupling.

Sixth—attach the wire which leads from the spark plug **on No. 1** cylinder to the terminal marked No. 1 in the distributor **plate; No.** 2 spark plug wire to the terminal **marked No. 2;** No. 3 spark plug to the terminal **marked No. 4, and** No. 4 spark plug wire to the terminal **marked No.** 3. (See page 296.)

Never allow the **ignition wires to lie on or near the exhaust pipe,** as the insulation will **burn off and** lay the wire bare, causing a short circuit. **Spark** plug gaps are 1/32" apart. Interrupter **points .020.**

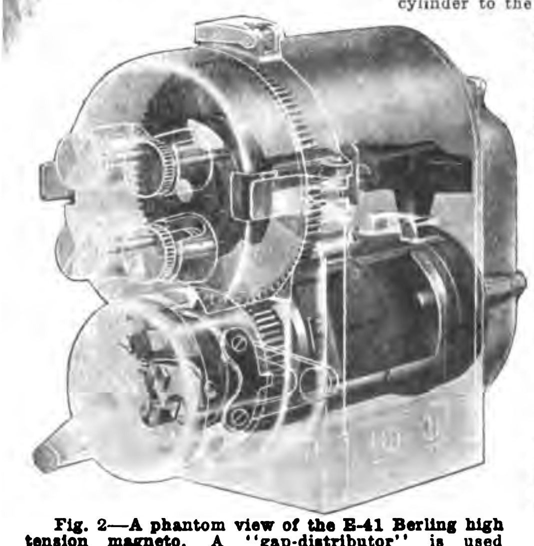


Fig. 2—A phantom view of the B-41 Berling high tension magneto. A "gap-distributor" is used (see pages 245, 247 261). **Usual setting; retarded, piston on top. Interrupter adj. .015 to .019"; plug .031". See page 927. (Ericsson Mfg. Co., Buffalo).**

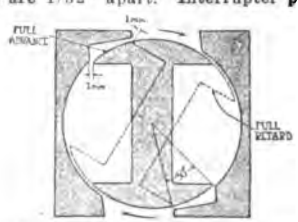

Special pole piece used on Simms magneto to give equal spark intensity at all speeds

A special feature of the Simms **magneto is the** design of the pole pieces which have **extensions on** the edges following the direction of **rotation of** the armature. These extended edges **keep the edges** of the armature shuttle within influence **of the pole in all positions from full advance to full retard. That is to say, that at the moment of breaking the current the edge of the shuttle is never widely separated from the edge of the pole piece. Therefore current is generated at low or high speeds without much loss of intensity.**

CHART NO. 150B—Example of Setting Magneto and Illustration Showing How The Magneto is Usually Driven. Note magneto faces rear of engine. **Berling High Tension Magneto. Simms.**

Timing the Remy Magneto, "RL" Model. (See page 264.)

Model RL is to be timed to the engine by the break of the contact points. When the piston is on exact dead firing center, cam house must be in full retard position, and the platinum points must just be separating.

The high tension cable from this cylinder, which is in exact dead firing center, should then be connected to the distributer terminal, corresponding to which the distributor segment is opposite.

The remaining distributor terminals should then be connected up in the proper firing order of the engine.

The position of the "inductor or rotor" type armature, is just the same as on a "shuttle" type armature; the interrupter should just be breaking when the "rotor" is just leaving the vertical position.

Sectional cuts explaining the Remy magneto with its inductor type of armature, are shown in chart 126. Set breaker points .025 inch gap.

****Timing the Eisemann Magneto.**

To set this type, turn engine by hand until piston of No. 1 cylinder is on the dead center (compression stroke). Place the timing lever of the magneto to fully retarded position, then turn armature of magneto until No. 1 appears at the glass dial of the distributor plate and make sure that the platinum contacts of the magneto are just opening. Fix the driving medium in this position.

In order to insure absolute safety when cranking on battery, the contact breaker of the battery system is arranged so that it will open 10 degrees later than the magneto contact breaker.

Timing the Splitdorf Magneto.

Set piston on top of compression stroke with interrupter **retarded.**

Now revolve the armature shaft in its direction of rotation until the oval breaker cam comes in contact with the breaker bar and just begins to separate the platinum contacts. Set coupling or gear at this point.

Pointers in Connection with the Timing of a Magneto.

In timing a high tension magneto to an engine, we will assume a 4-cylinder, there are several points to be considered.

Firstly—Which way is the armature of the magneto to revolve? This will be settled by the construction of the engine.

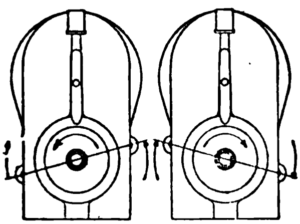

Fig. 5—Positions of full retard of the cam plate when looking at the driving end of the Simplex magneto. The first view is the counter-clockwise setting and the other the clockwise setting

The magneto will probably have to be driven off one of the timing wheels, and it will depend upon the direction of rotation of these as to which way the magneto must run.

***Clockwise and anti-clockwise:** Every maker of magnetos supplies machines to run either clockwise or anti-clockwise **when viewed from drive end.**

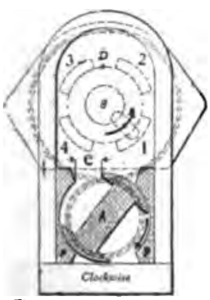

Fig. 2. Setting the Bosch Dual Magneto, when running "clockwise."

A glance at the illustrations showing the contact breaker (page 298) will show that the breaker arm should be actuated from one direction only. Any magneto can, of course, run backward without doing any damage to its parts, and frequently has to when backfiring occurs at starting, but for making a spark it is desirable to run in one direction only, as given by manufacturers.

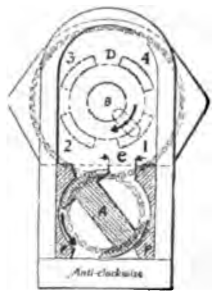

Fig. 2. Setting the Bosch Dual Magneto, when running "anti-clockwise."

****When a magneto is assembled the cam and contact breaker are set in the correct relative position.** The "break" of the primary current is made to occur when the "cheeks" or segmental-shaped sides of the iron armature almost bridge the gap of the top and bottom of the magnet poles. The position is not quite symmetrical, but the "maximum" or most favorable position is slightly in advance, in direction of rotation of a vertical line through the center of the magnets and armature, as shown in figs. 2.

It will be found in most types of magnetos that the contact rocker **has full retardation point;** that is, the actual break between the platinums agreeing with the armature in this position of maximum effect.

The reason is this: owing to the necessarily slow rate at which the magneto can be driven for starting, and as the spark

Dyke's four and six cylinder engine working models of a gasoline engine explain the relation of the position of pistons, valves, cams and magneto, as well as the principle of engine and how the magneto is attached and operated by engine.

*Figs. 2 as viewed from driving end of magneto. **The Eisemann dual system is similar to the Bosch dual. **See pages 809, 801 and 290. †See page 922 for diagram of wiring of model RL magneto.

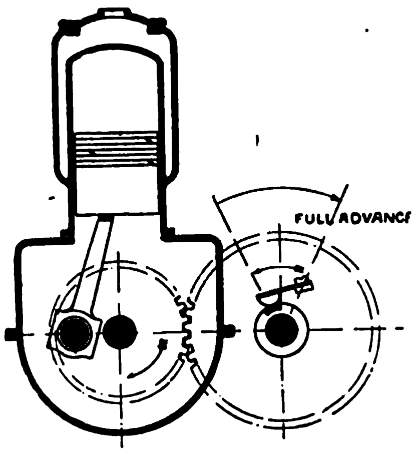

Fig. 1.—Spark fully advanced.

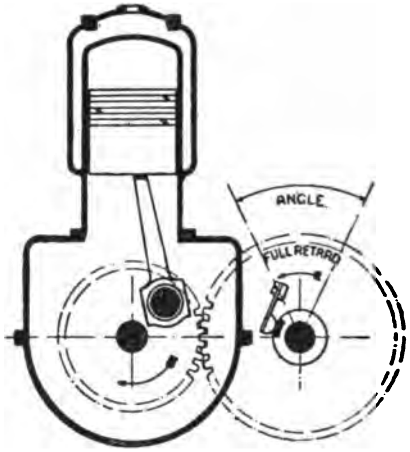

Fig. 2.—Spark fully retarded.

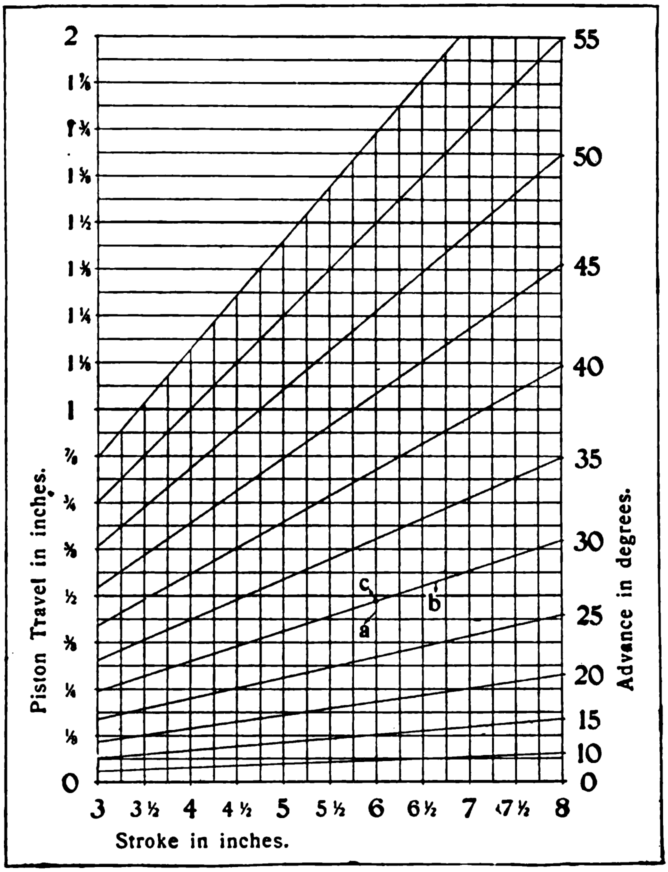
Fig. 1. The object of this illustration is to explain the meaning of advance of spark. Note the time of spark is occurring a considerable distance before the piston is at the top of its compression stroke. This would be causing the spark to occur at full advanced position.

Fig. 2. Note the contact point on commutator has been retarded or moved in the direction of rotation, therefore the spark will not occur until the piston has passed up on its compression stroke and part of the way down on its power stroke.

On a magneto, the contact breaker or interrupter instead of a commutator is advanced and retarded, but the principle is the same.

The angle of movement of contact maker is shown to make the principle clear, considerably greater than obtains in practice.



The relation of the piston travel to the rotation of the crank shaft depends on the stroke and the length of the connecting rod.

The piston travel of an engine is easily determined, and the determining of the rotation of the crank shaft in degrees, corresponding to any desired piston travel, may be ascertained from the accompanying diagram. In this diagram the relation between the crank and the connecting rod length is as 1:4.5.

In the diagram the vertical lines numbered at the bottom give the stroke of the engine in inches, the rotation of the crank shaft in degrees being indicated by the slanting lines and the figures at the right.

The figures on the left, and the horizontal lines indicate the piston travel in inches.

As an example in the use of the diagram, it may be desired to find the piston travel for an advance of 30° on a motor of 6 inches stroke. The vertical line for the desired stroke may be indentified by the figures at the bottom of the diagram, and this vertical line may be followed upward until it cuts the diagonal line indicating the desired number of degrees, which is 30° in the present case.

The horizontal line **nearest this** point, should be followed **to the** left, until it meets the **diagonal** line, and this followed **to the left-hand** side. In the **present instance** it will be seen **to indicate** about ½ inch. **This gives the** advance in inches, **corresponding** to 30°.

CHART NO. 151—Diagram for Determining the Advance in "Inches" or fraction thereof, to Set Piston when stroke is known and when the Time to Set the Spark is Expressed in "Degrees."

See foot note, page 311 for meaning of 1:4.5.

has to be slightly retarded to prevent a backfire occurring, the most use must be made of the maximum position, otherwise there would be too weak a spark produced to ignite the gas.

On the other hand, it must follow that on advancing the contact breaker for normal running, the "break" will be occurring at proportionately less favorable positions of magnetic effect; but another factor comes into play, which largely compensates for this, viz., the increasing speed of the armature.

In practice this works well, and prevents the generation of excessively strong sparks, which are not required, and only serve to fuse up the electrodes of the plug.

The spark is made sufficiently powerful for starting on, by the use of strong field magnets and breaking circuit in the most favorable position of the armature's rotation.

After starting, the intensity of the spark will increase as the speed increases, but it will never reach an excessive value, by reason of the advance of the contact maker timing the break before the maximum position.

The "breaking" distance between the platinums should be, .015 to .020 or .025 in. The amount of range provided for advancing and retarding, is greater on some magnetos than others; an average range is from 22 to 35 degrees.

No hard-and-fast rule can be given as to the best piston positions corresponding to full advance and retardation; but in general, a trial setting as per the average plan, fig. 1, chart 150A might be tried, in which the gear wheels are meshed so that, with the contact breaker fully retarded, the piston is on top of the compression stroke.

If it is found that the contact breaker cannot be properly retarded at slow speeds, without the engine tending to knock, another setting must be made, and the piston moved farther on the firing stroke.

After a few trials and careful noting of the pull of the engine, the best setting for the particular conditions will be attained.

Setting Time of Spark—Miscellaneous Systems.

The old style coil ignition system, with "vibrators and commutators" require a greater advance than magneto ignition. The reason for this is due to the time required for contact of commutator, contact of vibrator and a possible loss of time for the vibrator to start operating.

Quite often the trembler blade of a vibrator coil is adjusted so that the vibration is slow to take place, this will cause spark to occur too late. The trembler blades also occasionally stick, thereby causing missing.

The vibrator coil also gives a waste of current because the ordinary vibrator coil produces from four to ten weak sparks for each power impulse, whereas one good strong hot spark would fire quicker and save current. An illustrated example is shown on page 250.

The usual method is to place the spark lever midway between advance and retard position, so that it will have half of the motion to advance half to retard (see fig. 4, chart 152).

This should allow ample range for retarding and advancing, but a trial should be made with the engine running, and a note made as to how the speed responds to the advance and retard movement and variation in setting made as found necessary.

The amount of advance that can be given to any engine depends on certain variable factors. It is not possible to have as much advance on the ignition when the engine is running under a load as when it is running light and at a fast rate.

Note the setting of the spark on the Ford, fig. 2, chart 152, as an example of a coil with vibrator setting.

***Timing the low tension magneto, with make and break type of igniter:** The armature of the magneto must be positively driven off the engine by means of chain or gear wheels. On engines with cranks at 180 degrees, where the ignition has to take place at 90 degrees relative to the cam shaft, the armature has to be driven at crank shaft speed.

In the low tension "make and break" system the contact breaker is not fitted on the magneto; a connection from the outer end of the armature winding joins up to the terminal of the hammer-break device inside the cylinder.

The general practice when timing (see chart 152), fig. 5 is to arrange for the mechanism of the break to "trip" when the piston is just completing the compression stroke or a little earlier; say ⅛ of an inch (or an amount determined by experiment to give the best results), the armature being, as in the case of the high tension system, in "maximum" position.

Dyke's working model of a magneto explains the principle of a magneto. The armature is shown in section as well as the drive gears. The reader can easily figure the relation of speed of cam, armature and distributor, also actually practice setting the magneto with this model.

***When setting time of spark on a stationary engine**, the spark is set to occur, when retarded, slightly after compression stroke to prevent kicking back. This type of engine is usually equipped with a "make and break" igniter system.

Timing the Ignition of the Modern Battery and Coil System.

This heading would comprise such systems as the **Atwater-Kent**, page 248; Connecticut, page 252; **Delco**, pages 377, 390; **Westinghouse**, page 251; **Bosch**, page 253, and similar systems. By referring to the pages the ignition timing is given. (See also, page 317).

Timing Commutator and Vibrator Coil System.

Fig. 4: Owing to the lag and inertia of a coil trembler considerable range of advance is required to obtain the spark at the most effective position of the piston. (This system is seldom used—see page 215).

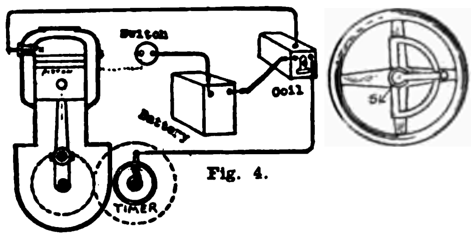


Fig. 4.

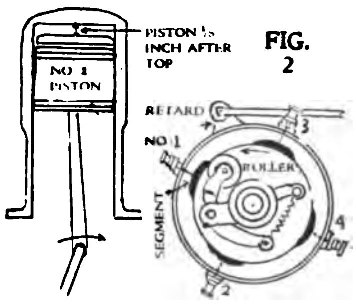
(1)—place piston on top of compression stroke; (2)—place spark lever in center position of quadrant (SL); (3)—set contact on commutator so it will make contact with No. 1 cylinder. This will allow for a range of advance and retard in either direction from the center.

Timing Ignition of the Ford.

Fig. 2: The Ford ignition timing is as follows: (1st)—bring No. 1 piston to top of compression stroke—then move piston **down after top**, about ⅛ inch; **(2nd)**—place spark lever on steering wheel at **full retarded** position (see page 771 showing position of spark lever to retard, which would be **up**); **(3rd)**—place **roller** of commutator, on No. 1 segment so it will just start to make contact with segment; **(5th)**—the firing order is 1, 2, 4, 3, therefore see that connections from commutator terminals are made accordingly; **(6th)**—set **spark plug gap** 1/32 inch or slightly less.

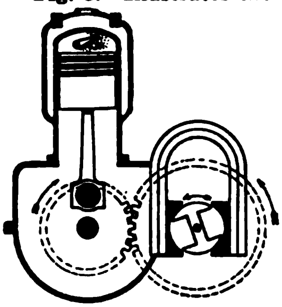


Note—This setting ought to bring the roller on cam shaft in line with hole provided for it. The Ford uses a multiple type vibrator coil and roller type commutator. A fly wheel magneto (page 265) supplies electric current. See also, pages 803, 804, 805 and page 785 for **valve timing**.

Fitting an Atwater-Kent system to a Ford (pages 248 and 810); set piston ¼ inch **down after top**—on power stroke—with interrupter retarded. This is possible, because (AK) has a wider range of advance and retard.

Timing "Make-and-Break" Ignition.

Fig. 5.—Illustrates the principle of timing a low-tension-magneto using a "make-and-break" ignition.



The armature is in one of the maximum positions just as the piston is completing the compression stroke and "break" or "igniter" mechanism has just tripped or broken circuit, (see text, page 315). This system is seldom used.

Fig. 5.

Checking Ignition Timing.

When gears are disengaged, which drive magneto or timer be sure they are marked—as indicated in figs. 15 and 16. When connecting high tension wires—first learn the firing order (see page 120 how to tell by position of cams) and then connect as explained on page 296. Remember the distributor on a magneto revolves opposite to armature. For instance, see fig. 16; crank gear (C) revolves to left (view supposed to be from rear of engine. Note page 812 showing how magneto faces rear of engine); idle gear to right; magneto gear to left and distributor to right.

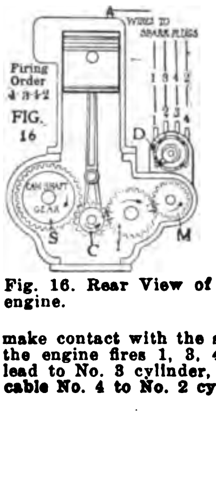


Fig. 16. Rear View of engine.

In fig. 16 the rotor of distributor (D) turns in a clockwise (right-hand) direction so that it next will make contact with the stationary segment No. 2. As the engine fires 1, 3, 4, 2, the cable No. 2 should lead to No. 3 cylinder, No. 3 to No. 4 cylinder and cable No. 4 to No. 2 cylinder. (See also page 296.)

Re-Meshing Timing Gears.

To assemble gears if removed (Overland, fig. 15 as example): Turn fly-wheel until 1 and 4 pistons are at top-dead-center, with No. 1, ready to fire (top of compression stroke). Key crank-shaft gear (C) and cam-shaft gear (S) to shafts so that fig. 1 on each will mesh. Then replace idler gear (I) so that fig. 2 on it will mesh with fig. 2 on crank-shaft gear. Then mesh fig. 3 on magneto gear (M) with fig. 3 on idler gear. See also, pages 112, 113, 89, 785.

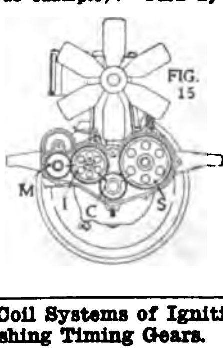

Fig. 15. Shows front view of engine.

CHART NO. 152—Setting the Time of Spark on Coil Systems of Ignition. Timing Ignition of the Ford. Checking Magneto Ignition Timing. Re-meshing Timing Gears. See also, pages 112 and 113.

No variable advance or retardation is as a rule provided, reliance being placed on the proportionately greater volume or intensity of the spark as the speed increases, thus causing more rapid combustion.

The factors to be determined in timing with low tension, are the time of break, piston position, and armature position.

Simple method to aid in setting the "make and break" igniter. The former can be very accurately set by the aid of an ordinary electric bell and battery, a simple circuit formed through the "break" device on engine. When the break hammer is in contact with the insulated stud the bell will ring; but, on revolving the fly wheel, the moment the circuit is broken between hammer and stud the bell will cease to ring.

If, as should be the case, the fly wheel is marked off to indicate piston position, a very delicate adjustment can be made. It is important in adjusting the hammer-break to obtain a break of sufficient length, but not an excessive amount. This amount varies according to the type of break mechanism used. An average distance would be about 3-16ths inch, with a maximum distance of one-eighth between the hammer or tappet and insulated stud. (see pages 215 to 217 and 260.)

Setting the Time of Spark on the Atwater-Kent and Delco Battery, Coil and Timer System of Ignition.

The time for setting the spark to occur when using the Atwater-Kent, Delco and similar battery and coil systems differs only slightly from the time the spark should occur with a magneto.

The method however differs as there is no armature to set. Instead, the timer shaft is set as explained under the timing of the spark as per page 250.

The Delco ignition is set in the same manner, see page 390. Also see Remy, page 318, 251 and Connecticut, pages 251, 364, 358.

How to Determine the Setting of Time of Spark on Leading Cars.

First turn to the index and find "Specifications of Leading Cars;" turn to the charts and find the make of ignition system being used. If it says "Bosch," then turn to the explanation in this instruction on setting the Bosch magneto. If it says "Atwater-Kent," or "Delco," turn to index for "Delco" or "Atwater-Kent" ignition system and you will find the timing instruction.

This same rule applies to timing the valves, carburetion and other adjustments.

Verifying the Ignition Timing.

It occasionally happens that cars turned out of the factory hurriedly to meet pressure of orders, are not as well adjusted in the setting of the ignition timing as they might be, with the result that the car may not prove an easy starter.

In fact, the writer had occasion to locate a trouble of this kind. The nature of the trouble was irregular firing and knocking when running slow. When running fast the trouble disappeared, but in taking a steep hill the engine would slow down, and right where a retardation of spark was necessary, the trouble would make itself manifest. The ignition was a low tension magneto used in connection with a high tension coil.

The cause of the trouble was found to be that the magneto had been set for the spark to occur too far before the piston was on top of compression stroke when spark lever was fully retarded—in other words, it was set too far advanced.

The result was, when running slow, the spark would occur and combustion take place before piston reached the top of compression stroke, hence the pound.

By remeshing the gears driving magneto, so the spark occurred when piston was on top of compression stroke, with full retard position of breaker housing, and points of breaker just separating at that time, this allowed the combustion to take place a little later. The trouble then disappeared.

Testing Ignition Advance.

*If the ignition is suspected of being set too far advanced, then test as follows:

(1) **Place No. 1 piston on top of compression or its firing stroke.** This can be found, by following out the wires and noting when cylinder to be tested will fire.

(2) **Place breaker box in "retarded"** position.

(3) **Note if the breaker box points are just separating when piston is on top.** If so, the setting is about right for magneto.

If, however, the points have already separated, then it is likely there is too much "advance," the amount being determined by the distance the spark occurred before top.

If a vibrator coil system, then the contact on segment ought to be made when piston is say, ⅛ inch over top of compression stroke with retard spark lever.

If a change is made of the setting, then a trial should be made with the engine running, and a note made as to how the speed responds to the advance and retard movement, and variation in setting made if found necessary.

*Understand, this rule must not be followed altogether. As some manufacturers set at full retard, slightly before top.

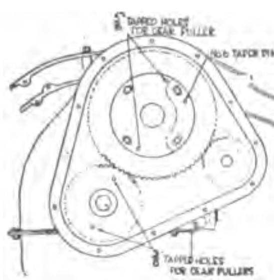

Fig. 2—Diagram showing location of tapped holes in camshaft and crankshaft gear

Fig. 3—Breaker and distributor mechanism. The brush is readily removed

Fig. 1—In removing the camshaft or crankshaft gear two carriage bolts which are part of the puller are screwed into tapped holes in the web of the gear

Disassembling.

(1.) Remove hood.

(2.) Drain radiator.

(3.) Remove radiator.

(4.) Remove fan pulley and sleeve.

(5.) Remove all bolts holding gear cover to engine.

(6.) Pry case free, taking care not to destroy the cork gasket. This should stick to the cover and be removed with it.

Removing Timing Gears: These gears need only be removed when to be replaced or a general overhauling of the engine, fig. 2.

(1.) Remove plunger on springs in gear shaft ends.

(2.) Remove inspection hole cover on flywheel and crank engine until 1-6-IN-O is at the top. This point can be felt by holding a file through the hole, with the point resting on the engine side of the flywheel face, and slowly cranking the engine. A hole is drilled in the flywheel at this point and the file will drop into the hole.

(3.) Mark gear faces so that they may be returned to the same position. (This is not essential if new gears are to be installed, but for ordinary overhauling will facilitate the assembly.)

(4.) Remove wires locking cam-shaft gear retaining bolts and unscrew bolts.

(5.) Remove dowel plate.

(6.) No puller is required to remove this gear, as each side of the gear is drilled and tapped 5/16 in., permitting two cap screws to be used to force the gear from the flange. The gear MUST be removed evenly.

(7.) Use the puller shown in Fig. 1 to remove the crankshaft gear.

(8.) Remove bonnet base strip on generator side.

(9.) Remove cotter pin and nut holding generator drive gear on its shaft.

(10.) Remove timer control rod and spring.

(11.) Disconnect wire at rear of generator.

(12.) Disconnect universal coupling.

(13.) Unbolt generator from base and lift generator off. (The shims should be marked and kept so they may be returned to the same position.)

(14.) Remove wiring from timer and plugs. Mark so that they may be returned.

(15.) Free timer from engine and remove, noting position of distributer brush, so that the timer may be replaced in the same position.

(16.) Remove the screw on timer drive shaft bearing plate, freeing timer drive shaft.

(17.) Remove screws on rear bearing plate.

(18.) Drive generator drive shaft out of gear. (It is poor practice to pull this gear off.)

(19.) Inspect all parts for wear, clean thoroughly and provide new parts where necessary.

The Assembly

(1.) Replace generator drive shaft in housing and drive the gear back onto it.

(2.) Replace crankshaft gear.

(3.) Adjust valve tappets so that they have .002 in. clearance between tappet and valve stem. The camshaft may be turned from the front to do this.

(4.) See that the point 1-6-IN-O is still at the center of the inspection hole in the flywheel case.

(5.) Turn camshaft counter clockwise until the inlet valve of number 1 cylinder starts to open. This can best be felt by placing a screwdriver in the slot in the valve, as in grinding. By turning the valve back and forth the instant it starts to open may be felt.

(6.) Press camshaft gear in position with the teeth so meshing that the retaining bolts stand in the center of the adjusting slots.

(7.) Replace retaining nuts on camshaft gear and bring them up so they pinch the gear onto the flange.

(8.) Turn flywheel backward about one-eighth turn and then back in direction of rotation, at the same time turning the inlet valve of No. 1 cylinder with a screwdriver.

(9.) Stop turning the instant the inlet valve starts to open.

(10.) Note whether point 1-6-IN-O is directly beneath the inspection hole in the flywheel case.

(11.) If it has not yet reached this point, using a drift, drive the flange nuts on the camshaft gear back in a clockwise direction twice the angular distance that the point 1-6-IN-O must go to reach the vertical.

(12.) If it is past this point, drive gear in opposite direction in a similar manner.

(13.) Check timing for No. 6 cylinder in same manner.

(14.) If dowel pin holes in gear and flange do not line up, drill new holes and replace strap.

(15.) Tighten bolts and lock with wire.

(16.) Replace timer gears and generator taking care not to draw the bearings too tight.

(17.) Set engine on 1-6-IN-O with inlet valve of No. 1 cylinder just opening.

(18.) Set distributing brush on timer to connect with No. 6 terminal, or spark plug wire.

(19.) Set timer in retarded position.

(20.) Set hexagonal cam on breaker so that the points are just breaking, Fig. 3.

(21.) Lock in position with lock nut.

(22.) Adjust breaker points to about .015 in. clearance, and lock adjusting nuts in position.

(23.) Check adjustment of ignition. An allowance of 1 in. late is permissible.

(24.) Replace timing gear cover, making sure that end thrust plungers and springs are in place, and that cork packings are not broken. This should be set in shellac on the case side only.

(25.) Replace fan pulley, fan belt and fan.

(26.) Replace bonnet base strip.

(27.) Replace radiator and hose connections, making sure that all connections are tight. Common rubber cement should be used on all joints.

(28.) Replace hood, fill radiator.

(Also see page 251.)

CHART NO. 153—An Example of Ignition Timing (Remy) and Valve Timing on the Chalmers 35—Incorporating a Method of Removing the Timing Gears—(Motor World.)

*Spark Control and Overheating.

As few motorists really understand just how the power efficiency of an engine is affected by the spark timing, (which is generally under the control of the operator) the following may be of interest:

When a combustible mixture has been compressed in a cylinder by the rising piston and the spark occurs, a very small portion of the mixture in the immediate vicinity of the spark is ignited; and if the mixture is of the proper proportions and suitably compressed, the flame propagation throughout the entire combustion chamber will be rapid.

This is as it should be. When combustion takes place intensely heated gases are formed, which in their effort to occupy a larger volume of space exert great pressure on the walls of the combustion chamber and upon the piston head.

As a gas or gaseous mixture is compressed it becomes heated, and the greater the pressure the greater the heat.

If a mixture is of proper proportions, the greater the pressure the more readily will it ignite, and the greater the speed of flame propagation or combustion.

On the other hand as the pressure of a combustible mixture is reduced, it loses its heat, and its speed of ignition and combustion is also reduced.

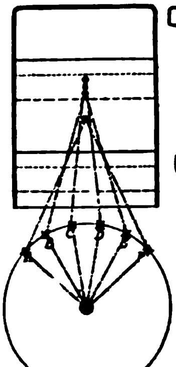

FIG.1

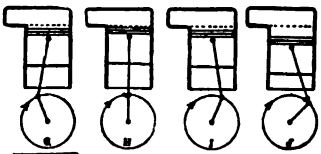

Fig. 2—Diagrams showing when sparks should and should not occur.

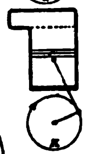


Several interesting conditions may be shown with the diagrams of fig. 2, which like fig. 1, represent different positions of the crank shaft, and of the pistons in the cylinders.

Thus it must be understood that to get the utmost efficiency out of a combustible charge it must be ignited at or near the point of maximum compression.

Let it be assumed that a car is being driven at a speed of about 30 miles per hour, and that the engine is necessarily turning over at a speed of about 1200 revolutions per minute, the spark lever advanced so that sparks occur when the piston is ascending as at (G).

Ignition we will assume, is complete at (H), and combustion at (I), at which point the maximum pressure of the expanding gases is being exerted.

Under these conditions the engine runs smoothly and cool.

Now by retarding the spark and advancing the throttle lever it is found that the speed of 30 miles an hour, still can be maintained.

The engine is generating the same amount of power, but with the spark retarded and the throttle advanced; but after about 30 minutes' running the radiator begins to steam and we see that the engine is overheated.

What is the cause? It is this: The spark is retarded so that now it occurs when the piston is at (I); compression is already reduced so that ignition is slower and is not complete until the piston is at (J), and combustion is still incomplete at (K).

The explosive mixture is now richer in fuel, so that more heat is given off than under the first mentioned condition; therefore, the expansive force is greater than before, so that the speed of the engine is the same, but note the area of wall surface of the cylinder at (K), which now is exposed to this more intense heat.

The water in the jackets not only has to take care of the heat absorbed by the walls of the combustion chamber, but also of an excessive amount absorbed by the cylinder walls.

Range of Spark Advance and Retard.

Fig. 1. Is a diagram showing the range of spark advance and retard representing different positions of a crank shaft and the relation of the piston in the cylinder at these different positions.

Referring to this diagram, if an engine is running at an extremely high rate of speed the spark might be advanced so as to occur in the cylinder when the throw of the crank shaft is ascending and at the point (A); thus combustion might be complete or so nearly complete by the time the throw reached the point (D), that a very strong pressure would be exerted upon the piston, which is as it should be.

If the engine were being subjected to an extremely hard pull, as in ascending a hill on high gear so that its speed is considerably reduced, and ignition were to take place at (A), combustion might be complete at (B) or (C), and the pressure or power-impluse on the piston head would tend to turn the crank shaft in a reverse direction.

If the car were traveling at a very low speed or if there were not sufficient momentum in the fly wheel or the car itself, the engine would be stalled, or killed, as the saying goes.

Of course, if the car or engine were traveling at a sufficiently high rate of speed to

*See also page 308.

carry the crank and piston over this dead center, a large percentage of the power would be applied in the right direction, but considerable would be lost; there would be what is known as an **ignition knock**, and the strain on the bearings would be quite severe.

On the other hand, if the engine has been slowed down considerably under hard pull and the ignition is retarded so as to occur at about (C) or (D), combustion might be complete at about (E) or (F), or perhaps even a little farther down where the leverage on the crank shaft is greatest, and thus the greatest amount of the downward pressure on the piston is utilized.

It must be remembered that the greatest power is dependent upon the momentum or torque of the fly wheel.

An engine always should be run with the spark advanced as far as possible without causing it to knock or lose power, and it will overheat, if caused to run for any great length of time with a retarded spark.

Finding Position of the Piston.

In the previous matter we have mentioned about placing the piston on top of compression stroke. To tell when piston is on top of compression stroke is explained below.

Usually a mark is placed on fly wheel to indicate when piston is at top. For instance, if a four cylinder engine, a mark will likely be on fly wheel as "D C 1-4," meaning "dead center up 1 & 4" or one and four pistons are at top of stroke. If a six cylinder it would probably appear as "D C 1-6 up," meaning pistons 1 & 6 on top. Or mark may be, "1-4 up" or "1-6 up," meaning the same.

It is necessary to find, however, just what stroke the pistons 1 & 4 or 1 & 6 are up on, therefore watch the valves; on compression stroke, both valves should be closed. Or watch when inlet valve opens—piston is then starting down on suction, therefore the next (up stroke) must be "compression."

The fly wheel will then have to be turned until this mark is centered with an indicator mark usually on cylinder or some central point, see pages 102 and 104.

From this point the fly wheel is turned to the right, to place piston before top of stroke, or to left, to place piston after the top of compression stroke. This rule applies when standing behind fly wheel, when fly wheel is on rear of engine.

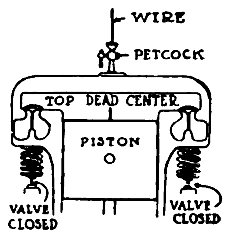
The exact point, however, when the piston is on top of compression stroke is rather difficult to determine.

If engine happens to be a "T" head motor with a compression cock in the center, then it is easy to find when piston is on top of compression stroke by placing a wire or bicycle spoke through the pet cock and turn the engine over; when the wire rises to its highest point the piston is on top of dead center.

On a four cylinder engine, when No. 1 piston is on top, No. 4 is on top also. On a six, when No. 1 is on top No. 6 piston is also on top.

Therefore, to find when this particular piston you propose to work from, is on compression stroke; watch the valves. Both valves will be closed. The exhaust cam would be at a position where it would open the exhaust valve after one movement or stroke—this stroke being the power stroke.

If cylinder is of the "L" head type it may not be possible to get a wire into the



cylinder. In this case open compression cock and place your finger over it, have some one crank engine slowly until you feel compression; let this escape gradually. When the gas has ceased escaping, the piston is at or near, top dead center. The compression stroke is found by watching when both valves are closed.

This plan is uncertain however, and the best plan is to remove lower crank case and turn the crank until the connecting rod and crank shaft throws are straight up and down, in line; at the same time watch the valves as mentioned above.

This procedure however, is not necessary if there are marks on the fly wheel to indicate just when pistons are on dead center.

To determine the end of the compression stroke in any cylinder (Overland as example); turn the crank until the exhaust valve in that cylinder, which is the one directly beneath the priming cup, has just reached its seat; and then turn the fly wheel approximately one revolution, stopping when the mark 1-4 UP (or 2-3 UP) is at its highest position and in line with the guide mark on the back end of the crank case. Another method is to turn the engine while the hand is held over the open priming cup and identify the compression stroke by the escape of air. After the fly wheel is in the proper position install the timing unit as directed.

INSTRUCTION No. 25.

ENGINE STARTERS: Ignition or Switch. Primer and Ignition. Compressed Air. Acetylene Gas. Gasoline and Air. Mechanical Starters. Parts of an Electric Starting Motor.

Ignition Starting.

The first form of self-starter was the ignition starter. It is still used but to no great extent, in connection with the priming systems and gas systems of starting as explained in chart 154. A special form of switch however, is sometimes provided which causes a spark to occur in all cylinders simultaneously.

It is possible to start any engine occassionally on the switch, if the cylinder in which the spark is made at the time, happens to have a charge of gas and the ignition is a battery and coil system, either as an auxiliary or regular system. If, however, the magneto system and breaker is used in connection with a non-vibrating coil, then the chance of obtaining the spark is not so great. The breaker points will not permit the opening and closing of circuit when engine is idle.

Therefore a special connection is usually provided on the coil in the form of a button switch (see page 280). This applies to four or more cylinder engines. The principle is this: there is always a certain amount of unexploded gas remaining in one of the cylinders when engine stops, especially if driver has taken the precaution to open his throttle before engine stops. Therefore, if a spark occurs in the cylinder this unexploded gas will combust and give enough momentum to start the engine.

As stated above, if a coil system is used, the switch can be thrown on and a quick movement of the spark lever, its full length will cause contact to be made on the timer or commutator, thereby causing a spark in one of the cylinders.

Naturally the cylinders must be in good condition. The piston rings must be tight so the compression will not be lost by leakage. When stopping the engine the throttle ought to be opened part way so as to admit a full charge of gas to the cylinders, in order to make starting easier. The engine must of course be speeded up, but by holding the clutch out.

Priming Starter.

The priming method of starting was the next method used. Instead of depending on the pistons to draw in a charge of gas, a special pump was devised as shown in fig. 3, chart 154. This pump forced a charge of carbureted gas into the cylinder.

Gas Starter.

The acetylene gas idea of starting developed from both of these systems. The Presto-lite Co. worked out a very satisfactory system for starting as explained in fig. 5, chart 154. This system also employed a special electric connection for igniting the gas.

Compressed Air Starter.

The compressed air system was first used by taking the pressure from the exhaust, storing it into a tank, then distributing it to the cylinders. The compressed air starter is divided in two classes: the type which uses a pump, operated mechanically from the engine to store fresh air into the air tank, as shown in fig. 4, chart 154. The other type; the exhaust gases are stored into a tank.

Gasoline and Air Starter.

The Christensen gasoline and air starter, fig. 6, page 322, is used on aeronautical engines, as the Thomas, Sturtevant, Roberts, Duesenberg, Hall-Scott, Curtiss, Wisconsin and others. Also motor boats, trucks, tractors and automobiles.

Principle: This starter does not crank the engine but starts it as follows: The engine when running, uses gasoline and air, properly mixed, as its fuel. When not running it cannot be started ordinarily only by cranking by hand or some other starter. The Christensen starter supplies this mixture to the engine in ready-made form, under compression, to each of the cylinders in firing order so that the engine is starded on the first touch of the button.

The parts are shown in fig. 6 and consists of the **compressor;** a **clutch** for engaging and disengaging same; a **carburetor chamber** (independent from engine carburetor) and a **distributor,** timed with the firing order of the engine; a **control valve,** which is used for starting the engine and for engaging the **air compressor;** a **tank** for holding the air and a **gauge** telling how much air the tank contains.

Into each engine cylinder a **starter check valve is screwed,** (usually in the priming cup opening) and a **pipe** runs from the check valves to the distributor.

Method of attaching: The starter unit is usually driven by Oldham coupling from the crank shaft or cam shaft, and is mounted in the most convenient place. (The Christensen Engineering Co., Milwaukee, Wisconsin.)

Mechanical Starter.

The mechanical starter is made in many and varied forms, one being shown in chart 154.

Electric Starter.

The electric starting motor has many advantages over other systems, in that the motor is easily applied and manipulated. The source of electric supply is derived from a storage battery which is kept recharged by an electric generator (dynamo).

Summary.

Therefore, we have the several classes of self-starters classified as follows: **Ignition or switch starter; primer and ignition; acetylene gas; compressed air; gasoline and air; mechanical** and **electric.**

Electric Starter Used Most.

The electric starter is the system in general use and will be treated in the next instruction.

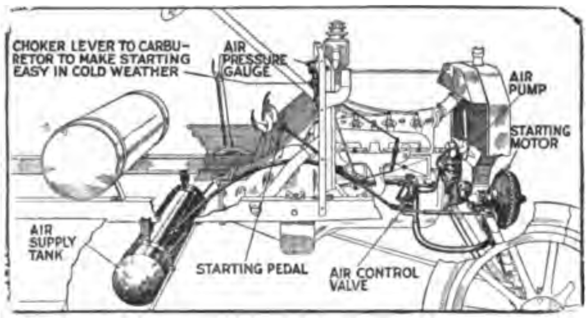


Fig. 4.—Compressed air starter: The Stewart starter for the Ford, cranks the engine from the front end of the crank shaft in exactly the same manner it would be cranked by hand. To start the engine, it is only necessary to press the pedal which is installed on the foot-board.

The starter motor, or cranking unit, is an air-tight chamber, circular in form and replaces the crank handle.

Passing through this is a shaft which engages the engine shaft, the same as the crank handle formerly did. Within the cylinder is a stationary head; also a revolving valve.

This valve is attached to a collar through which the starter shaft passes. In operation, the charge of air is admitted into the starter motor at a point between the stationary head and the revolving valve. This air pressure forces the revolving valve to make almost one complete revolution.

Inside of the collar, attached to the revolving valve is a pawl which engages the grooves or teeth in the starter shaft. A "driving" clutch is attached to the end of this starter shaft.

A "driven" clutch is installed on the end of the engine crank shaft.

The driving clutch engages with the driven clutch in the same manner as formerly, when the car was started by the old crank handle. (Stewart Speedometer Co., Chicago, Ill.)

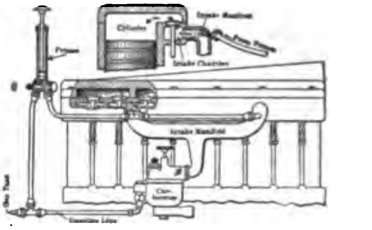

Fig. 3.—A primer starter: Cylinder primers are all operated very much along the same lines, the fuel being injected into either the cylinders themselves through special priming cocks or into the intake manifold. A hand operated pump is usually used to draw the gasoline from the supply tank to the feed pipe. The gasoline is brought into the primer cylinder from the carburetor supply pipe. It is then forced into the intake manifold through a special form of spray nozzle. An upward stroke of the handle fills the primer cylinder, and a downward stroke forces it into the valve chambers of the engine. With all priming systems it is necessary to have a spark at the correct time—see text, page 282 for "starting on the switch."

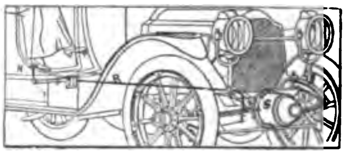

Fig. 2.—A mechanical starter: This device (S) is attached to the front of the car in place of the ordinary starting crank. It is about the size of an ordinary automobile headlight and looks like one reversed. There are two powerful springs in the device which are released by a very slight pressure on a pedal (H) which is located near the drivers seat. (American Ever Ready Works, Long Island City, N. Y.)

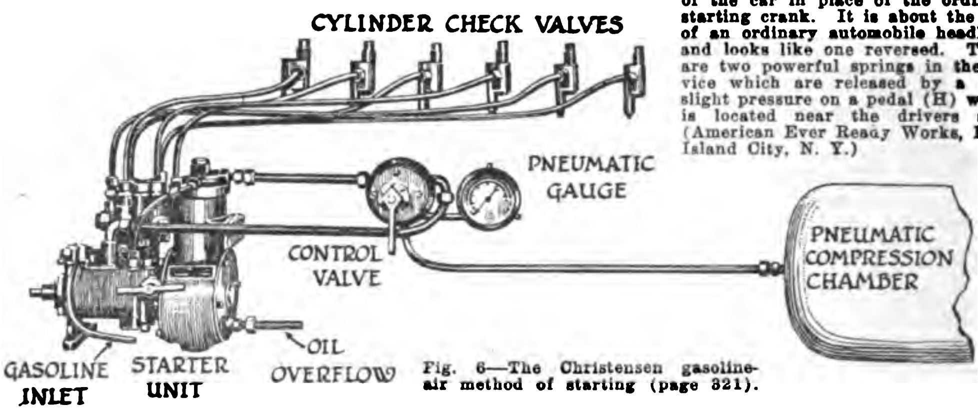

Fig. 6—The Christensen gasoline-air method of starting (page 321).

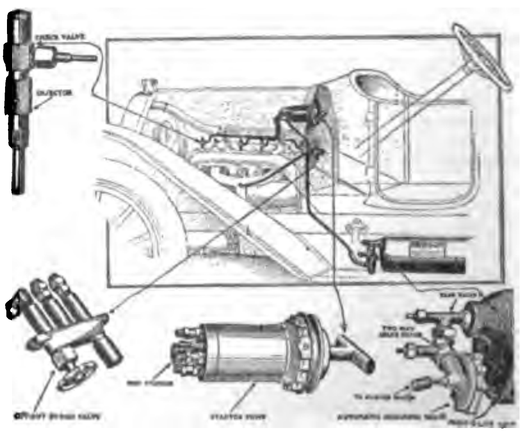

Fig. 5.—Gas starter: The Prestolite gas starter system permits the starting of the engine by the injection into each cylinder of a measured amount of prest-o-lite gas, which is exploded by pressing the button on the ignition switch. (See ignition starting, page 282.) The driver charges the cylinder with gas by making one or two movements of the handle, which is located on the dashboard. There is placed at the tank an automatic reducing valve, which reduces the pressure beyond the tank to two ounces. Whether the tank pressure be 150 or 250 pounds, the pressure in the lines can only be two ounces. On account of low pressure it is necessary that the gas be forced into the cylinders, as the cylinder compression is many times stronger than two ounces. This is accomplished by a pump which is placed on the dash in easy reach of the driver. In cold weather the driver can press a by-pass valve button and cause the gas to pass from the tank directly to the intake manifold. (Prest-o-lite Co., Indianapolis, Ind.)

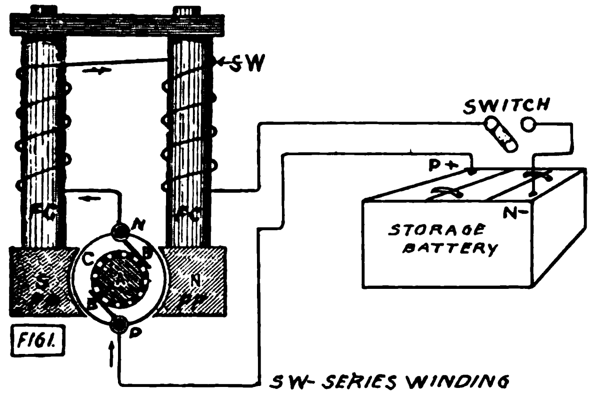
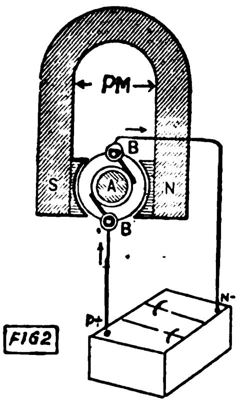
Compressed gas ,tank was a type of starter formerly used on the Winton. Part of the exhaust gases from the engine was stored up in a tank, during the exhaust stroke. This gas was then used for pressure, to force the piston (which was ready to commence its power stroke) down.

CHART NO. 154—Engine Starting Devices; Mechanical, Air, and Gas.



FC- FIELD CORE. A- ARMATURE. C- COMMUTATOR. B- BRUSH. PP- POLE PIECES.
SW.- SERIES WINDING ON FIELD CORE.



PM.- PERMANENT MAGNETS

Starting Motor—Simplified.

Fig. 1.—A simple form of a series wound electric motor. The field cores are magnetized only when the current from the battery flows through the "series" wire winding, hence the term, "electro" magnetized field. The lines of force come out at "N" pole and pass in at "S" pole.

There are two poles or pole pieces (PP) to this motor, hence it is called a "bi-polar" motor. If it had four or more poles, as per chart 160A, it would be called a "multi-polar" type.

The winding on the field core is "series" wound, meaning, one part is connected with another in series; for instance, start at the battery and follow the current path and note the succession of parts connected.

***A "permanent" magnetized field** is shown in fig. 2. The magneto or fields (PM) are permanently magnetized.

The armature, however, on both machines is of the "drum" wound type—the armature shown on page 258, is a "shuttle" wound armature.

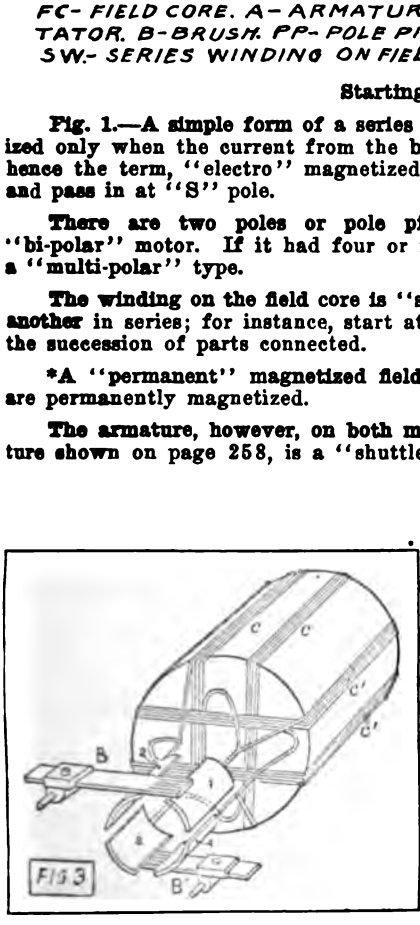


Fig. 3: A drum type of armature, used on all electric starting motors and generators for charging batteries.

The field however, can be "electro" or "permanent" magnet type.

B—brushes; commutator segments are 1, 2, 3, 4. There are two conductors from each coil. Note one end or conductor, of two different coils is connected to one commutator segment.

Armature—"Drum" Type.

Fig. 3.—On a drum armature, the coils are wound longitudinally over the surface of the armature core drum.

C—are the coils of wire, c[1] is the core, usually made of laminated iron. 1, 2, 3, and 4 are the commutator bars, or segments on which the brushes rest and carry the current to the armature coils. Each segment is insulated one from the other by mica. There are as many segments as there are coils of wire.

On a "shuttle" type of armature as shown in fig. 7, page 332, the winding is quite different—note the illustration.

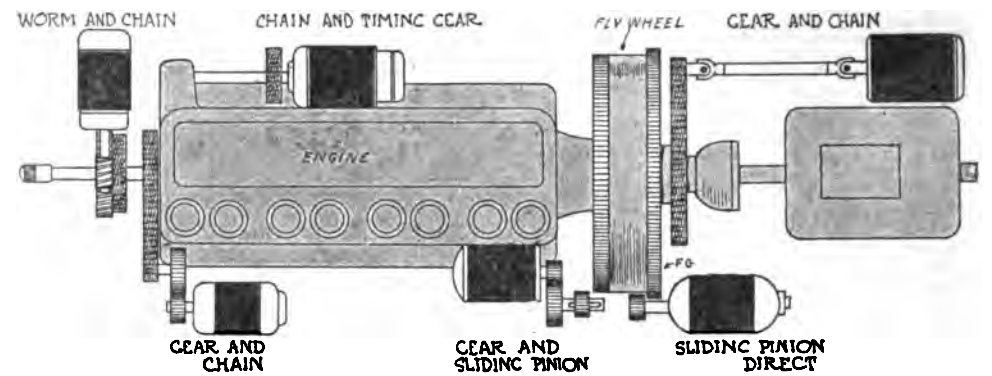
The parts of an armature are; core, coils or winding, shaft, copper commutator bars, mica insulators and the binding wires. (see fig. 4, page 330.)

The core is usually made of sheets of iron placed side by side and then turned on a lathe until round. Slots are then cut into the laminated core (L), to hold the armature coils.

Bands of fine brass wire, (BB), are then placed around the armature to hold the armature coils in place when revolving.

CHART NO. 158—Parts of an Electric Starting Motor.
Charts 155, 156, 157 omitted (error in numbering).

*Permanent magnets are not used for starting motors as considerable current is required, therefore the magnets would have to be very large. Permanent magnets are sometimes used on generators. The current produced in a generator for automobile work is seldom over 22 amperes.



Automobile engine viewed from above, showing several of the extensively used methods of applying the electric starter

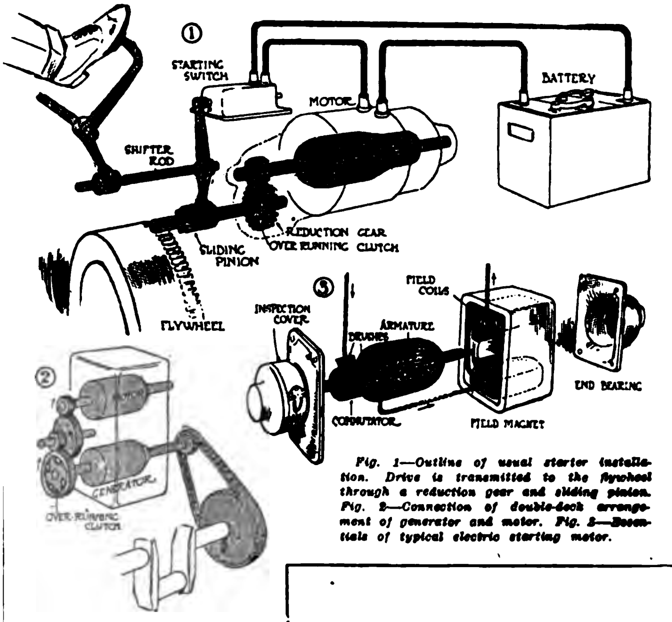


Fig. 1—Outline of usual starter installation. Drive is transmitted to the flywheel through a reduction gear and sliding pinion. Fig. 2—Connection of double-deck arrangement of generator and motor. Fig. 3—Essentials of typical electric starting motor.

Illustrating the various methods of applying the electric starting motor to engine.

When starting engine by chain or gears, there must be some form of release, so that the motor will not continue to run after engine is started. This release is usually in the form of a roller clutch or gear shift.

The method of starting through the fly wheel is the most popular system. Also see pages 326 and 331 for the Bendix starter.

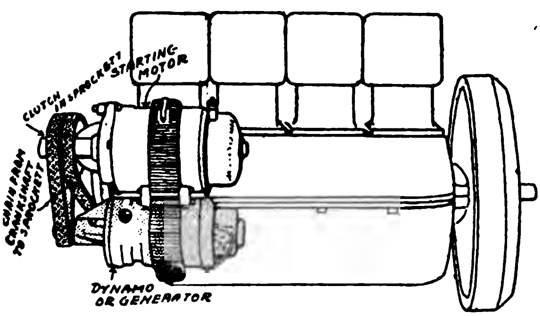

Fig. 8—Showing application of starting motor to crank shaft by chain and sprocket. Note clutch is in sprocket. Both chain and sprocket run with engine, but clutch in sprocket cuts out motor after engine is started.

This system formerly used by the Gray and Davis on the 1914 Overland.

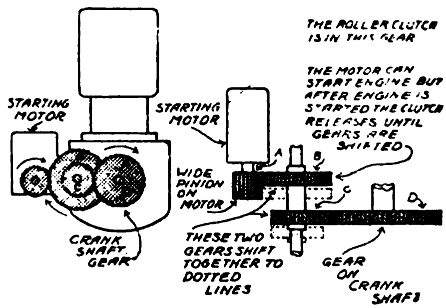

Fig. 7—Showing application of starting motor to crank shaft by gears. Note clutch is in B. The Westinghouse starting motor is connected in this manner on the Dorris car. A feature worth mentioning is that the gears are all out of mesh after motor serves its purpose. (see page 328.)

ART NO. 159—Application of the Electric Starting Motor to the Engine; through the **Fly Wheel, Transmission Shaft** and through the **Crank Shaft.** Note different methods of each.

The most popular method of drive is through the fly wheel using the Bendix Inertia gear shift method.

INSTRUCTION No. 26.

THE ELECTRIC STARTING MOTOR: Mechanical and Automatic Gear Shift Method Explained. Types of Motors. Starting Switches. Reduction Gears. The Rushmore Displacement Type of Automatic Electric Gear Shift. Bendix Inertia Gear Drive.

The electric starting motor is an electric device or motor for turning over the crank shaft of a gasoline engine.

The electric motor is a device for transforming electric power into mechanical power. The electric motor receives its electric current for its motion, from an electric storage battery. **The storage battery receives its charging current from an outside source or an electric generator,** usually run from the gasoline engine. Quite often this generator (also called a dynamo), is made a part of the starting motor, as will be explained later. (see instruction 27.)

***Parts of Electric Starting Motor.

‡**Principle:** To know the principle upon which an electric starting motor is constructed, it will be necessary to know the names of the parts·

The magnets or "field" cores (FC) (page 323) are either "electrically" magnetized or "permanently" magnetized.

When electric current is passed through the "coil" winding, on the "field" magnets, the latter are "**electro**" magnetized. They are "**permanently**" magnetized (PM), when the field magnets are of the type shown in fig. 2, chart 158.

The "electro" magnetized pole pieces may have two or more poles, one must be a north pole and the other a south pole, similar to a common horse shoe magnet. This is necessary in order that the magnetic lines of force from the pole pieces attract the magnetized coils on the armature.

When the current passes through the wire surrounding the soft iron field core, the pole pieces acquire magnetism. When the flow of current is stopped, then the pole pieces lose their magnetism. Hence it is termed an "electro" magnet.

The windings on electro magnets, can be wound three different ways, series; shunt; and compound. The winding shown in fig. 1 is called a "series" winding, and is usually of heavy coarse wire.

††**The "permanently" magnetized pole pieces, are shown in fig. 2.** Wire is not wrapped around the field cores, but the magnets retain their magnetism permanently. One pole being "N" and the other "S" at all times.

The pole pieces (PP), at the lower end of the field cores, as shown in fig. 1, are the north and south poles of the magnetized field cores. The pole pieces are placed very close to the armature and are the parts between which the armature revolves.

The pole pieces in fig. 1, are called "bi-polar" type, because there are two poles. When there are more than two pole pieces, as in fig. 1, chart 160A, it is called a "multi-polar" type.

The armature on an electric starting motor is the part which revolves between the pole pieces. There are several types of armatures, but for starting motors, and generators to recharge batteries and supply current for lights, the "**drum**" type, fig. 3, is generally used.

The "shuttle" type armature, fig. 7, chart 162 and fig. 1 chart 120, is used for magneto ignition. The shuttle type of armature, is used only on magneto type of magneto generators and generates an "alternating" current, being used principally for ignition.

The source of current from the storage battery, to operate the electric motor is "direct" current.

***The commutator on the armature,** passes the current **to** armature coils from **brushes** on the motor. On a generator it transmits the current **from armature.** It is the part placed on the end of armature on which the brushes rest and to which the terminals of the armature coils connect, as shown in fig. 3, chart 158, see also chart 161.

There are as many copper segments on the commutator as there are coils on the armature. (see fig. 3, page 323 and note connections of coils c^1 to commutator segments 1, 2, 3 and 4). The segments are insulated, from each other, with mica between.

**Commutator troubles usually arise from too much oil on the commutator, causing a coating to form across the insulation, between the insulated commutator segments.

†**Brushes on starting motors are the parts (B), chart 161, and 3, page 324, resting on the commutator segments and which conduct the current to the commutator.** They are usually made of copper, bronze or brass wire gauze and also metal graphite which contains copper. A great quantity of current passes through a starting motor brush, **therefore starting motors usually have four brushes,** whereas a generator has **two** brushes, unless it is of the third-brush type.

*Don't confuse the meaning of a commutator on an electric motor or generator with the commutator used for ignition, as shown in chart 106.

**See also pages 409, 404, 406, 331. †See foot note page 408 for generator brushes and starting motor troubles, also read foot note bottom of pages 407 and 405.

***To learn the fundamental principles of an electric motor and dynamo we recommend Swoopes' Lessons in Practical Electricity, see ad in back of book. ‡See also, page 400.

††Not used for starting motors but sometimes used for generators in connection with an auxiliary electro-magnet, per fig. 8, page 332.

Mechanical Method of Starting Motor Gear Shift.

Position 1—when switch is at position (1), the starting motor switch is off and starting motor idle. (see fig. 6.)

Position 2—starting pedal is depressed slowly, this causes contact to be made at (P) with (P1), at which time resistance (R) is in the circuit causing armature to rotate slowly. This slow rotation allows pinion (J) to mesh easily with fly wheel.

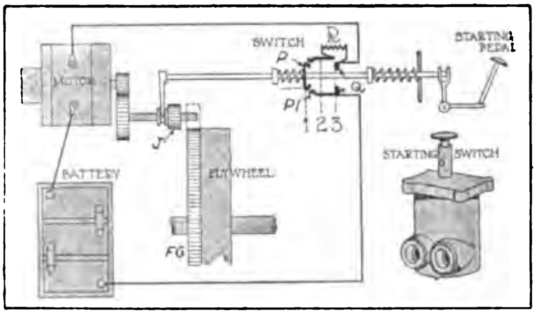

Fig. 6.—Mechanical method of applying starting motor to drive fly wheel.

Position 3—starting pedal is depressed fully. This causes (P) to make contact with (Q) at which point the resistance (R) is cut out and full voltage applied to starting motor terminals in order to crank the engine.

After engine is started, the starting pedal is released and the spring de-meshes the pinion (J) from flywheel gear (FG) and switch cuts-out and assumes position (1).

Note the reduction gear drive. Also the type of switch as it appears from outside view. This is one of the Westinghouse principles. This concern also supplies automatic and other principles—see page 338.

The Automatic Method of Starting Motor Gear Shift—The Bendix Principle, Also called the Inertia Gear Drive.

Fig. 8.—The Bendix "automatic" shifting pinion as used on a large percentage of the different makes of electric starting motors, also called the "inertia" gear shift, is pictured in fig. 8. This illustration is not exactly as it appears today, but explains the principle clearly (see page 331).

This type as used on the King (page 331), the reduction is 10½ to 1, or 12 tooth pinion on a 126 tooth gear on the fly wheel. The teeth are each 10 pitch and the starting motor will crank engine at speed of 150 to 200 r. p. m.

No arrangement of levers to slide the pinion into mesh nor any over-running clutch is required. It is only necessary to operate the switch of the motor, or press a switch button, and this can be done at the wrong time, i. e., when the engine is already running, without damage.

The parts are few and simple. The **armature shaft** has a screwed extension provided with an outer bearing (B), and carries the pinion (P).

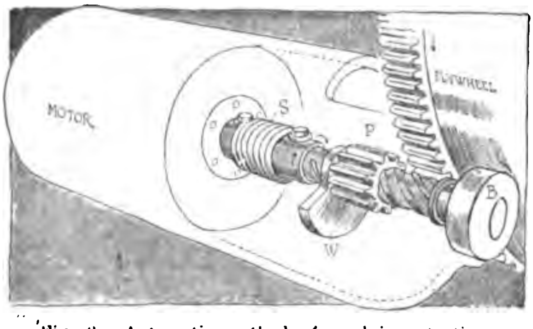

Fig. 8.—Automatic method of applying starting motor to drive fly wheel.

A weight (W) is solidly attached to the pinion and the latter is loose enough on the shaft to always occupy the position shown, with the weight underneath when the shaft is idle. The leading **screw has a** triple thread.

On starting the motor, inertia of the weight (W) causes it and the pinion to be carried quickly along the shaft into mesh with the teeth on the flywheel where it remains performing the operation of cranking until the engine commences to fire, when the direction of the drive is reversed, coming from the flywheel to the pinion, throwing out the pinion.

Action is easy to understand. But a query will naturally arise as to what would happen if the starting switch is not released and the motor continues spinning. It would seem that the pinion would again return and either get into mesh or continue chattering at the edges of the teeth. Neither happens. The pinion simply continues to rotate out of mesh until the switch is released. This is due to a secondary function of the weight (W). Immediately the pinion is thrown out from the flywheel the speed of the motor is such as to cause a binding of the pinion on its shaft due to the one-sided position of the weight. The action involved is that of the center of gravity of the weight attempting to get into the central plane of rotation of the pinion and the slight necessary looseness of the pinion on the shaft allows a temporary binding as a result.

The spring (S) is simply to ease the shock of starting by permitting a slight play between the motor shaft and the screwed extension. The teeth of both flywheel and pinion are beveled on the entering side for easy engagement. As shown the motor is geared by a single reduction to the engine, but the device is equally applicable to a double reduction.

CHART NO. 160—Application of the Electric Starting Motor to Fly Wheel of Engine; the "Mechanical" and "Automatic" Method Explained.

Note:—The Bendix is also known as the Eclipse-Bendix.

Type of Electric Motors.

Although there are many different makes of electric starting motors, we have dealt only with the type in general use, which is the "series" wound field cores, with the "drum" type armature as explained in the charts.

We have given the names of the parts, also explained, that when the current from battery flows through the field coils, thence through the armature coils by the way of the brushes resting upon the commutator segments, which are connected with the armature coils, the armature, is then caused to revolve by magnetism, the pole pieces drawing the armature coils around. We will not attempt to explain why this armature is made to revolve, because this would necessitate a lengthy explanation and deep study of electrical engineering, not required by the average student.

Application of the Electric Starting Motor to the Engine.

The starting motor can drive the gasoline engine through the **fly wheel**, or by connection with the **crank shaft**, or drive through the **transmission shaft.**

The drive through the fly wheel is the most popular. There are two general methods used; (1) by gears as per A B C D, chart 160, which necessitates throwing the gear (J) in mesh with the fly wheel gear (FG) by **hand or foot.**

The other method is "automatic;" by pressing a button or foot switch the circuit is closed between the storage battery and starting motor. The "inertia" gear pinion (P) then automatically meshes with fly wheel gear as explained in chart 160 and 161A. This system is the most popular.

Another "automatic" method is where the gear is shifted "electrically," as in chart 161. This type is also called a "displacement" type of armature.

The drive through the crank or transmission shafts; can be by means of gears or chains as illustrated in chart 159.

After starting engine: In each instance some means must be employed to **disengage** the motor and engine after it is started, this is done by means of the **shifting gear** or clutch. See illustrations in charts 159 and 160.

Starting Switches.

The switch with resistance was formerly used with starting motor. This resistance prevents the full flow of current going to the motor, until armature is in motion. The resistance is in the form of German silver wire or other like substance which offers resistance to the flow of current. A further depression of switch, see fig. 6, chart 160, shows how the resistance (B) is cut out when switch contact (P) is in full contact with Q.

Switches for the "automatic gear shift" do not require resistance. See chart 160B.

*The Storage Battery.

The electric current is supplied to the starting motor from a storage battery. The voltage is usually 6 volts, but some systems use 12 to 18 volts, others 24 volts.

The voltage of storage battery can be ascertained, by counting the number of cells. For instance, if there are three cells then the battery is a six volt battery. If there are six cells it is a 12 volt battery. **Each cell gives two volts**—no matter how large or how small. (see instructions 32 and 32A.)

***The amperage or quantity of current consumed by a starting motor varies.** The average length of time the starting switch is down is about 10 seconds. Therefore, this great quantity of current being drawn from the battery it must have large heavy plates as well as large connections from one cell to the other.

Large wire for conducting the current to the motor is also necessary. (see pages 425 and 427.)

The average cranking current is 200 amperes or more when first starting—for say ½ of a second, then 150 amperes as the engine flywheel turns. The voltage of a charged battery when being used for starting, drops to approximately 5.4 volts. See page 410.

(This test was made on a leading battery at a temperature of electrolyte of 86° F.) This of course varies according to compression, size of engine, etc.

The overload on the battery, it will be noted, is considerable, in fact, it is a temporary dead short-circuit for an instant, but being only momentary—a good battery will stand it. (see pages 427, 400 and 408.)

†Charging the Storage Battery.

A starting and lighting storage battery, could be charged by removing it from the car and taking it to a charging station, but owing to the great amount of current used, the size of the battery required, in order to last for a satisfactory period of time, would necessitate entirely too large a battery. **Therefore a dynamo, also termed a "generator,"** is operated from the engine. When the engine is running the car at a speed of ten miles or more per hour, this generator, generates electric current and stores it into the storage battery. The generator is treated in the next instruction.

*See "index" for explanation of "volts and amperes," also index for "storage batteries." Only "direct" current is used for starting motors. See "index" for "direct" current.

†The positive terminal of a storage battery is usually grounded, if system is a single wire. The negative could be grounded, as it would make no difference.

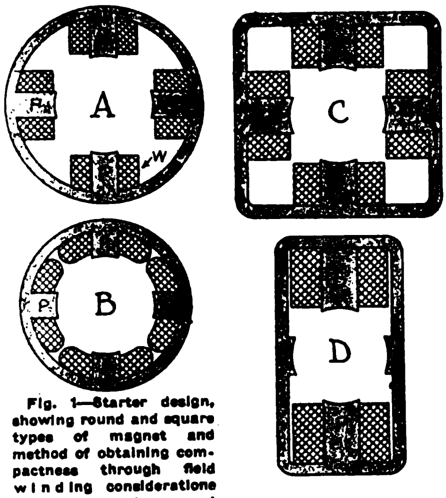

Fig. 1—Starter design, showing round and square types of magnet and method of obtaining compactness through field winding considerations and filling of magnet spaces

Field Magnets.

Or "pole pieces" are usually fitted with poles for the field windings (W) as shown in fig. 1. All starting motors have two or four poles (P) as shown.

The illustration on page 328 shows the principle of winding but are never constructed as illustrated on that page. A-B-C are "multi-polar" types with 4 poles and windings. D, is of the "bi-polar" type with two field windings. All starting motors are series wound.

When the multi-polar field is used the conductors on armature, revolving between them, cut the magnetic lines of force many more times in one revolution so that as the size of machine increases the speed decreases—which is an advantage.

Fly Wheel and Crank Shaft Drive.

Figs. 4 and 5 is a typical example of a starting motor (the Westinghouse). This motor is for fly wheel drive and could be equipped with the "Bendix inertia gear drive" page 826. Or with the Bijur below.

Fig. 6 shows double reduction gearing inside of motor housing, if starting motor is intended for crank shaft drive—which allows for slew speed connection, by chain or gears to crankshaft—see page 324, fig. 7.

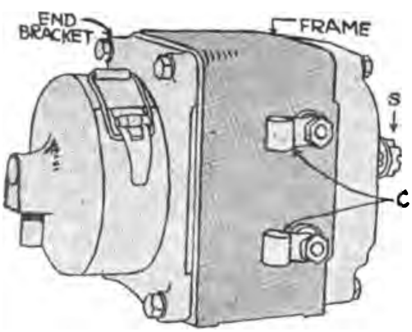

Fig. 4. For fly wheel drive.

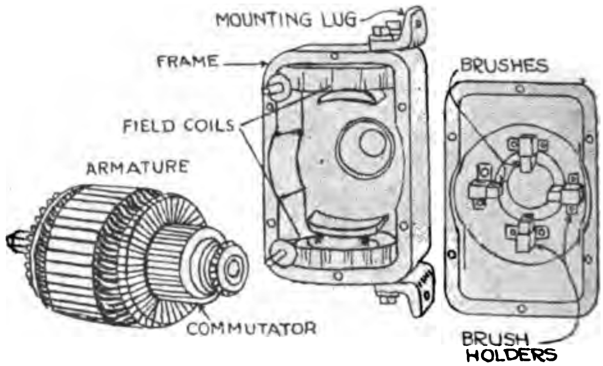

Fig. 5. For fly wheel drive.

The Bijur Double Gear Drive.

The Bijur double geared pinion shift (fig. 7) for starting motors driving through the fly wheel is similar in some respects to the Bendix (page 826) and can be attached to the armature shaft (A) of any starting motor with shaft machined to fit it.

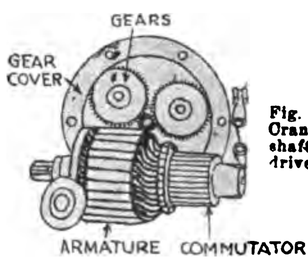

Fig. 6. Crank shaft drive.

Name of parts; A—armature shaft; B—drive shaft; D—driving gear; E—clutch; H—sleeve; L—clutch spring; M—pinion which meshes with fly wheel gear or pinion; O—light spring; X—pinion on end of armature shaft.

To start engine: Driving gear (D) rotates drive shaft (B) through clutch mechanism (E & F). This causes pinion (M) to screw itself to left along the shaft (P) and after meshing with teeth of fly wheel (M), continues to travel in mesh until (M) comes in contact with sleeve (H). It then pushes (H), the whole clutch assembly and driving gear (D) in same direction and compresses clutch spring (L).

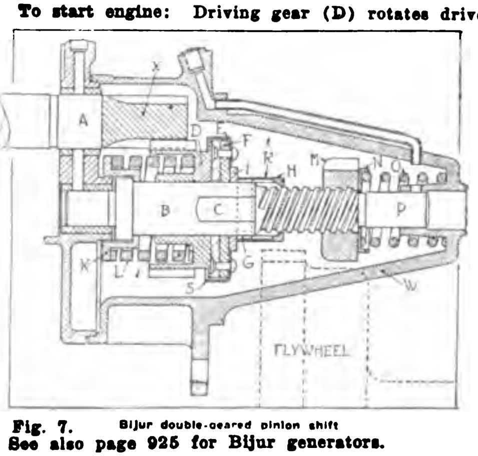

Fig. 7. Bijur double-geared pinion shift
See also page 925 for Bijur generators.

When the members are in this position there is sufficient pressure between the face of the driving gear (D) and the clutch member (E) to cause the clutch to transmit to the driveshaft the power required for cranking. This it continues to do until the engine begins firing.

When the engine starts the pinion (M) is rotated faster by the flywheel than by the electric motor. It, therefore, screws itself to the right and out of mesh with the flywheel teeth. On coming out of mesh the pinion is cushioned by the spring (O).

CHART NO. 160A—Field Poles or Magnets of a Starting Motor. Example of a Starting Motor For Fly Wheel and Crank Shaft Drive. The Bijur Double Gear Drive. See page 373, address of Electric Motor Mnfg'rs.

(Single-Reduction Motor Has Screw Shift Directly on Motor-Shaft Extension)

Starting Motor Switches.

Can be operated by "hand" or by "foot." If hand operated it may be in the form of a "single pole" switch or a "push button." If by foot it is usually by a foot pedal.

Starting motor drive systems are divided into three systems of drives; fly wheel, transmission and crank shaft drive.

Switch for crank shaft drive: a "geared starting motor" connected to the crank shaft is usually employed (see fig. 2, chart 159). The starting motor drives through an over-running clutch on the engine shaft. Pressure upon the starting pedal of switch, closes circuit through the starting motor and battery. Releasing the starting pedal cuts off the current from the battery to motor. The switch that is used with this application has only a short travel as there are no gears to shift by the operation of the switch pedal.

Switches for fly wheel drive may be divided into three clasifications as mentioned below.

Non-automatic mechanical shift, employs a switch lever that shifts the pinion (gear), also closes starting switch, first spinning the motor then shutting off the power till gears mesh with motor gear, turning from its momentum, finally throwing on full power and cranking the engine, see fig. 6, chart 160.

Automatic mechanical shift. Worm shaft mechanism to throw pinion into mesh automatically without shock when motor starts; throws pinion out when engine picks up, see fig. 10 and 11, also chart 160. Note that a hand or foot operated switch or an electro-magnetic switch with push button can be used (see below).

Bosch fly wheel starting motors (known also as the Rushmore system) operate on the electro-magnetic principle, but without extra gear shifting solenoid. "See chart 161."

Electromagnetic shift. A solenoid on one end of the motor throws a spirally cut pinion into mesh with gear on flywheel when the starting switch is closed and releases it when the engine picks up. Either foot switch or electrically operated switch with push button control can be used, see fig. 3 and 4. Note the type switches which can be used with this system.(Note in fig. 4—word over armature—reads: "starting magnet," should be "shifting magnet.")

The "electromagnetic" gear shift, is the Rushmore principle, chart 161, also see figs. 3 & 4 above.

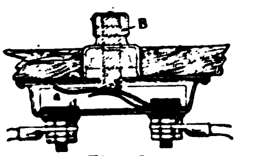

Fig. 9.

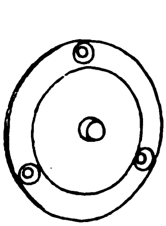

Fig. 8—Push-Button Switch for Magnetically-Operated Starting Switch.

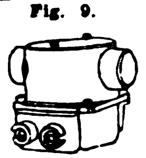

Fig. 7 — Electro-Magnetically Operated Starting Switch Automatic Pinion Shift.

Types of Starting Switches.

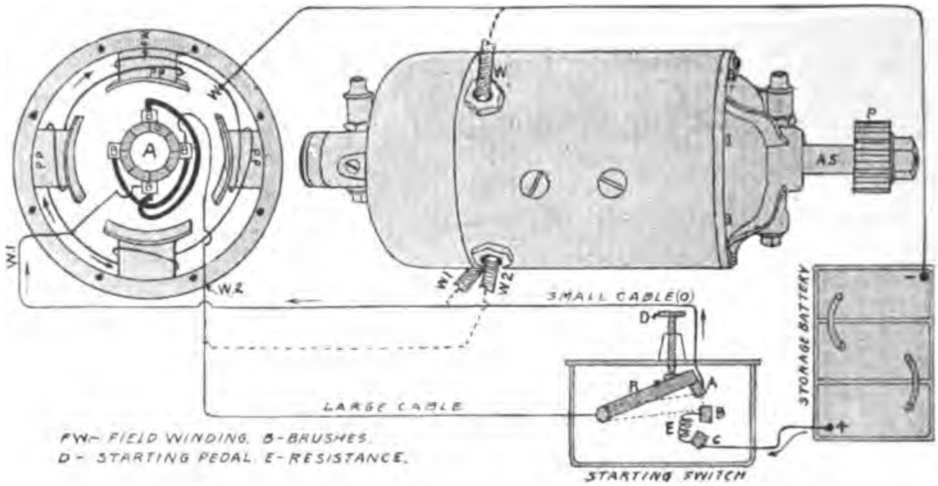
Fig. 9. Shows a foot operated starting switch for automatic pinion shift" drive as "Bendix." Contact is closed at (a) and (d) when (B) is depressed.

Fig. 8 shows the "push-button" switch. Fig. 7 the electro-magnetically-operated switch for the "electrically-operated automatic pinion shift" as shown in diagram of fig. 11 and chart 161, and also the automatic mechanically operated pinion or gear shifts see chart 160, fig. 8.

The principle of the electro magnetic type switch: The operation of this switch is controlled by a push-button, (see fig. 8) which closes an auxiliary circuit from the battery. This circuit energises the electro-magnetically operated switch as per fig. 7 and as shown in diagram of fig. 4 and 11.

See chart 160 for switch of resistance type used with the "non-automatic" gear shift.

CHART NO. 160B—Starting Motor Switches.



This description will serve the purpose of explaining all starting motors if the reader will bear in mind **that the only difference between this starting motor and others, is in the movement of armature against the tension of spring (see below) which causes gear (P) to mesh with flywheel gear (FG).**

Other starting motors are wound exactly as this one is wound, but the shunt wire or cable O or WI is omitted, which is necessary in this instance as will be explained.

Other starting motor armatures do not shift, instead a Bendix drive, or other means for connecting gear P to FG is provided.

Principle of this starting motor is as follows: Switch arm (R) is pressed down slowly by foot pedal (D), until connection is made from A to B. Note current from battery must then pass through resistance (E). The amount of current is thus limited. A small portion of the current will then flow through armature (A), while the greater portion flows through the motor field coils around pole pieces (PP), forming a strong electro-magnet of the field pole pieces (PP).

Result is the armature is drawn endwise against tension of spring into the magnetic center of the motor or, in other words, into its working position between the pole pieces. The passing of the small amount of current through the armature causes the armature to rotate slowly, and as the rotary motion occurs simultaneously with the shifting of the armature endwise, the meshing of the motor pinion (P) with the gear ring on the engine flywheel (FG) is accomplished quickly and positively.

Immediately after connection is made at A and B, the switch pedal D is pressed down until B is in contact with C, therefore the resistance (E) and the connections A and B and shunt cable O or WI, are cut out of the circuit and a straight series motor connection (which is connections for all other starting motors) is established, allowing the entire current to pass through the motor field and armature windings in series, from (+) battery to C, then through arm R to brush B; to lower brush B; through field windings; out W back to (—) battery, thus causing crank-shaft of engine to turn over until engine starts firing.

As soon as the engine starts, the starting motor is relieved of its load, and the current passing through it drops rapidly in volume, this being a characteristic of all series starting motors. In consequence, the strength of the field magnets is lessened to a point where the spiral spring in the end of the armature shaft overcomes the magnetic attraction holding the armature, and returns it to the original or non-operating position; it is this action that automatically and positively throws the armature shaft pinion (P) out of mesh with the flywheel gear (FG). Thereafter, until the starting switch is released, any current which continues to pass through the armature will merely cause the latter to revolve freely but without meshing with the flywheel, due to the fact that the amount of current utilized when the motor is running free and shunt wire O is out of the circuit, is not sufficient to overcome the tension of the spiral spring. The switch should be released quickly.

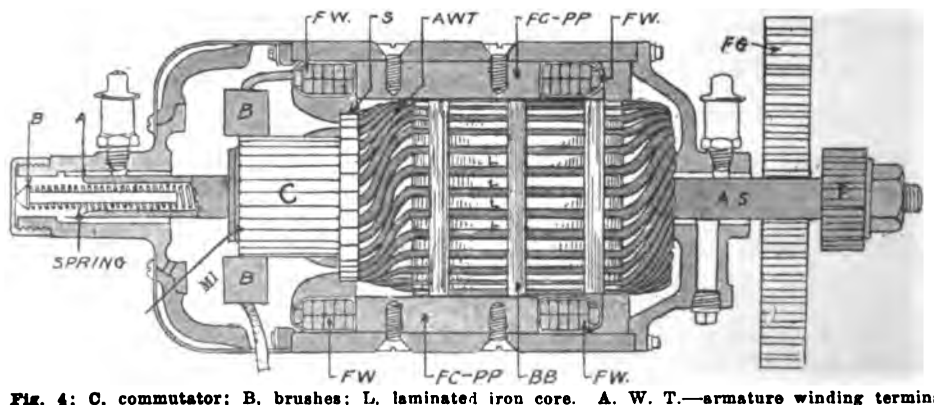


Fig. 4; C, commutator; B, brushes; L, laminated iron core. A. W. T.—armature winding terminals. B. B., brass bands around armature to hold coils in place. F. C. and PP., field core, or pole pieces. FG flywheel driven gear.

CHART NO. 161—The Rushmore Principle of Starting Engine through Flywheel with "Displacement" Type of Armature. This system is now known as the **Bosch** System. It is also called **n "Automatic Electro-Magnetic Gear Shift"** system.

Bendix Starting Motor Inertia Gear Drive.

The winding on the starting motor as well as on others, is a series winding and would be similiar to starting motor shown on page 330, except there is no shunt wire (O) from switch to starting motor. The path of the circuit would be a straight series connection from battery to switch; switch to armature brush; armature brushes to field winding; field winding back to battery. See lower illustration, page 360, and note one wire from switch to battery can be grounded.

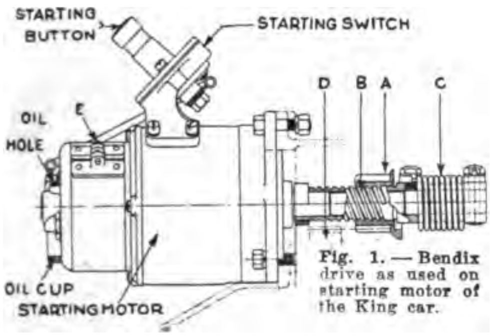

Fig. 1. — Bendix drive as used on starting motor of the King car.

This armature does not shift, instead, the gear A shifts, which meshes with flywheel gear D. The action being as follows: When starting button of switch is pressed down the connections are made as explained above, which causes armature to rotate rapidly. This causes gear (A) to travel towards motor on the coarse threaded sleeve (B) and mesh with gear (D) on flywheel. B is connected to armature shaft through spring (C) which allows a certain amount of flexibility and prevents too sudden application of the gears.

As soon as gear (A) is fully engaged with flywheel gear (D), it comes up against a stop and is locked firmly to sleeve (B), thus rotating with the starting motor armature shaft and allowing starting motor to crank engine.

When the engine starts under its own power and the starting button is released, the small inertia gear (A) is thrown out of mesh with the flywheel gear (D), and the starting motor comes to rest.

Note: The Bendix type of drive shown in fig. 8, page 326; the spring is positioned at inner end of sleeve and gear A travels in opposite direction. The principle however is exactly the same. In this construction counter-weight on gear (A) is in the form of a flange.

†Care of Starting Motor.

Lubrication: The bearing at the commutator (rear) end is fitted with a wick oil cup underneath the bearing. The wick dips into the lubricant and the upper end rests against the armature shaft, so the oil is constantly fed to the bearing. The wick should be cleaned with gasoline and the oil cup filled with non-fluid oil or vaseline once every 3000 miles. Oil hole is on top of bearing bracket.

Commutator: The commutator and brushes can be exposed by unscrewing the screw in (E) and removing the band cover. Do not touch the commutator so long as the motor starts properly. If it becomes dirty, clean with a piece of canvas moistened with gasoline; if rough, polish with No. 00 sand paper while revolving. See pages 407, 404 for "Care of Starting Motor."

Bendix Starting Motor. Troubles.

In case the starting motor fails to start the engine when the starter button is pressed, the following will be found helpful in tracing the trouble: (1)—Ignition switch in "off" position. (2)—Throttle closed; (3)—Carburetor not choked; (4)—Loose ignition wire connections; (5)—Interrupter breaker points out of adjustment; (6)—No gasoline in main tank; (7)—No gasoline in gravity tank. Remove carburetor float chamber cover and if no gasoline, see that shut-off cock underneath gravity tank is open. If there is gasoline in the main tank and none in the gravity tank, see gasoline feed instructions for remedy, page 165.

Starting motor runs, but does not crank engine. This trouble is only apt to occur in extremely cold weather when the oil congeals, causing the starter inertia gear to stick, and not move into mesh with the flywheel gear. A slight tapping on the starting motor housing will usually overcome the difficulty, but if this fails, start the engine with the hand crank and when motor is warmed up, it will operate properly.

Starting motor does not run. This might be caused by any of the following: (1)—Loose connections at either starting switch, starting motor or battery; (2)—Battery discharged. (Test solution with hydrometer; (3)—Dirty starting motor commutator; (4)—Worn or loose brushes. (See pages 407 and 422.)

If pinion goes into mesh with a "bang" and there is considerable noise while cranking, it is evident that the clamping bolts (R) fig. 2, have loosened. Be particular to line up the motor properly before drawing them up. By turning the threaded sleeve (B) with the fingers, the pinion (A) can be moved into mesh, and unless it meshes easily, it is not in line.

Starting switch—good contact and a quick release, is important. Examine spring occasionally as it must be in good order to prevent damage to gear teeth. Keep clamping bolts (that hold down motor) drawn up snug at all times, otherwise motor will shift out of line.

Occasionally a Bendix drive gear will stick in mesh, and will not release after the engine has started. This is often caused by improper alignment of a starting motor. Or if the gear meshes harshly, or spins considerably without meshing, proceed as follows: (1)—Remove bolt R, spring C, and threaded sleeve (B); (2)—Wind a strip of emery cloth around a stick and clean inside of sleeve B; (3)—Clean armature shaft; (4)—Apply small amount of light graphite grease to inside of sleeve (B) and replace parts; **(5)—Don't grease any other part of this drive mechanism as the action of the starter depends upon the inertia weight on gear A, and this action is hindered if grease, or dirt is on threads of B;** (6)—See that starting motor is in perfect alignment. If not, place 1/32" shims under it.

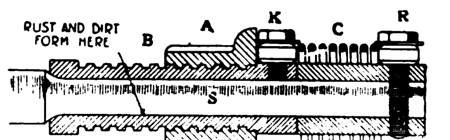

Fig. 2—Bendix drive troubles may develop from rust and dirt collecting on the inner drive shaft and sleeve. This should be cleaned out by means of emery paper, being careful no trace of emery is left.

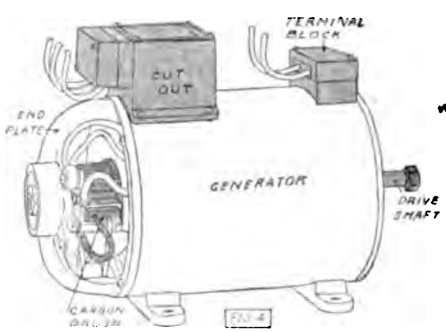
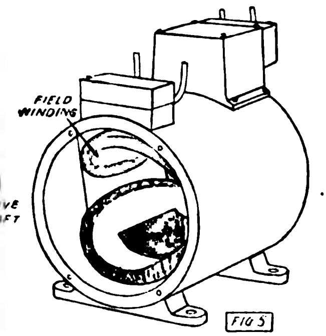
CHART NO. 161A—Example of a modern Starting System; the Electric Starting Motor with a Bendix Inertia Gear Drive. The Bendix drive is used on different makes of starting motors and is the most popular system in use. (See also, fig. 8, page 326).

See page 360, for King wiring diagram. See also page 668 for clutch adjustment of the King Car. †Refers to the starting motor used on the King Car.





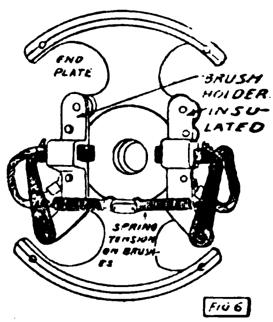


Fig. 4. A modern direct current (dynamo) generator. The cut-out is sometimes placed in the generator or on the inside of the dash.

Fig. 5. There are two "field poles" (PP). Around the field poles are windings. When armature revolves current flows through the field windings causing field poles to become magnetized. therefore the field poles (PP) are "electro-magnetized." When the field poles become magnetized the "lines-of-force" pass from one pole to the other and as armature revolves between the poles, the lines-of-force are cut and current generated, as explained on page 267. The question would then arise, where do field poles obtain their intial lines-of-force to start with? See answer on page 737.

Fig. 6. Illustrates the brush holders and brushes, which are mounted on end of generator as shown in fig. 4. There are usually two brushes on a generator and four brushes on a starting motor, for reasons explained on page 325. There are also, usually four field poles on a starting motor, due to the fact that considerable power is required and the pulling power of the "electro-magnetized" fields must be very strong.

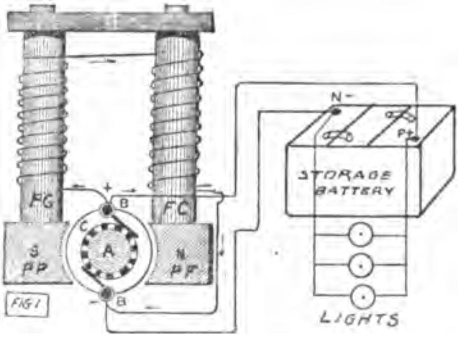

Fig. 1. A shunt wound dynamo. FC, field poles or core; PP, pole pieces; A, drum armature; C, commutator; B, brushes.

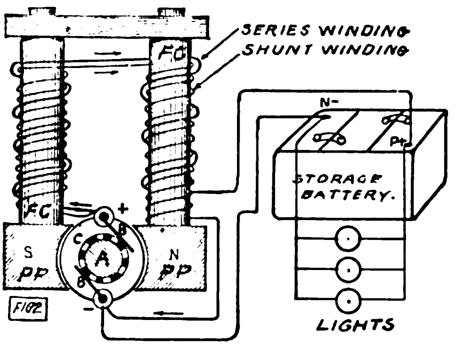

Fig. 2. A compound wound dynamo. Note the two windings on FC.

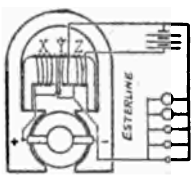
Fig. 1. A "shunt wound" generator. Note connections from field windings is shunted across the circuit at the brushes. As the speed of armature increases, greater the flow of current through the shunt field windings, and greater the lines-of-force produced in PP, and consequently greater the output of generator. For this reason an external "regulator," to cut down the strength of the magnetism of the field poles (PP) is required. Usually a "voltage type regulator," as explained on pages 342 and 925 are employed, where generator is a plain shunt wound generator.

Fig. 2. Illustrates a "compound wound" generator. Note in addition to the "shunt winding," a "series winding," is also wound on the field poles. The external "regulator" is seldom used with this system but is **inherent** or within the winding as explained on page 345, under "bucking-series regulation," wherein the "series winding" opposes the "shunt winding" at high speeds, thus reducing the magnetism in field poles and preventing an excess of voltage and current at high speeds.

Fig. 3. On above generators the fields are "electro-magnetized," that is, they are magnetized by the flow of current through the field windings. In fig. 3 (Esterline generator), there are "permanent magnets" in addition to the "electro-magnetized" field—classed as a "compound generator."



The permanent magnets serve the same purpose as the shunt field. At low speeds the field windings assist the permanent magnets and at high speed they oppose them, so the output is maintained fairly constant. An auxiliary winding (Z) is used to increase the output when lamps are turned on. Armature is "drum" type.

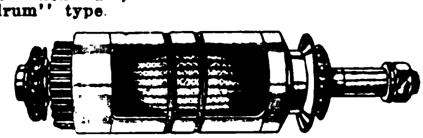


Fig. 7. A "shuttle" type of armature used on magnetos which generates "alternating" current. Note instead of a commutator, there is a "collector ring". Not suitable for charging a storage battery. (see also, page 256).

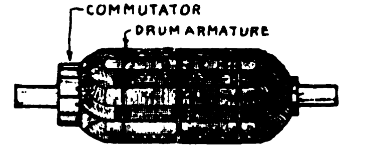
Fig. 8. A "drum" type of armature used on "direct" current generators which is suitable for charging batteries. All generators produce alternating current, but the "commutator" with two or more brushes direct the flow in one direction, thus establishing a positive (+) and negative (—) terminal at the brushes, whereas the current taken from a "collector ring" on a shuttle type armature alternates from positive to negative and visa versa.



HART NO. 162—Principle of The Direct Current Generator.

ote: Cut-out is not shown connected in figs. 1 and 2 but is very necessary. See page 334 for purpose and escription of a cut-out.

INSTRUCTION No. 27.

THE ELECTRIC GENERATOR: Principle, Construction, Operation and Drive. The Magnetic Cut-Out. Series, Shunt and Compound Windings. Regulating Methods; Bucking Series, Mechanical Governors, Third Brush, Voltage or Potential and Thermal. Ignition from Direct Current Generator.

Relation of a Generator to an Electric Motor.

****The electric generator** is similar in many respects to an electric motor. The principal difference being in the winding. The motor is usually "series" wound and the copper wire is heavy or coarse, in fact it is in the form of copper strips on some motors. With a few minor changes the electric generator can be run as a motor, using the same winding.

The series motor possesses great starting power, but under a light load may attain a dangerously high speed. **A series dynamo**, to be used as a motor, and run in the same direction as it does as a dynamo, must have the leads from the brushes interchanged.

A "series" wound generator will rotate in an opposite direction to that as when run as a motor.

A "shunt" wound generator when used as a motor, will turn in same direction as when used as a generator.

The shunt wound motor has not such great starting power as a series wound machine, but runs much more uniformly in speed under a varying load. Brush leads remain as in dynamo for the same direction of rotation.

A "compound wound" generator, when used as a motor will turn in an opposite direction—providing that if the "series" part is more powerful than the "shunt" and in the same direction if the "shunt" is more powerful than the "series"—this is called a differential winding and will be explained later in the Entz and other systems where the same machine is used for a motor or generator.

The compound wound motor is about equal to the shunt motor in starting power, and runs at an almost constant speed under all loads. Brush leads for motor remain as in dynamo. To reverse direction of rotation of motor, current must be reversed through armature.

The generator, however is usually separate and distinct from the starting motor. The Delco however, (in some of their systems) employ one armature with two commutators; one operating when used as a generator and the other when used as a motor. The Entz system is another example of one armature with two windings, used for both a generator and starting motor, see page 352.

**Principle of the Generator.

***Dynamo machines.** This machine is based on a discovery of Faraday, who found that when a conductor is moved across a magnetic field, a momentary current of electricity is generated in it by what is called **induction.**

The dynamo consist of two main parts—(1), a means of producing a strong magnetic field known as the "field magnets"; (2), a series of conductors in which the currents are generated by induction, called the "armature."

One of these parts must be capable of rotation relative to the other. If one conductor on such an armature be connected to a galvanometer it will be noticed that during half a revolution, either of the armature or field magnet, the current is in one direction through the conductor and that for the other half of the revolution the current is in the opposite direction.

Such a current is called an "alternating" current, and the machine producing it is called an alternating current generator, or a "magneto."

****If such a machine is fitted with a number of metallic segments insulated from each other, called a "commutator,"** to which equidistant conductors of the armature are joined and two brushes are placed on opposite segments (for a two-pole machine) of this arrangement so that the armature of the machine can be rotated while the brushes remain fixed and make contact with the segments as they rotate, and so arrange the brushes that just as the current is reversed in a conductor the segment attached to that conductor is under the brush, the current produced will be continuous in direction. A machine so arranged is termed a **continuous** or "**direct**" **current dynamo.**

A dynamo is perfectly reversible. If electrical energy is supplied, it is **transformed into mechanical energy and when** thus used is spoken of as a motor.

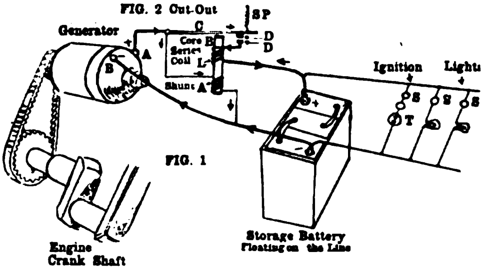
*A dynamo and generator are referred to as the same. **Those desiring to go deeper into the principle of the dynamo and motor—we recommend "Lessons in Practical Electricity"—see ad back of this book.

**All dynamos would be alternating if current was taken direct from armature by a collector ring or spring as on a magneto. The commutator (see fig. 3, page 323) commutates or directs the flow in one direction.

Principle of Reverse Current Cut-Out.

Purpose of a direct current generator and storage battery, and how the generator is driven is explained on page 337.

Purpose of an automatic cut-out is explained on page 337.



How the Cut-Out Operates.

When engine is idle, battery supplies current for ignition, lights, horn and at all times supplies current for the starting motor, if charged. The battery is disconnected from the generator (fig. 1) through points D of cut-out being open, when engine is idle or running slow.

When engine is started and running less than 10 m. p. h. car speed, the generator current is building up magnetic strength around iron core B through the fine wire shunt winding A. As speed increases, voltage of generator increases up to a certain point (explained under "regulation" below).

When engine speed reaches about 10 m. p. h. (high gear), generator speed is sufficient to generate enough voltage (about 6.8 volts), to overcome voltage of battery (6 volt battery in this example), also for shunt coil A to magnetize core B and draw blade C to it. This closes circuit between generator and battery and battery begins to be **charged** and generator supplies the current for lights and ignition. Battery simply "floats on the line." Generator current is now flowing through both coils A and L in **same direction.**

When generator slows down, so that voltage of generator is less than that of the battery, battery will **discharge** through series coil L and in doing this it is flowing around this winding L in opposite direction to what it did. This **reversed** current flow opposes the now weak flow of current from generator around coil A, with result core B is **demagnetized** and releases blade C, which is drawn from B by spring SP. This opens points D and battery is now disconnected from generator.

Above action is repeated over and over as engine speeds up and slows down. See also, pages 337, 342, 344, 339, 338, 864B.

It is also necessary to regulate the output of a generator—see below.

How the Output of a Generator is Regulated.

The purpose of regulating the output or current generated by a generator is explained on page 337.

The different methods of regulation are explained on pages 337, 343, 345.

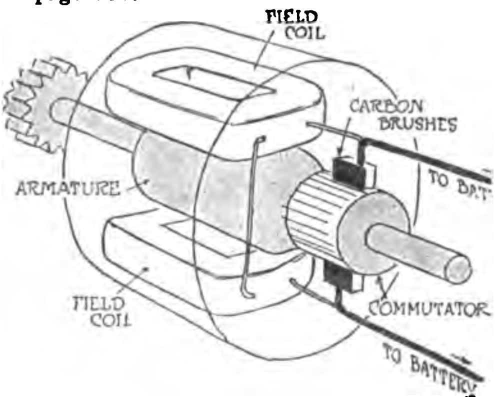


Fig. 3. A shunt wound generator—showing how current is taken from brushes to energize field magnets. A plain shunt wound generator usually requires a magnetic type of current regulator as in (A).

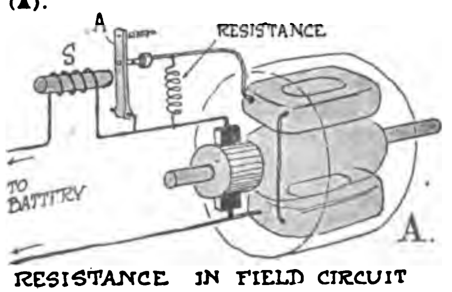

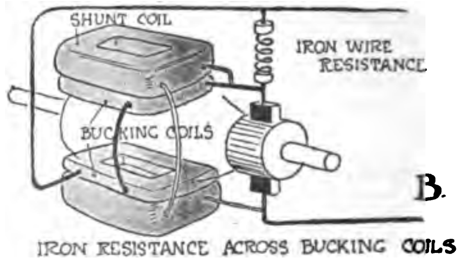

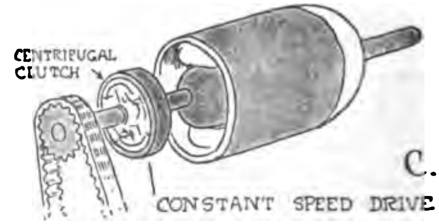

A—"Magnetic" method of regulating the output of a shunt wound generator by cutting resistance into the field circuit through magnet (S)—see page 342, fig. 9.

B—The "thermal" method—see page 339, fig. 1.

C—A "mechanical governor" method. A clutch releases over certain speeds, thus keeping the speed constant—see page 351.

The "third-brush" regulated generator, page 925 and 889, and "reversed compound field windings" on generator (page 345), require no external device as a regulator, to keep the output constant.

CHART NO. 163—Purpose of the Direct Current Generator, Storage Battery, Cut-Out and Regulation of Output of Generator. (Motor Age.)

*There are two general adopted methods of regulation; the "constant voltage" and the "constant current" regulation—see page 925. Each involves different methods—see also pages 843, 345, 864O and 410.

*Parts of the Direct Current Generator (Dynamo.)

The parts of the generator are: (1) The armature; in which the current is generated. (2) The field cores or magnets; "permanent" or "electro." (3) The pole pieces; bi-polar or multi-polar. (4) Commutator. (5) Brushes; metallic or carbon. (6) Regulation of current output.

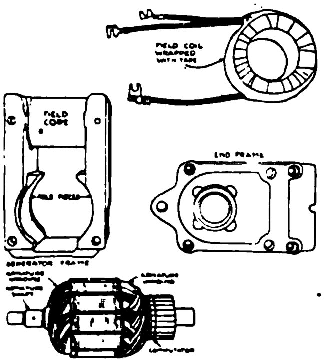

Fig. 1. Parts of a direct current generator with one field winding above armature.

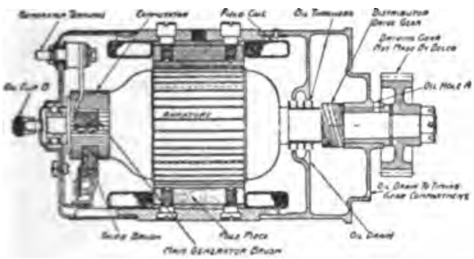

Fig. 2 Parts of a direct current generator with two field windings, one on each side of armature.

The Generator Windings.

The windings on the field-cores of a generator; instead of a plain "series" winding as on a starting motor, there is a "shunt" or "compound" winding, see figs. 1 and 2, chart 162. Note the terminals of the field winding are connected to the brushes, instead of one end of field winding going to the battery as in fig. 1, chart 158.

The word "shunt" means an additional path established for the passage of an electric current or discharge. Another winding, is the "compound winding," see fig. 2, chart 162.

Continuous or "direct" current dynamos are divided into three classes, differing in the manner in which the field magnets are wound.

1. **Series machine.** Coils on field magnets consist of a few turns of large wire, through which all the currents generated flow; joined in series with armature and external circuit.

2. **Shunt machine.** Coils on field magnets consist of many turns of small wire arranged as a shunt to external circuit, and allowing only a small fraction of the total current generated to flow through them.

3. **Compound machine.** Partly excited by shunt and partly by series coils.

The field core is that part of generator on which the wire winding is wound. When wound with insulated wire and a current of electricity passes through them, they are called "electro magnets," meaning that they are magnetized when running; at which time current flows through the wire winding and magnetizes the core thereby producing the magnetic field in which the armature revolves.

A generator which generates a "direct" flow of current can have either a "permanent" magnetized field magnet, as in fig. 3, page 332, or "electro" magnetized fields, where the fields are magnetized only when armature is revolving—but in every instance the armature must be "drum" wound type and not the "shuttle" type. The "electro field magnets" are more popular.

Sometimes "permanent" magnets are used for the field magnets, for instance fig. 3, chart 162, on a "direct" current generator, and the appearance being similar to a magneto, the impression is formed that it must produce an alternating current. By referring to page 256, the subject of "alternating" current magneto type of generator is explained.

Armature.

The type of generator used for charging storage batteries and also for ignition when used in connection with a storage battery and lighting system generates a "direct" flow of current.

A generator which generates a "direct" flow of current must have a "drum" type of armature. If armature was of the "shuttle" type, as per fig. 4, page 256, it would make but two waves of current at each revolution; the waves being strongest just as the end of armature breaks from the pole piece, and not being provided with a commutator, to change the direction of the induced current, this armature would generate **alternating** current; because alternating current does not flow in one direction continuously is the reason why it is not suitable for charging a storage battery. To charge a storage battery the current must flow in one direction continuously.

*See also page 733. Generators usually have 2 brushes because the current output is seldom over 22 amperes. The starting motor usually has 4 brushes because the current required for starting motor is over 100 amperes.

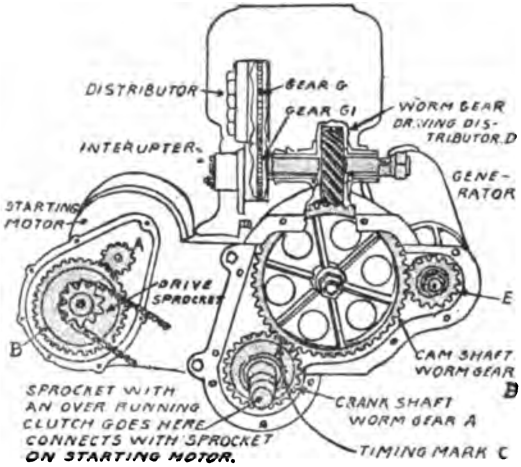

Fig. 1. Driving the generator from cam shaft, also distributor and "interrupter," but independent from each other. The starting motor drives "through the crank shaft" by a silent chain and over running clutch. This system is a "three unit" system formerly employed by "Studebaker Six." See page 244, fig. 4, for description of this "interrupter" timer.

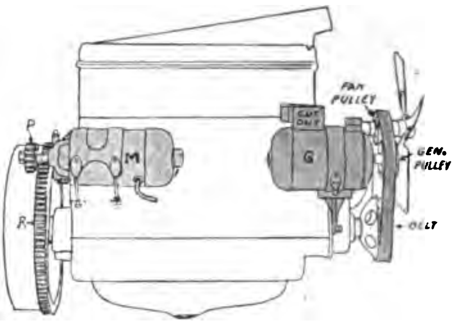

Fig. 5. Generator driven by belt which drives the fan. Starting motor is the "automatic electro magnetic pinion shaft" drives through fly wheel. This system would be termed a "three unit system."

The ignition is the Atwater-Kent system and is driven from cam shaft separate. This system formerly used on Regal.

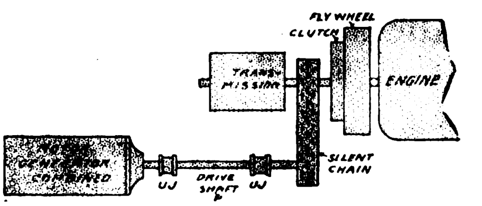

Fig. 3. The generator and starting motor are combined in one. Drive is through transmission shaft by means of a silent chain. The ignition is independent. This is a "two unit system." This system formerly used on Chalmers, see chart 171.

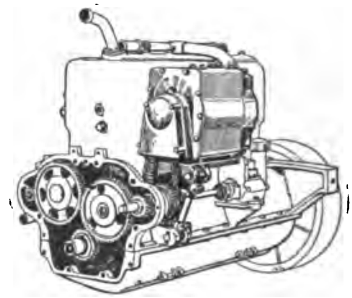

Fig. 6. Generator, driven by gears and silent chain.

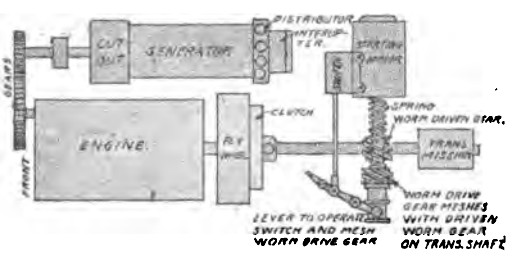

Fig. 4. Generator driven by gear from crank shaft. The starting motor drives through the transmission shaft. Ignition is the "interrupter" type mounted on the generator but driven independent of the armature shaft, otherwise, on account of the clutch on other end of armature shaft the timing would be thrown out of time. Reo system.

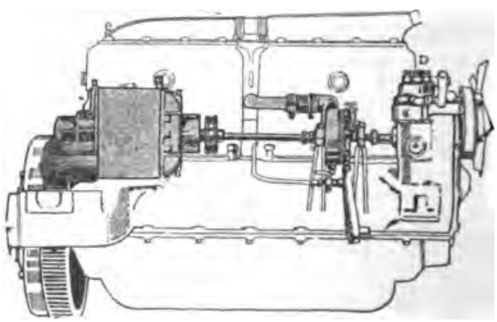

Fig. 7. Generator and motor combined. One armature serves for both. Generator driven from pump shaft also distributor and timer. Starting motor drives through the fly wheel. Delco system used on Hudson, Cadillac, Olds, Buick, and others.

CHART NO. 164—Various Methods for Driving Generators. "See Specifications of Leading Cars," **giving** makes of systems used on various cars.

Charging Storage Battery—from Generator—how Connected and Disconnected from Generator by the Automatic Cut-Out.

Drive: The electric generator is operated by belt, chain, shaft, or gear drive from the engine, and supplies electric current to charge the storage battery and also for lights, ignition, etc.

Purpose: When the engine is not running, or is running at a very low speed, the lights and ignition are supplied entirely by the battery. This provides a "constant" source of supply of current for ignition.

Automatic cut-out: A magnetic switch, called an automatic "cut-out" is placed in the circuit between the generator and storage battery. This device automatically connects the generator to the lighting system and battery when the engine is running at—say, approximately 7 to 10 miles per hour car speed or over, so that generator can charge battery and supply current for lights and ignition.

When running at less speed, the "cut-out" disconnects the generator from the battery and lighting circuit, and the battery then supplies the current.

If lights are burning when generator is connected to battery, then the generator furnishes part of the current to them; as the speed increases, the proportion of current supplied by the generator increases, until at high speed the generator supplies all of the current to the lights, and in addition, charges the battery. **The amount of current the generator supplies to the battery,** depends upon the number of lamps burning, and the speed of the engine.

Therefore the purpose of the automatic "cut-out" is to open the circuit (as at D, page 334), when the generator is running slow or not running at all, so that current will not flow back into generator. Also, to close the circuit when generator is running fast enough, so that the generator will charge battery and supply current to the lights.

Floating a Storage Battery on the Line.

This term refers to the storage battery used in connection with a generator, where the storage battery supplies current for lights, when generator is running slow or not running at all, as explained.

The generator charges battery and supplies current for lights, when running at sufficient speed. If the speed of engine is varied, part of time the battery would be in use and part of the time the generator—the battery would then be "floating"—see chart 163. The "cut-out" would be changing from one to the other—owing to the variable speed of engine.

***Regulation of Out-put of Generator.**

In a dynamo, the voltage increases with speed. The dynamo begins to charge the battery, at about 7 to 10 miles per hour, but it is also desirable to charge battery and supply current for lights at a higher speed.

As the voltage increases with speed, then the lights would be burned out and generator would be injured by excessive sparking at commutator, and an excessive amount of current would flow to the battery.

Therefore some form of "regulation" must be used to keep the voltage or potential and amperage or quantity of current constant at high speeds.

****Methods of Regulation.**

Regulators are classed as, "current" (amperage) regulators and "voltage" regulators, and operate in various ways.

(1). By methods of winding the field coils as shown in figs. 1 and 2, chart 162; compound and shunt connected, which controls the current (amperage) production at high armature speeds, and holds the current to the proper output. See also, page 343.

(2) **By electrical magnetic devices** as shown in charts 165 and 168; which forces the current to travel through a resistance, thereby weakening the strength of the magnetic field and consequently the output of the dynamo. These regulators can be wound to control the voltage or the current.

(3) **By a mechanical governor** which controls the speed of the armature to a fixed number of revolutions (see chart 170 fig. 3).

(4) **Thermally,** by an increase of resistance coming into play in connection with the shunt field winding by means of a rise in temperature, due to increased current flow—as explained in Rushmore generator system (chart 166, figs. 1, 2 and 3).

All regulation methods will be explained, under the description of different electric systems. For instance under "Delco" the "**variable resistance**" "**reverse series**" and "**third brush**" regulation will be treated, which are also explained on pages 345 and 925.

There are two principles of compound windings in general use: "differential compound" per page 343 and "cumulative compound" per page 347.

*It may be well to mention that voltage means pressure, and amperage means quantity. The generator may be reading 5 amperes of current to the battery at a pressure of 6½ volts, but while the 6½ volts would go to each light, the 5 amperes would not go to one light, alone, as the lights cannot take but from 1 to 5 amperes each, according to their size. In other words no matter what quantity of current goes to the battery, the resistancec of the lamp filament allows only so much current to pass through it—yet if a higher voltage goes to the battery, then the lights would be burned out. For as the voltage increases above the voltage the lamps are intended to use, the lights get brighter until filament burns out. **See also page 343 and 345.

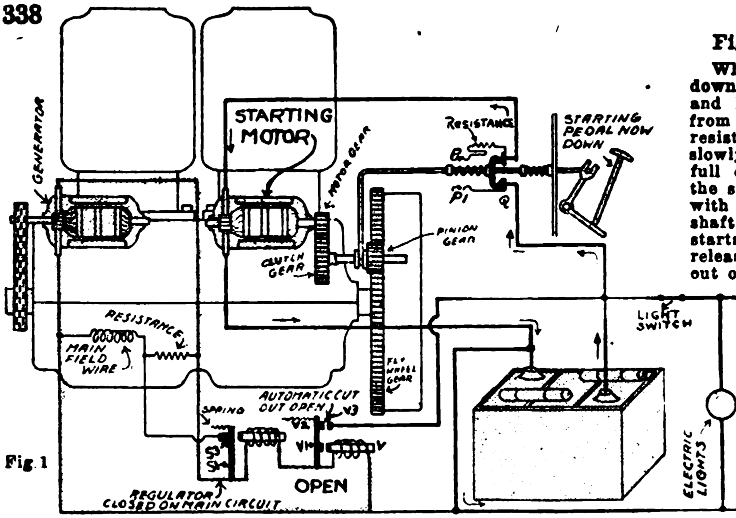

Fig. 1

Fig. 1: Starting Engine.

When starting pedal is pressed down, switch makes contact at (P and P1), causing current to flow from battery to (P), thence through resistance, causing motor to turn slowly. Further depression of pedal full contact is made at (Q). At the same time pinion gear engages with fly wheel gear. Engine crank shaft then revolves and engine starts— at which time the pedal is released and pinion gear is thrown out of mesh and switch opened, or in other words, starting motor is then out of service, as it has done its work in starting engine. The storage battery supplies current for ignition and lights until a higher speed is reached. Note the circuit is open between storage battery and generator at (V3).

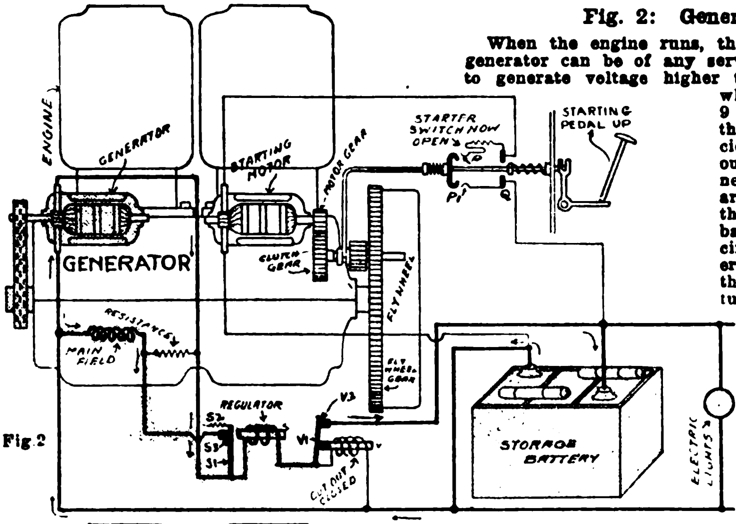

Fig. 2

Fig. 2: Generating Current.

When the engine runs, the generator runs, but before generator can be of any service it must run fast enough to generate voltage higher than the battery. Therefore when engine is running about 9 or 10 m. p. h. car speed, the generator generates sufficient voltage to cause "cut-out" core (V) to become magnetized enough to draw cut-out arm (V1) to it—at which time the circuit is closed between battery and generator. Follow circuit from top brush of generator through regulator coil, thence (V3) to battery. Returning from battery to lower brush. The "main field" winding is merely "shunted" across the wires from brushes. Generator now supplies current for ignition and lights and battery is "floating on the line," see fig. 1, page 334.

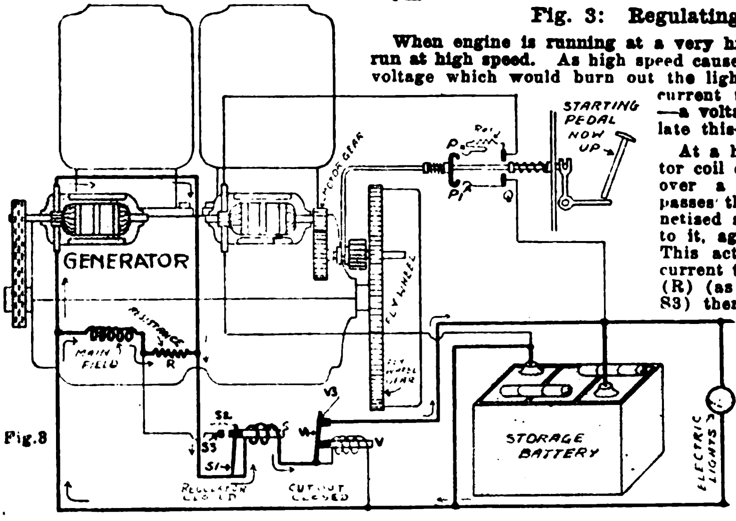

Fig. 3

Fig. 3: Regulating Current.*

When engine is running at a very high speed, generator will also run at high speed. As high speed causes generator to produce a high voltage which would burn out the lights and increase the charging current to battery more than desired —a voltage regulator is used to regulate this—note resistance (R).

At a high rate of speed the regulator coil core (S), is wound, so that if over a certain amount of current passes through same, it becomes magnetised sufficiently to draw arm (S1) to it, against tension of spring (S2). This action forces the "main field" current to travel through the resistance (R) (as its circuit has been opened at S3) thereby weakening the field magnetism. When weakened sufficiently, the arm is drawn back again to (S3) by tension of spring (S2).

In actual practice this arm (S1) vibrates in running back and forth constantly, owing to variations of speed of engine.

Referring to fig. 2 again, note this resistance is not in action, because the field current flows through the path which has least resistance. But in fig. 3, it must flow through the resistance (R), because of the opening at (S3).

CHART NO. 165—A Simplified Example of Starting Motor and Generator at Starting and Various Speeds, showing Operation of "Cut-Out" and "Regulator," also Switch with Resistance.

*See pages 334, 344 and 342, explaining how and why the "cut-out" is demagnetized on reversal of current flow of battery and how and why it opens the circuit between battery and generator when engine speed is reduced, which is not explained in this chart.

Thermal Principle of Regulation.

The word thermal pertains to heat. Therefore we will see how heat can control the output of a generator (dynamo).

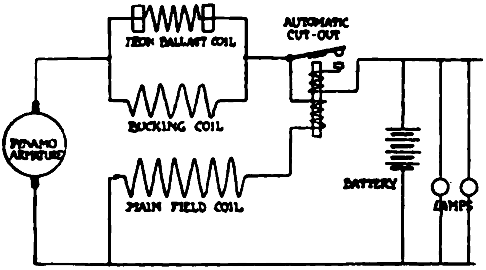

Fig. 1—Diagram of Rushmore generating system. The bucking coil is a "series" winding on the field. The main field winding is "shunted" across. Cut-out is the usual magnetic type.

***Before reading further, study fig. 2. The path of current flow** is from right brush (follow arrow points), to battery, through battery to iron ballast coil, through ballast coil to left brush of generator. A "shunt" or main field winding," which is wound around the field pole is connected or shunted across the wires from brushes, which serves to excite or magnetize the field poles, so that when armature revolves, **lines-of-force are produced. Greater

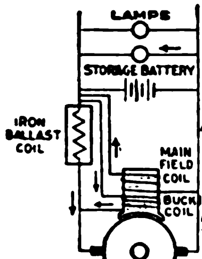

Fig. 2.—Diagram showing the main-field winding and bucking-coil or series-winding and location of "ballast-coil" in circuit.

Fig. 3.—The "Iron wire" "thermal" type regulator of current, called "ballast-coil" which allows a certain quantity of current to pass, but beyond that quantity the iron wire heats and offers resistance to flow of current in field, therefore the current **must** go through the bucking-coil or series winding (in figs. 1 & 2) which action does not permit the current to increase but keeps it at a constant strength.

the speed, greater the lines-of-force, consequently greater the output. **Therefore the purpose of the "bucking coil,"** also called a "series winding," is **to reduce the magnetic strength of the field poles at high speeds,** by means of counter excitation, produced by the bucking coil, which consists of a few turns of magnet wire wound on the field poles. **This "bucking coil" does not come into action so long as the current can pass through the "ballast coil". The amount of current passing through this "bucking coil" is determined automatically by the varying resistance of a small coil of iron wire, called the "ballast-coil," (fig. 3)** which is made in the form of a cartridge fuse and carried in clips on the switch-block in the main line between the dynamo (generator) and the battery.

At low dynamo speeds and outputs of current this "ballast coil" is cold and acts as a short circuit or an easy path for the current flow, which diverts the current from the field bucking coil.

As the output increases the iron wire on ballast coil becomes heated, although its resistance remains practically the same as when cold until reaching a certain "critical" temperature, just below the dull red heat, its resistance goes up with a jump so that, practically speaking, it will not permit another ampere to pass and after that any excess current must pass through the field bucking coil.

At car speeds below 15 miles an hour, the dynamo acts as a simple uncontrolled shunt wound machine, while at the higher speeds, owing to the counter effect of the bucking coil the resultant excitation is barely 1/6 of the excitation due to the main shunt field coil alone. In other words, at **high speeds, the current passes through the bucking coil instead of the high resistance of the heated ballast coil.** Note the bucking coil is in series with the circuit, connecting as it does, above ballast coil to brush terminal. **The current then flowing through the bucking coil around the field poles, bucks or opposes the shunt or main field winding, which reduces the magnetism or lines-of-force in field poles, consequently the output is reduced. Thus the effect of controlling the bucking coil by the** current output is to produce an approximately constant current **at high speeds.**

In order to keep the current in the "main shunt field coil" as nearly constant as possible, it is connected **at a point beyond the ballast coil (fig. 2) instead of directly across the brushes. Thus it does not feel the fluctuation of voltage at the brushes.**

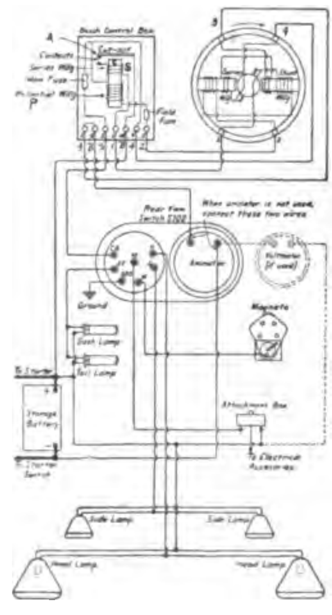
. **The voltage is determined by the storage battery** and is simply the voltage required to force the specified current against the counter electromotive force plus the small internal resistance of the battery. Assuming that the battery is in good condition the dynamo voltage will be slightly in excess of the open-circuit voltage of the battery i. e., from about 6¼ to 6½ volts, depending upon the state of charge.

The battery is absolutely necessary to control the voltage of dynamo and must never be disconnected therefrom while the dynamo is in use.

Inherent Principle of Regulation.

Inherent method refers to any method of regulating the output of a generator without the use of external agents, as resistance units or a separate mechanical regulator—see page 343.

Note the shunt and series windings on generator field poles. We know that when armature revolves, it cuts "lines-of-force" between the field poles. These **lines-of-force on a generator with a winding on the field poles, are increased as the armature speed increases. Therefore as speed of armature increases, voltage increases. The generator current passes through the potential or voltage winding (P) of cut-out. When generator reaches the speed where voltage is higher than battery, then cut-out points (A) close, therefore generator charges battery.



As speed continues to increase, the output also increases, therefore to prevent excessive output, the series-field bucks the shunt-field, as explained on page 345 ("bucking series regulation"), thus weakening the field magnetism or lines-of-force. Therefore we have a method of regulation which is inherent or within the windings of generator.

CHART NO. 166—Rushmore (now known as Bosch) Thermal Principle and Bosch Inherent Principle of Regulating the Current Output of a Dynamo (Generator).

***Note the cut-out is not shown in fig. 2, but must be provided and placed in the circuit as shown in fig. 1** Its purpose is merely to connect and disconnect the battery to generator.

****See page 267 for explanation of "lines-of-force"** produced by a "permanent-magnet" as on a magneto **and page 737 by an** "electro-magnet" as on a dynamo.

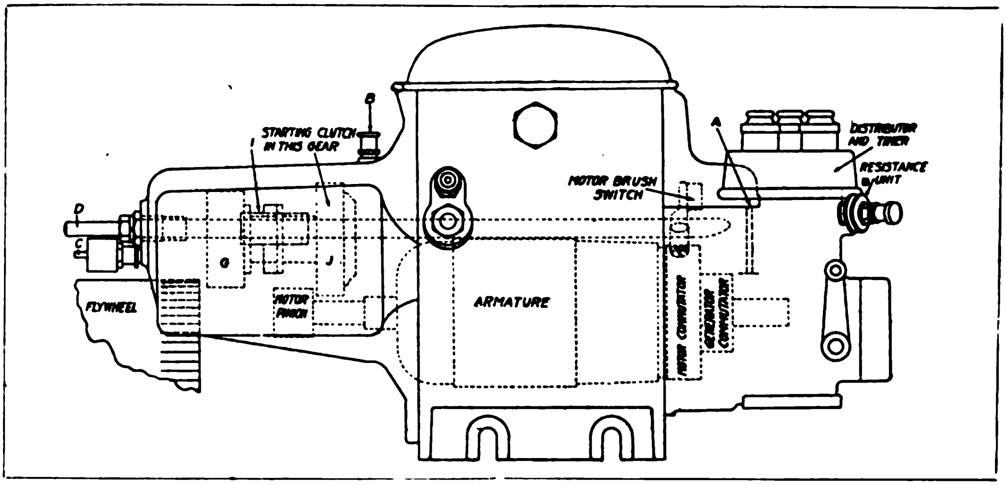


Fig. 1.—A single unit system (one type of the Delco system, as an example. Combines a **starting motor, generator** (direct current), and **ignition** all in one machine.

The one armature and one set of field magnets serve for both the motor and generator. There are two separate windings and two commutators, however. Ignition timer and distributor are mounted with this unit, but the distributor drive spiral gear is not attached to the armature shaft as would naturally be inferred but is connected to the pump shaft, or shaft driving the generator. In other words if connected to the armature shaft the action of the clutch used in connection with the generator drive (not shown above) would affect the timing operation.

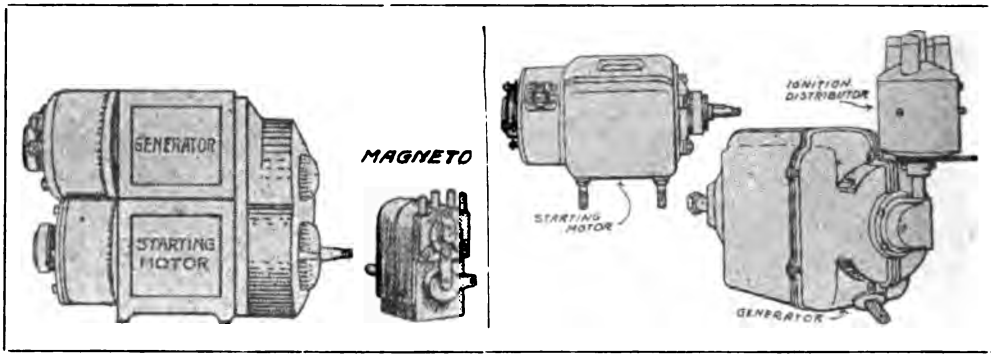

Fig. 2.—The two unit system, divided into classes; A and B.

A—Where starting motor and generator are combined in one unit and the magneto (or coil and distributor) for ignition in another, it is called a "two unit" system. The above illustration is supposed to illustrate a "double decker," meaning, generator is placed over motor, using a separate armature and separate field magnets, see page 352.

B—Starting motor in one unit—generator and ignition in another. This is also a "two unit" system.

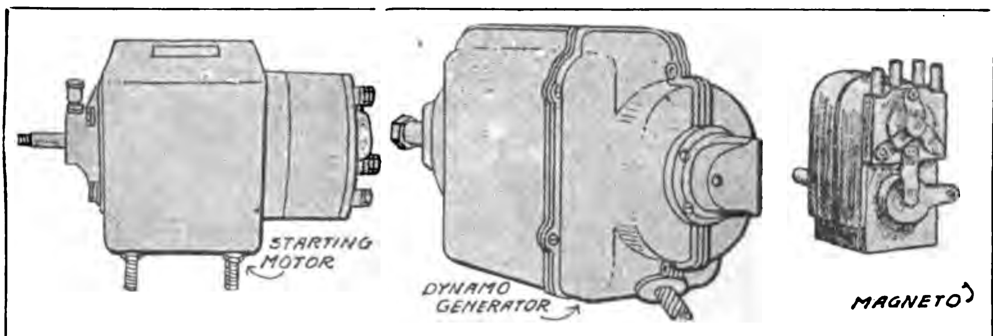

Fig. 3.—The three unit system—These are separate parts. The ignition can be of the "magneto" alternating current type, or of "coil and distributor" direct current type, in fact any ignition system separate from the generator and motor, can be used.

CHART NO. 167—Different Methods Employed to Combine and also Separate the Starting Motor, Generator and Ignition.

NOTE—There are many other types of motor-generators, but we will not show all of them in this treatise, but will confine our instruction to the general principle. After the principle is mastered, then the reader ought to be able to understand all systems.

Driving the Generator.

The generator must run when the engine runs, because it is necessary to recharge the battery and supply current for lights; and in many instances, ignition also. Ignition current, however, for starting, is provided by the battery.

The generator is usually driven from crank shaft or cam shaft, by means of chains or gear, or driven from the pump shaft. In some instances, it is driven from the drive shaft of the transmission. (See chart 164, fig. 3).

Over running generator clutch; when the **starting** motor and generator are **combined, for instance see fig. 7, chart 164,** note the starting motor drives through the fly wheel and generator is driven through the pump shaft. A "clutch" must be provided between this pump shaft and armature shaft, else the starting motor could not be independent.

The overrunning clutch enables the motor to turn the engine over when the power comes from the motor, but permits the engine to run forward without turning it. Therefore when power is cut off the motor, the engine can continue to run on its own power but the motor comes to rest. **(The roller type clutch is the type in general use,** see figs. 5 and 6, page 351, for the principle).

Ignition from the "Direct" Current Generator.

The modern ignition system is explained in instruction 19. Note the distributor and "timer" or distributor with "breaker" or "interrupter" are the approved methods.

Distributor drive method. The ignition distributor is quite often an integral part of the generator but is driven independent of the armature shaft if an "over-running clutch" is used between generator drive and generator, as explained above under generator clutch. If however, the starting motor and generator are not combined and the clutch is not used, then the distributor and timer can be driven from armature shaft, providing armature and ignition shaft are driven at proper speed.

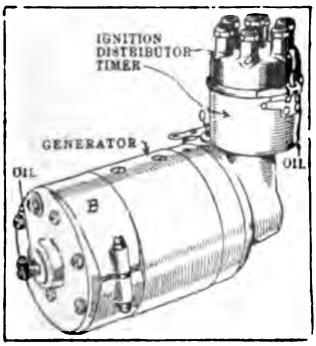

Fig. 1. The modern method of driving the generator and ignition unit, is to mount the ignition unit on the generator. The latter is driven by a silent chain at 1½ times engine speed and ignition shaft is geared to armature shaft and turns at ½ engine speed.

It is evident that if the distributor and timer were driven from armature shaft and a clutch was between the drive shaft of generator and the ignition system the latter system would be thrown out of time. This would appear to be the case as in fig. 1, chart 167, where the starting motor, generator, and ignition unit are combined—but note, the ignition shaft, is independent of the armature shaft—see page 377 "distributor and timer shaft, how driven" and "generator clutch" page 386.

A modern method is shown in fig. 1 below and fig. 2, page 340. The starting moter in this instance, is separate, therefore this would be called a "two unit" system.

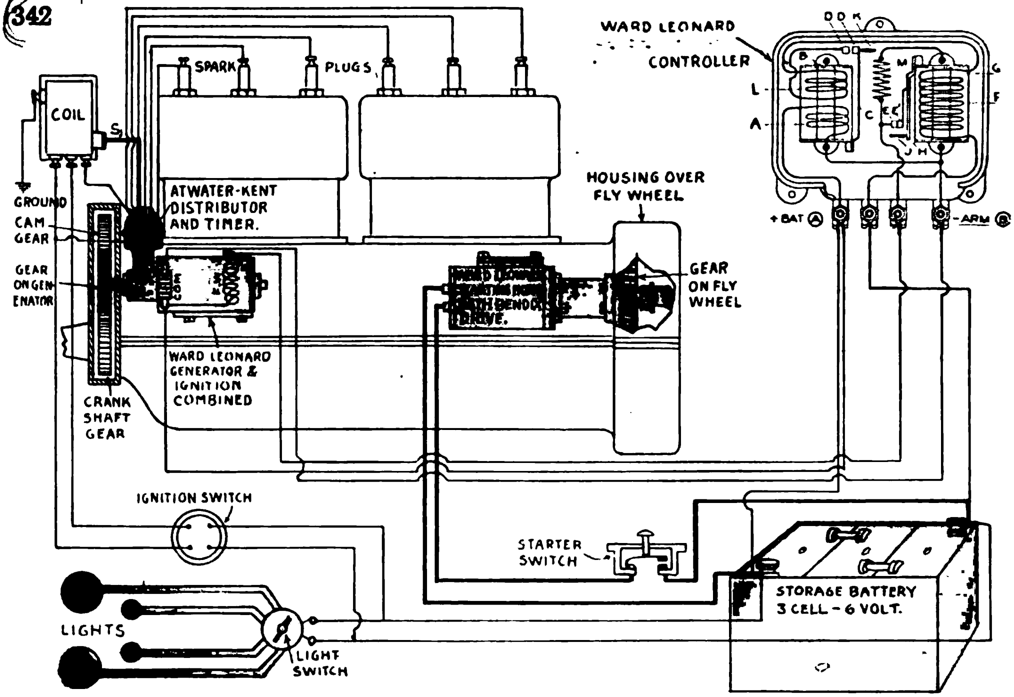
"Magneto ignition" term is often applied to the coil and battery system, and is no doubt confusing, as it implies that the current from the coil and battery system was "alternating," whereas it is a "direct" flow of current taken from the direct current generator when engine is running, or from the storage battery when starting or engine is running slow. This "direct" current passes through the primary winding of the high tension coil and is "interrupted" or contact "made or opened" suddenly by the timer or interrupter as explained in figs. 2 and 3, page 242.

This is why the term "magneto" ignition is sometimes referred to in connection with a generator of the "direct" current type; because the **timer** is of the "interrupter" type which gives a "single" spark, and not of the "commutator" type as explained in fig. 1, page 242, which gives a "succession" of sparks—see page 248.

The high tension coil used with the modern direct current generator system, is a double wound coil **without vibrator** as explained in fig. 4, page 245.

This coil is sometimes mounted on the generator, or, it can be mounted on dash, under hood or any convenient place.

A "constant" source of electric supply is provided with the coil and battery system. In other words, the battery is kept charged by the generator, hence it is always available as a **constant** source of electric supply for ignition and lights.



Starting Motor.

Starting Motor starts engine through flywheel and can be of any make of starter as Westinghouse, Remy, or any other make. In this instance it is equipped with the Bendix drive, as explained on pages 326, 331. This is a very popular method.

The starting motor has no electrical connection with generator. The current for starting motor is always taken from battery.

Generator.

Generator supplies current for charging battery and also for lights and ignition when running above 7 or 10 miles per hour car speed. When speed is less, battery supplies current for ignition, lights, etc. Note generator in this instance is driven by a gear from cam gear. It is often driven by a silent chain.

Ignition in this instance is a timer-distributor driven from generator armature shaft, therefore it must be driven at same speed as cam-shaft, the reduction being made on gear on armature shaft.

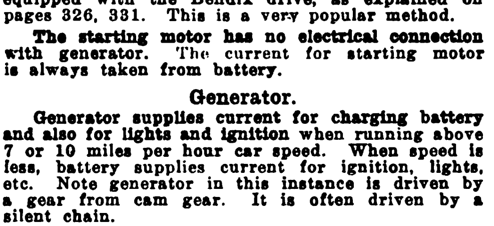
Control of Generator and Battery Current.

The Controller in this instance includes the automatic "cut-out" and the "regulator".

The Automatic Cut-Out.

Purpose of the cut-out is to connect and disconnect the battery and generator. The cut-out points DD, fig. 9, are **normally open when engine is idle or when first starting engine,** thus the circuit between battery and generator is open which prevents the battery current from flowing back into generator. In this instance, current for ignition and lights is taken from battery.

Fig. 8 & 9.



After engine is started and the speed of generator increased, the voltage of generator builds up through the fine wire winding of shunt coil A. When speed of engine reaches about 7 to 9 miles per hour car speed, the magnet core B becomes magnetized sufficiently to attract arm C, thus closing the two spark-proof points DD, establishing the circuit between generator and battery. Generator then begins to **charge** battery and also supplies current for ignition and lights. The battery is then "floating on the line" being charged, as explained on pages 334, 344, 864B.

When engine speed becomes less than 7 to 9 miles per hour car speed, then generator voltage becomes less than that of the battery voltage, therefore the battery voltage being higher, flows back through the coarse wire winding of the series coil L. **This reversal** of flow of current through coil L demagnetizes core B, at which time, tension of spring K separates points DD, thus opening circuit at DD.

The above action is constantly changing as speed of engine increases and decreases.

When engine stops, points DD are open, thus preventing battery from discharging back into generator. See also, pages 344, 334, 864B.

The Regulator.

Purpose of regulator is to prevent generator from generator too high a voltage or amperage. As the speed of a generator increases the voltage increases, which produces more lines of force, consequently a higher amperage. If too high a voltage was produced the lamps would be burned out and excessive sparking would occur at the brushes, excess current supply and consequent trouble at commutator.

To prevent this, a regulator, in this instance of the voltage type is employed. By observing fig. 9, note current from generator flows from brush through coil F and from field winding through points EE, H and coil F. If generator speed is such that the amperage reaches in excess of ten or fifteen amperes (varies according to setting, but is usually ten) then core G of coil F becomes sufficiently magnetized to attract arm H against tension of spring J, which opens the field circuit at EE. When this is opened, a **resistance** coil M is introduced into the field circuit, **through** which the field current **must** flow, which weakens the fields thus decreasing the amperage. When decreased to say 9 amperes, then the coil F does not magnetize the core G enough to overcome the pull of spring J, thus points EE are again closed, thus establishing a path for the field current to flow around the resistance M, consequently the field strength is restored, and current tends to increase.

Under operating conditions the finger H automatically and rapidly vibrates at such a rate during the increase and decrease of engine speed, so as to keep the **current constant. As a result the** generator will never produce over a predetermined voltage or amperage, no matter how high the speed of engine. See also, page 344.

CHART NO. 168—A Modern Starting, Generating and Ignition System. Don't confuse the "Cut-Out" with the "Regulator"—See also, page 334. See page 429 for Testing Circuits.

Starting Motor, Generator and Ignition—how combined or separated.

A "three unit" system, is shown in fig. 3, chart 167. Here the generator is one separate unit and the starting motor and ignition each, separate.

A "two unit" system, is shown in fig. 2, here the starting motor is in one unit and the generator and ignition another or the starting motor and generator could be combined and the ignition separate.

A "single unit" system, is where the three are combined in one; starting, generating and ignition.

The different systems in general use will be treated farther on. It will be advisable for the reader to study each carefully and then determine in his own mind, after reading the description of each system, the following points: (1) Is it a single, two or three unit system? (2) How driven? (3) Is starting motor and generator combined, if so how? (4) What method is used for regulating current output? (5) How is the ignition system driven? (6) Is the ignition timer the type shown in fig. 2 or fig. 3, page 242?

Example of a Modern Starting, Generating and Ignition System—see chart 168.

The starting motor in this particular instance (page 342) is a 6 volt "series" wound motor fitted with the **Bendix** drive as explained in fig. 8, page 326 and 331. It drives through the fly wheel as shown.

The starting switch used with the Bendix drive is the push button type which can be operated by hand or foot. There is no resistance in connection with this switch and when pressure is applied to the button full current of the battery is at once impressed on the starting motor. The switch contact is held only for an instant.

To start engine, press the button of starter switch. The pinion on the end of armature shaft then meshes with the gear on fly wheel, as explained in chart 160.

As engine crank revolves, the generator armature revolves, which turns the timer and distributor shaft (see Atwater-Kent systems, chart 117.) The current from the storage battery supplies the ignition current, which passes through the high tension coil. The engine then starts and continues to run on its own power.

After engine starts, the starting motor has served its purpose and is now idle and is not used until starting is again necessary.

The generator begins to generate current the moment its armature is started in motion by the gear from cam shaft (quite often a silent chain) but does not generate sufficient current to overcome the voltage of the battery until speeded up, say from 7 to 10 miles car speed, therefore the battery supplies current for the ignition (lights also, if on), until the generator attains sufficient speed to generate sufficient voltage to overcome the voltage of storage battery, at which time the generator supplies current for ignition and lights and begins to charge battery.

The automatic cut-out (see chart 168), disconnects the battery from generator when engine is running slow or not at all and connects the generator with battery when generator is running at sufficient speed to overcome the battery voltage. This cut-out is explained in chart 168 also see figs. 1, and 2, chart 163 and note how the battery "floats on the line." This contact lever C, fig. 8, chart 168, vibrates back and forth, owing to the speed of engine.

The Ward-Leonard regulator, per pages 342, 344: Amount of current supplied to battery is governed by the "regulator" as explained in chart 168. On this particular type of regulator, **note how resistance (M) is inserted into the field circuit of generator** thereby weakening it. This causes the amperage to decrease. If it decreases say below 9 amperes, the contact is closed. If it increases above 10 amperes, the contact is opened, throwing in the resistance (M) again, and in this way the **amperage** output is kept fairly constant.

Difference between the "cut-out" and "regulator" is exemplified in chart 168.

The cut-out principle explained in this chart would be called the "automatic," or "magnetic" or "vibrating" type principle of the reverse current type (page 342, 334).

The controller of the Ward-Leonard system consists of the "cut-out" and "regulator" mounted together—fig. 8, page 342.

A careful study of chart 168 will make the principle of this system clear.

Different Regulation Methods.

We might class the different methods of regulating the voltage and amperage of a generator under three heads; (1) constant current with inherent regulation; (2) constant current with external regulation; (3) constant voltage or potential regulation.

Inherent Constant Current Regulation.

Inherent or constant current regulation is so named, because its method for regulating the current or amperage output does not depend upon external agents, as a separate mechanical regulator, etc., but its connections are embodied **internally,** into the generator proper. With this system, the current output is constant but voltage slightly varies, see page 925.

The inherent or constant current regulation control may be a "third-brush" system, "bucking series," that is, a differential compound winding, or "cumulative" compound winding, or a "thermal" principle, all of which would come under the head of "constant current" or "inherent" methods of regulation.

***Third brush regulation:** This principle is explained on pages 925 and 389, and consists of a third brush, which regulates the output. It is used quite extensively and

*See also Ford, page 864C.

—continued on page 345.

The internal wiring of the Ward Leonard controller is shown in Figure 9

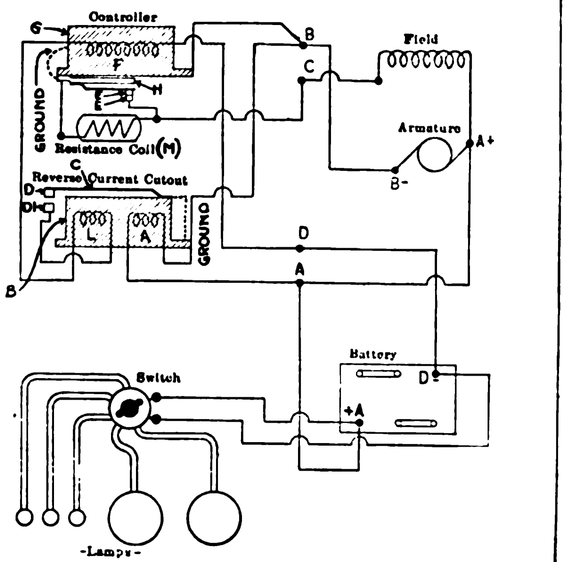


Fig. 9

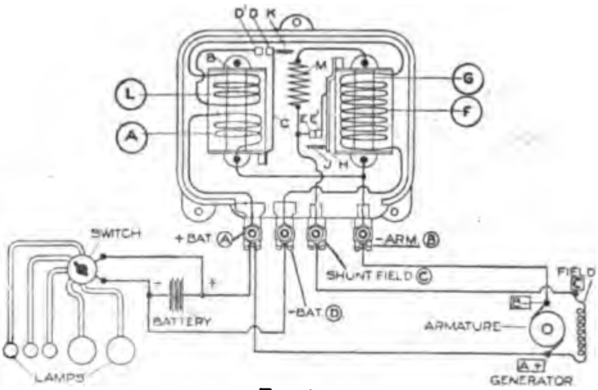

Fig. 10

Explanation of cut-out and regulator circuit: The †path of charging current is from (A+) on generator, to A on cut-out, thence through battery to (D) on regulator, thence through windings (F and L) to contact point D1, across D1 to D, then down lever (C) to magnet frame, then from ground connection on magnet frame to part (B) of controller and from there to (B—) of generator—thus completing the circuit. The purpose of resistance (M) is explained on page 342.

Circuit Details of the Reverse Current "Cut-Out."

Although the subject was dealt with in chart 168, the winding (L) and other "cut-out" diagrams were not fully explained. By referring to illustrations on upper, right hand illustration of chart 168, and fig. 10, this page, note there are two coils (L and A) wrapped on the core (B); one "shunt" (A), and one "series" coil (L). This iron core (B) attracts and repels an iron lever (C). Attached to this lever (C) are contact points (D) at which the contact between the generator and battery is made and broken. **The shunt coil** (A) is connected directly across the two brushes of generator and therefore the full generator voltage is impressed across the ends of this coil similar to fig. 2, page 334.

The series coil (L) of cut-out is connected in "series" with battery and generator through controller or current "regulator" coil (F). The current from generator, to charge battery, must pass through the "regulator" coil F.* Therefore, this series coil (L) of cut-out carries the charging current when battery is being charged—fig. 2, page 334 will probably make this idea clear.

Why Reversal of Current In Cut-Out Coil L.

The coil (L) is employed to insure perfect **de-magnetization** of the core (B) on reversal of current, so it will release blade (C) quickly, explained as follows:

When the engine is started, the generator is driven by the engine, and it, therefore, increases and decreases in speed with the engine. When the engine is speeded up the generator follows with corresponding increase in speed and the voltage of the generator rises as the speed increases. As soon as the generator voltage gets to a point above the voltage of the battery, the shunt coil (A) has built up sufficient strength to magnetize iron core (B), which then **pulls** the iron lever (C) towards the magnet core, thereby **closing** the contact at the points (D). As soon as this contact is made, the generator is connected to the battery, and **a charging current** will flow from generator to the battery through the series coils (L) and regulator coil (F) which are in series with the generator and battery. The generator continues to charge as long as contact points (D) remain together, but when the engine speed is decreased, so that the generator voltage falls below the battery voltage, the battery will discharge through the generator and therefore through the coil (F); under **discharge conditions** current flows through winding (L) in the **opposite direction** to that which it does under **charging conditions**. While in the winding (A), the flow of current is in the same direction. This **reversal of the flow of current in (L)** causes the winding to buck or work against each other, therefore **demagnetizing** the core (B) which allows the spring (K) to pull lever (C) **away** from the magnet core, thereby opening the contact at the points (D), which disconnects battery with generator.

CHART NO. 168A—Detail Explanation of the "Cut-Out," Called a "Reverse Current Cut-Out."

*See page 342 for explanation of the "regulator" coil (F). This part of the controller is to regulate the output of generator, whereas the "cut-out" merely opens and closes circuit between battery and generator.

†This path is established when generator is running fast enough to charge battery. When running slow, current travels through shunt coil winding A in fact, as long as generator produces current at all, it travels through this winding—see figs. 1 and 2, page 334.

comes under the head of inherent or constant current regulation.

Bucking series regulation: This method would also come under the head of inherent or constant current regulation. A simple explanation of the working of the "bucking series" winding is given below.

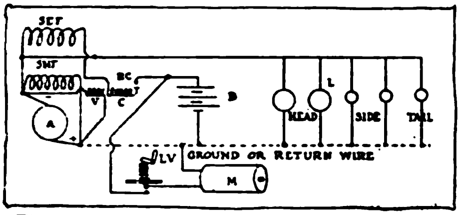

Fig. 1.—Wiring diagram of Westinghouse six-volt system, showing grounded return wire with "bucking-series" method of regulation.

Machines of this type are **differential-compound wound** generators with internal connections such as shown in fig. 1. The series field (SEF) increases in strength with increase of output and opposes the shunt field (SHF), thereby reducing the resultant field and keeping the voltage and current within permissible limits. A separate mechanical regulator is not used.

With this type of generator the storage battery really regulates the voltage and the series winding and speed of generator determines the current or ampere output.

*A reverse current cut-out (RC) is provided and is so adjusted that on the average car the battery circuit is cut in above 10 miles an hour and cut out below 7 miles.

When the generator is connected to the battery by the automatic switch (RC) the current rises rapidly with the speed until a value of from 5 to 7 amperes is obtained if the lamps are not burning. Above this, the output rises very gradually, the curve being nearly flat for all motor speeds so that the danger of an excessive charging rate to the battery in day touring, when lights are off, is eliminated. The idea is that the current comes primarily from the shunt field winding and should be kept as nearly constant as possible, although the speed of generator is increased or lamp load is added.

This is accomplished by what is termed the **reversed** compound field windings on the generator, or the addition of a **series coil** which has a **bucking** or opposing effect to the flow of current in the shunt coil winding. This effect is obtained, by causing the curent in the series field coil (SEF) to flow in **such a direction** that its effect on the magnetic field of the generator will oppose the effect on the magnetic field of the shunt field (SHF).

For example: when the lights are turned on the output of the generator increases proportionately, explained as follows: assume that the lamp load requires 6 amperes and the generator output is 5 amperes, then 1 ampere must be **taken from the battery.** This **battery current must go through the series field (SEF)** on its way to the lights in order to complete the circuit, thus it assists the shunt field (SHF) instead of bucking it, therefore the current value will rise as lamp load increases, but not excessively, as the bucking effect will come into action and prevent it, explained as follows:

Now assume that the generator output is 7 amperes and the lamp load is 6 amperes. This leaves 1 ampere which will now be **taken from** the generator to the battery, to charge it. This 1 ampere must pass through the series field (SEF) —but will pass in a **reverse** direction to what it did when it came from the battery—this change of direction through the series coil causes the series coil to buck or oppose the shunt field (SHF) instead of assisting it, as in the above case. **Therefore,** as the speed increases the effect of the series coil bucking or opposing the shunt coil and the de-magnetizing effect of the armature current will be more and more pronounced and thus prevent excessive current rise as the generator speed is increased to relatively high values. The effect of this action is to proportionate to the speed of the generator and to the quantity of lamp load **so that at all times the output of the generator will be greater with lamp load than without.**

Series bucking coil and thermal method of regulation: Another method of causing the series coil to buck the shunt coil is by means of a thermal principle, explained on page 339. The difference here is in the addition of an iron wire ballast or thermal coil which permits the current to flow through it and not through the series coil at low generator output, but as generator output increases the iron wire heats and offers resistance and current must flow through the series coil which then bucks the shunt coil and thus regulates the output fairly constant. This would be termed an inherent method of regulation—although, the iron coil is placed separate from generator, the action is not mechanical.

A cumulative compound **winding** is shown in fig. 4, page 351 and explained, page 347.

Constant current or inherent methods of regulation would therefore include those methods where the regulation is controlled internally, as per page 339; the "bucking-series" or "differential-compound-winding"; the "cumulative-compound-winding" and the "third-brush" regulation, per page 925.

Constant Voltage or Potential Regulation.

An external device is used, known as a "voltage regulator" which operates mechanically. The voltage is kept constant but the current output varies with this system, as explained on page 925.

The voltage is regulated through a range which permits the charging of a storage battery at a high current rate when battery voltage is low, and at a much lower rate when battery voltage is high. In other words, the **charging current depends upon the state of charge of the battery** or its specific gravity. A nearly discharged storage battery will take a heavier charging current, which charging current will be reduced as the battery becomes charged.

***Don't confuse the action or purpose of the battery cut-out** (called a "reverse current cut-out," principle which is explained on pages 334, 344) with that of a "current regulator" or "voltage regulator." In fact a "cut-out" is used with either the "voltage" or "current" regulation system, however, on some "constant current systems," Delco, for instance, the "cut-out" is eliminated. (see page 383.)

See page 925 about removing **battery** with a constant current and a voltage regulation system and note difference.

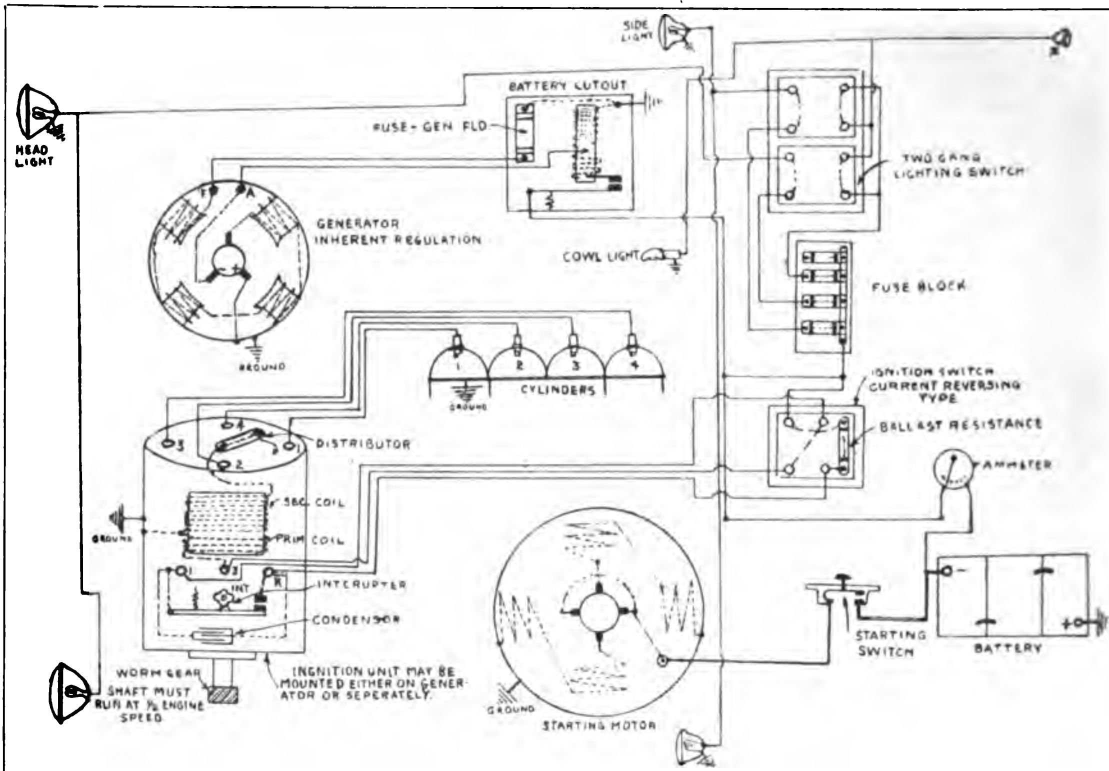

Fig. 1. Westinghouse starting, generating, lighting and ignition diagram. Note the complete ignition unit is mounted on the generator. The starting motor is separate.

The generator in this instance is a 6 volt generator which can be driven by a silent chain or gear drive.

The cut-out is shown, which is of the usual **reverse current** type of relay (note relay and cut out are synonymous). It's purpose is to open and close the circuit between the battery and generator as explained in charts 168 and 168-A.

The regulation of this generator is called the "inherent" or "constant current" regulation system employing a third-brush system, and is different from voltage regulation.

The single wire or **ground return,** using the frame of the car is employed. Note "ground" to generator frame, fig. 1.

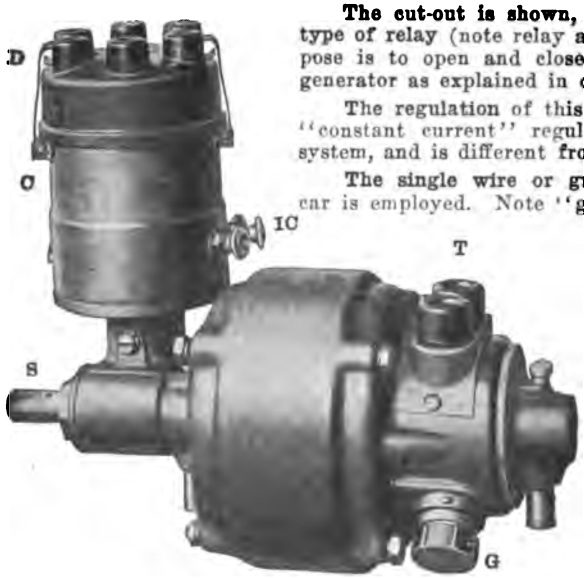

Fig. 2. Westinghouse generator with the ignition distributor and timer and high tension coil mounted on the generator. The coil is beneath the distributor and timer. The generator is driven by a silent chain from cam shaft, the distributor shaft is driven from a spiral gear on armature shaft (S), and is of course driven at cam shaft speed. T, generator terminals (see fig. 1, F-A); G, ground connection terminal.

The starting motor is of the series wound type, with ground to motor frame.

The Westinghouse vertical ignition equipment consists of a vertical ignition unit as shown in this, and chart 168-C, diagram fig. 7. An ignition switch, a ballast resistor and a battery.

Equipments are made for 6 or 12 volt circuits and for use on 4, 6 or 8 cylinder engines. The system shown in this chart and 168-C is a 6 volt battery and generator.

The ignition unit is made up of four essential parts, namely, the interrupter (IC, connections to it), the condenser (see fig. 1), the induction coil (C, and fig. 1), and the distributor (D), all included in one case.

(see also pages 347, 348.)

CHART NO. 168B—The Westinghouse Starting, Lighting and Ignition System, using a Reverse Current type "Cut-out" between Battery and Generator with an "Inherent" system of "Regulating" the Output of Generator—a "two unit single wire" system.

*Cumulative Compound Winding.

The generator is compound-wound with a shunt field, SHF, and series field, SEF, fig. 4, page 351. Unlike most compound-wound machines used for electric lighting the two field windings assist one another instead of oppose as per fig. 1, page 345. For this reason this is called by the electrical engineer a "**cumulative**" compound instead of "differential" compound machine; that is, it is so wound that the output of the dynamo increases as more current is required. This provides an automatic control of the load.

The purpose of the additional field, SEF, is to increase the output of the generator as the lights are turned on, without increasing the speed of the generator. For example, with all lights out, the generator will deliver about 6 amperes, while with all lights burning it will develop 12 amperes. Between these two points it will deliver additional amperes in proportion to the number of the lamps burning, that is, with half the total number, 9 instead of 12 amperes will be the output.

This method would be termed an "**inherent constant current**" method of regulation.

The Mercury Type Regulator.

This system is now seldom used, but will be explained in order to show the first principles of a Delco motor-generator and the "mercury" method of regulation. This would be termed a "**voltage regulation**" method.

In order to clearly understand the system it will be necessary for the reader to study the principle of the entire 1914 system. For explanation, see page 380.

Mechanical Regulator.

On page 351 a **mechanical governor method for regulating the output** of a generator is explained.

The clutch on the **generator** (fig. 3) is of the "friction" type actuated by centrifugal governor motion.

Westinghouse Vertical Ignition Unit Mounted on Generator.

This system is explained on pages 346 and 348. One part which is not fully explained in charts is the Ballast resistor. Its purpose is explained below.

The ballast resister is a resistance unit (see pages 346, 348) having a high temperature coefficient, placed in series with the primary coil of the ignition unit. This resistance with the resistance of the coil keeps the primary current at the correct value when normal voltage is applied. It has many other functions. If the engine is left idle with the ignition switch on, the resistor gradually heats up causing its resistance to materially increase and cut down the primary current (see also "ignition resistance unit," page 378). This decreased primary current very much reduces the probability of burning at the primary coil.

When the engine is running a certain amount of primary current will flow at each closing of the contacts. As the engine speed increases the time of contact is shortened and the time allowed the primary current to build up materially reduced. As this current reduces in value the resistor tends to cool, consequently reducing the value of the resistance. In this way the total resistance of the circuit is reduced and the current in the primary coil may be built up very rapidly.

Roller Type Clutch.

The starting motor and generator used in the 1914 Overland (page 351), is used as an example in order to bring out the **unusual driving method and action of a roller type of clutch.**

The "roller" type of clutch is used on other systems and it will be worth while to study its action. See page 351.

How One Armature Serves for both a Motor and Generator.

The Delco system, explained under instruction 28A, is a system of this type.

Another system, using the same armature for motor and generator was the "nonstallable" Entz system formerly used on the Chalmers. (see page 352.)

This Entz motor-generator system consists of the following parts: (1) storage battery 18 volts, 9 cells; (2) motor-generator; (3) shaft with universal joint to start engine and drive generator (fig. 3, page 336); (4) silent chain running in oil connects the motor generator drive shaft with engine shaft by means of a sprocket located just ahead of the flywheel; (5) a switch on the dash which opens and closes the circuit.

U. S. L. Graphite Pile Regulator.

The generator takes the place of the flywheel. Construction and principle is shown on page 353.

The regulation of the 1914 system was similar to the system explained on page 338. Instead of "resistance wire" being cut into the field shunt winding, in this instance "graphite" piles are used. Graphite offers resistance to the flow of current, therefore the same effect or principle

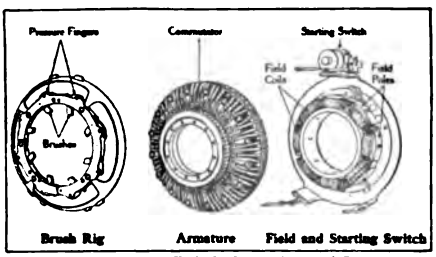

Fig 1: Parts of the U. S. L. fly wheel type of Generator.

is the result—weakening of the field current at high speeds. The regulation system is not used on the later models of the U. S. L., but is merely shown in order that the reader will understand the principle.

†See pages 337 and 345, for explanation of "constant current" or "inherent" regulation and "voltage" regulation. ***The "differential" compound winding** is explained on page 345. The difference between "cumulative" and "differential" winding is explained on this page.

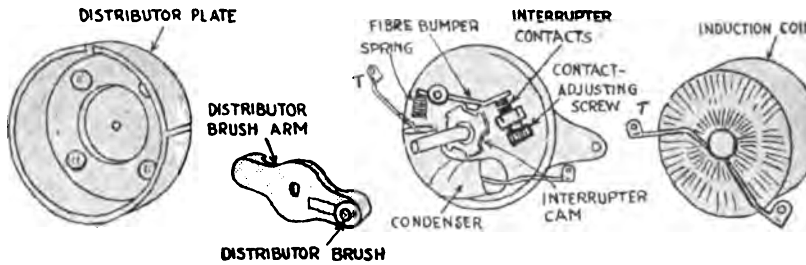

Fig. 1. View of the parts of the Westinghouse ignition unit as per page 346. See also page 251 and 252

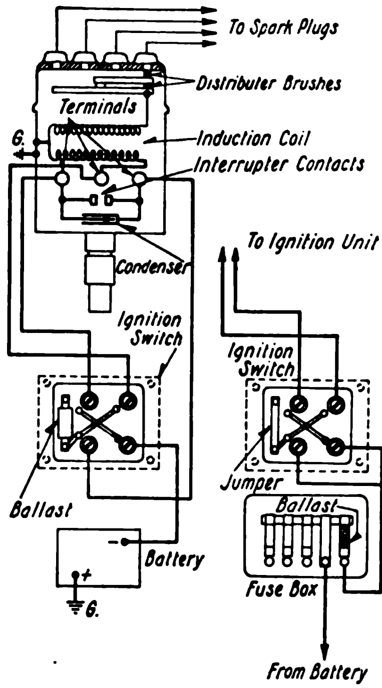

Fig. 7. Diagram of connections of the Westinghouse vertical ignition unit.

Operation—With the ignition switch turned to the "on" position and the engine turning over, each segment of the interrupter cam (fig. 1) in turn passes on and off the fibre bumper. As each segment passes off the bumper, the interrupter contacts close, closing the circuit from the battery to the primary winding of the induction coil (fig. 7). Then as they pass on the bumper, the contacts are opened, interrupting the circuit, thus inducing a high voltage in the secondary of the induction coil. This high voltage is directed by the distributor on the top of the ignition unit to the proper spark plug, causing a spark as it jumps the spark gap of the plug inside the cylinder, and igniting the charge therein.

The ignition switch is double-pole with the internal parts so arranged as to reverse the direction of current through the interrupter with each operation of the switch. The reversal of current principle and purpose is explained under "polarity switch," page 248.

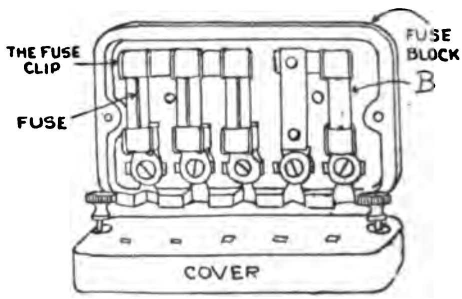

Fig. 4. Fuse block with ballast resistor. The fuse block and ballast resistor (B) may be combined in one unit or separate. Instead of the ballast resistor being on the back of the switch as in fig. 3, it can be placed along side of the fuses protecting the lighting current.

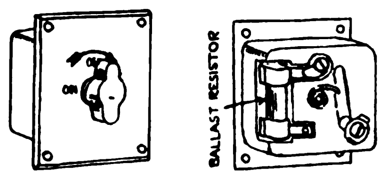

Fig. 3. Front and rear view of the "ballast resistor" on the back of the switch (fig. 2). Purpose of which is to protect the ignition interrupter points from burning. A 5 ampere fuse may be used to relieve an emergency but ignition must be turned "off" when engine is not running. (See page 347, explaining the "ballast resistor.")

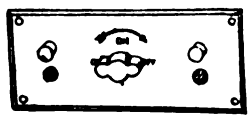

Fig. 2. The double pole ignition switch arranged so it will reverse the direction of flow of current through the interrupter, see page 248, explaining the function of a "polarity" switch also called a "current reversing type" of switch also note lighting switches.

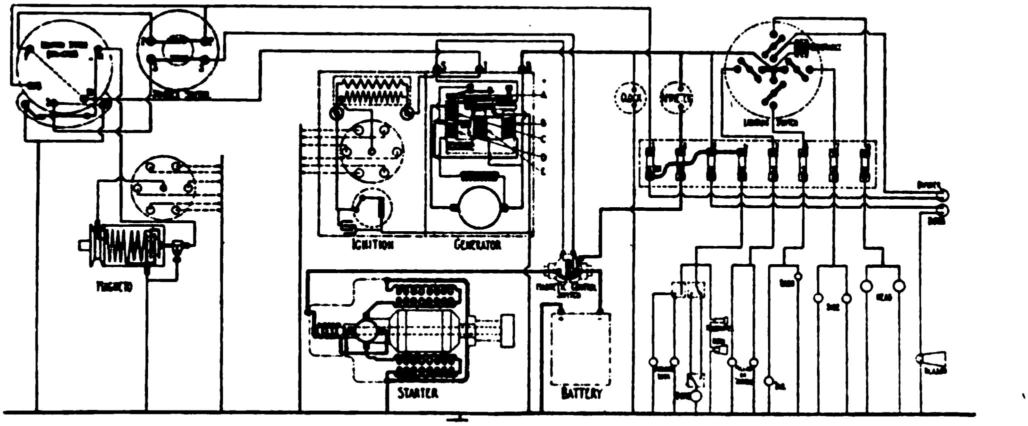
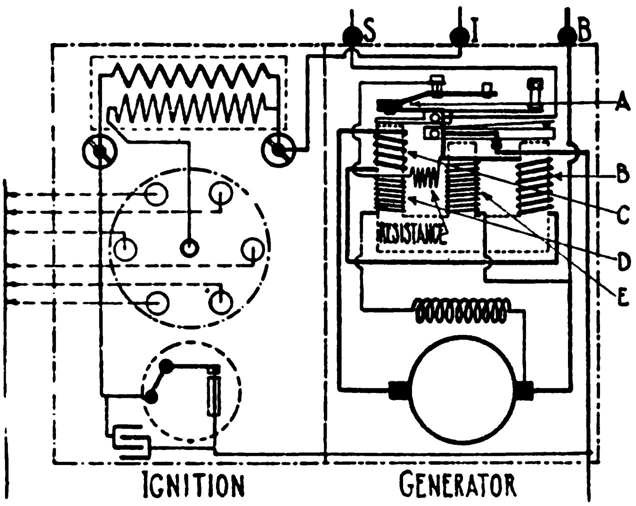
CHART NO. 168C—The Westinghouse Vertical Battery and Coil Ignition System as used with the electric system shown on page 346. See also pages 251 and 252 for clearance of interrupter and plug gap.





Wiring Diagram of Model C4 and B4 Pierce-Arrow—see page 277 about Late System.

This generator is an ordinary shunt wound machine, with a separate voltage regulating device, and differs from the previous machine, which had differential field windings. To explain this type generator in brief, would say that it has a cutout switch which operates exactly on the same principle as did the switches on the elder machines, but in addition there is a device for throwing a resistance into the field circuit from time the voltage rises above a predetermined point, 6.8 volts.

Voltage regulation: The shunt field current goes from the right hand brush up through the shunt field, through coil "D," then up and across the voltage regulating points "A" and down through the series coil "B," series regulating coil "C" and back to the other brush of the generator. As the voltage tends to go high, the current flowing through coil "E" and "C," and consequently the magnetic pull of core "C," becomes of such magnitude that points "A" are pulled apart. In such case the shunt field current has to pass from coil "D" through the resistance unit and then through coil "B," coil "C" and to the other brush. With the resistance in the shunt field circuit, the voltage tends to drop below six volts, but as soon as this drop starts the points "A" close again and boost up the voltage. These breaker points "A," vibrate at a high rate of speed and in doing so hold the voltage at the correct value. The coil "D," used in connection with this vibrating voltage regulator, is a compensating coil, used to offset the effect of stray fields set up by the generator.

The cutout switch: Current leaving the right hand brush of the generator passes through the shunt cutout switch coil "E" and then through coils "B" and "C" and back to the other generator brush. This is the usual type of cutout, similar to the Ward-Leonard shown in chart 168.

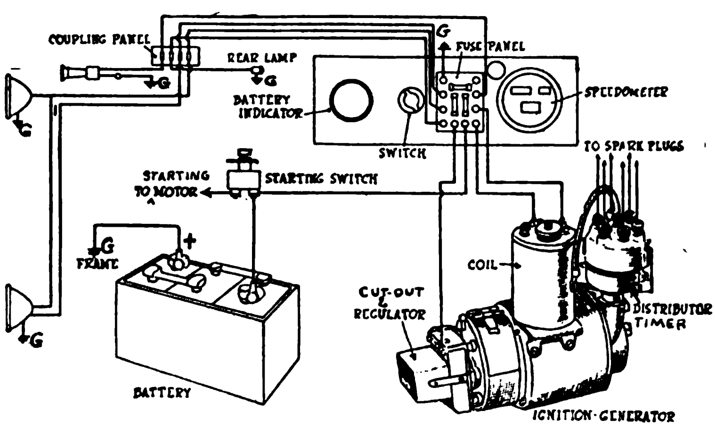
Westinghouse ignition unit is composed of a very compact high tension coil with a mechanical breaker in the primary circuit operated by a cam on the end of the generator shaft. High tension current is led from the coil to the high tension distributor and then from there to the plugs. The coil and distributor units are built up in one housing and electrical connections are established with terminals of the generator by means of the two screws holding this housing in place. Primary current going to the ignition unit goes from one terminal of the battery to one side of the magnetic control switch, then up through the main lead for the lighting switch, first going through the 30 ampere fuse and then through the ammeter. From the ammeter, ignition current goes down to the top of No. 3 fuse and then across on the copper strap to the bottom of No. 1 terminal post in the fuse box. From here it passes up through the small resistance unit of .6 ohms and from there to the point "PB" on the ignition switch. When the ignition switch is thrown on "B" or "MB," positions, then "PB" and "IG" are connected. From "IG" on the switch the current goes directly to the central terminal "I" of the generator and then through the primary winding of the H. T. coil, down across the breaker points to ground and back to the battery. Note that when the dash starting button is pushed that in addition to closing the starting circuit, by connecting the two points "SS" it also connects the points "P" and "PB" on the ignition switch; and point "P" is connected to point "IG" whenever the switch is unlocked. Thus whenever the engine is started with the ignition switch on magneto position, the battery system of ignition is in action as long as the starter button is held down.

The ignition switch, aside from the connections noted above to be used when starting, has an additional magneto ground, which is operated by pushing against the switch lever when same is in magneto position.

Starting motor: Current goes from the battery across the magnetic control switch to the solenoid mounted at the front end of the motor. When current passes through this solenoid it pulls the starting pinion into mesh with the flywheel. From the solenoid the current passes to one pair of motor brushes, through the armature winding, to the other pair of brushes, and then through the field windings to ground to the battery. (Similar to chart 161.)

The electric clock: The electric clock is wound up by energizing a small electro magnet, which operates every four and a half minutes; in other words, this clock will not run more than four and a half minutes after disconnecting the battery. The clock is set by means of a small knob, located on the back of same and is regulated by small lever located under figure 6 on the dial

CHART NO. 168D—Westinghouse Electric System with Generator Equipped with "Voltage or Potential Regulator." Ignition is from two independent sources; Battery and Bosch High Tension Type Z-R-6 Model 4 Magneto. **Pierce-Arrow** car as example—see also pages 496 and 500.



Remy Electric System.

Type:—Two unit. **Voltage:**—6. **Voltage regulation:**—Third brush and vibrator.

The equipment varies with each make of car, but that used on the Velie may be taken as an example.

Ignition Coil:—Mounted on top of generator. **Distributor and timer:** at one end, geared to armature shaft. **Cut out or relay:**—at other end.

Wiring—The negative line brush is insulated from the metal rocker ring, while the positive line brush and the field brush, are connected to it, the circuit from the battery to these brushes being through the frame of the generator.

The cutout and regulator are combined on the same Bakelite base. As soon as the generated voltage is greater than that of the battery the cutout points close.

The regulator consists of an electro-magnet, an arm operating on bronze pivots, two sets of contact points and a resistance unit.

When the generator is running at a speed lower than that required for maximum output, the contact points are held together by a spring and current supplied to the generator field passes directly through these points.

As soon as the speed increases and the generator output tends to rise above the desired maximum, the contact points are opened, forcing the field current through a resistance, consequently reducing the strength of the current with the result that the voltage generated is limited. This action takes place with such rapidity that the voltage actually remains constant at the prescribed maximum.

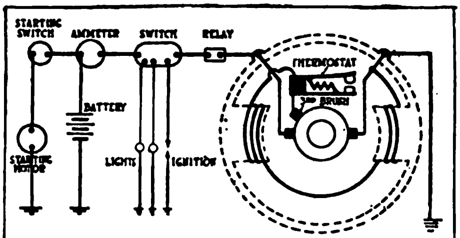


Diagram of connections with Remy thermostat

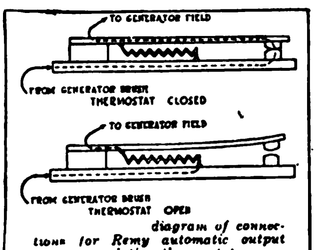

diagram of connections for Remy automatic output regulating thermostat

The Remy automatic regulator controlled by the temperature, which switches a resistance into the field windings as soon as the temperature of thermostat rises above 150 degrees. Normally the contacts are kept together, but when thermostat element is heated, the points separate. The resistance (shown between the two springs) is then thrown into the field circuit.

Fuse—A fuse is provided on the regulator base so that the generator will be protected in case the battery should become disconnected.

Ignition—The breaker gap should be .02 or .025, and the rebound spring should be at least .02 in. from the breaker arm when the points are at maximum opening. Spark plug gaps for best results should be .025 to .03 in. (also see chart 118 and page 251.)

It is important to see that ignition switch is off whenever engine is stopped, as otherwise the battery will discharge. The engine should never be operated while battery is disconnected unless the generator fuse on the regulator-cutout is removed.

Troubles.

If lights, ignition, starting motor and horn are dead the cause may be a loose or broken connection at the battery terminals, or where the battery is grounded to the frame; a loose or broken connection at the starting switch or at the starting motor, or wire between the battery and fuse block; a loose or broken connection at the starting switch or starting motor or wire between the fuse block and the lighting switch broken and either fuse No. 1 burned out or the horn open-circuited.

If all lights go out and ignition and starting motor are dead, there may be a loose or broken connection at the starting switch or starting motor.

If all lights go out and ignition and horn are dead the difficulty may be a defective connection between the battery and the fuse block or between the latter and the lighting switch and either fuse No. 1 being burned out or the horn open-circuited.

All lights out and ignition dead shows that the wire between the fuse block and the lighting switch is defective or that the ignition circuit is open, and either fuses Nos. 2, 3 or 4 are burned out.

If the lights are inoperative but the ignition is o. k. the trouble is in the wires between the lighting switch and the fuse block, fuses 2, 3, 4, and the wires to the lamps.

If the ignition is dead and the lights are o. k. the trouble is somewhere in the ignition wiring.

If the lights go dim and the battery is not discharged and after examining the bulbs to see that they are not of lower voltage, greater candle power or lower efficiency, look for a short circuit in the wire between the battery and the fuse block, between the fuse block and the lighting switch or between the switch and the generator. If the generator protective fuse is blown, look for a short circuit, but if not examine the cutout.

CHART NO. 169—The Remy Two Unit Electric System. The Starting Motor is not shown, but the Starting Switch and Connections are shown. One wire from switch connects with starting motor terminal, the other terminal of motor is grounded and circuit is completed through frame of car. **Remy Electric Thermostat.**

Cumulative Compound Winding.

Fig. 4 illustrates an inherent constant current method of regulating the output of a generator as employed on one of the early Gray and Davis generators. SHF is the shunt field winding. SEF is the series field winding. Therefore, as there are two windings on the field pole it is called a **compound winding.** The two principles of compound winding is known as the "differential compound winding" as explained on page 345, fig. 1, and the "cumulative compound winding" as explained on page 347 and illustrated in fig. 4.

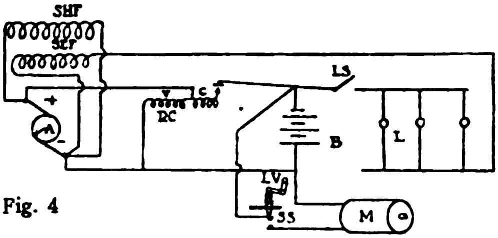

Fig. 4

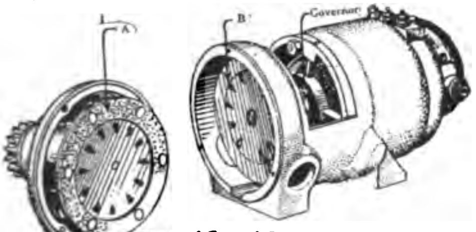
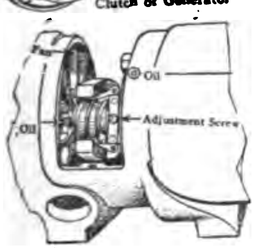
Names of parts of fig. 4: A, armature; RC, reverse current cut-out; V, cut-out voltage winding (see A, fig. 1, page 334 and fig. 6, page 864B); C, cut-out current or series winding; LS, light switch; B, storage battery; L, lights; M, starting motor; SS, starting switch.

Mechanical Regulation.

Illustrations below explain the mechanical governor principle of regulating the output of a dynamo. This method was used on the early model Gray and Davis generator.



Clutch of Generator



Governor of Generator

The mechanical regulation of maximum output is effected by a centrifugal governor, which keeps the speed of the machine constant. For that reason this may be placed in the class of **mechanically regulated machines.**

Variations in speed are taken care of by the automatic "friction" type of clutch.

The friction clutch (A & B) will slip more or less according to the speed of the engine, and the amount of such slippage is controlled by a governor.

As soon as the speed of the armature increases beyond the rated number of revolutions, the governor will act on the friction clutch. In other words, the two clutch halves (A & B), will be pulled apart and slip in such a manner that the armature will rotate not faster than the pre-determined speed.

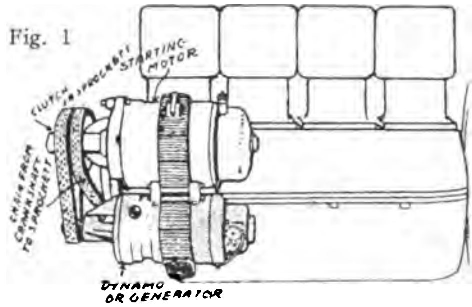
A cut-out for connecting and disconnecting battery to generator (not illustrated) was used with this system.

1914 Gray & Davis Electric System.

As used on the 1914 Overland, is shown in fig. 1. Note starting motor is mounted over the generator.

Generator is driven by a silent chain from the double sprocket on the starting motor shaft. This double sprocket with a "roller" type of clutch was a feature of this early system and is explained as follows:

Fig. 1



The starting motor is started by current from a storage battery, thus starting engine by means of a silent chain connected with a sprocket on crankshaft of engine. After engine is started, the sprocket to which starting motor chain is connected, is then operated by crank-shaft of engine. **The action of the roller clutch permits the two sprockets to run free of the starting motor, thus the generator is operated from the crank-shaft without operating the starting motor.**

Just how this clutch permits this action is explained as follows.

Action of the Roller Clutch.

The roller type of clutch is a popular type of clutch and its action should be studied carefully. In fact, this type of clutch is now used on a popular make of motor-generator, the Delco, as per fig. 16, page 398, but in a different manner than shown with this Gray and Davis system.

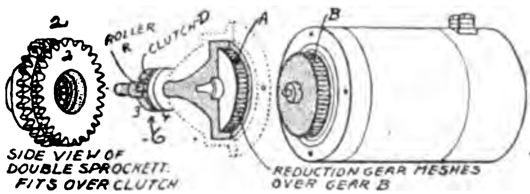


Fig. 2. Showing double sprocket (2); roller clutch; gear A attached to clutch; gear B attached to starting motor armature shaft. Parts are separated.

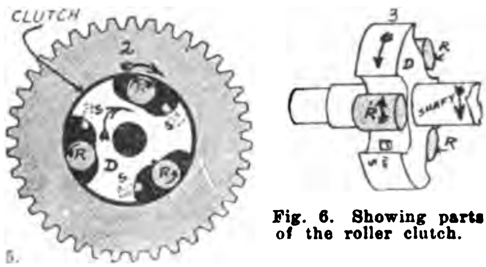

Fig. 6. Showing parts of the roller clutch.

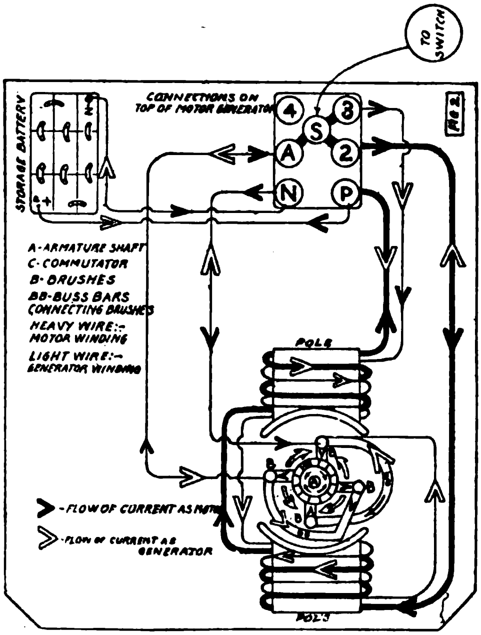
Refer to illustrations above and note that starting motor is geared, by means of reduction gears A and B, to clutch member D. **When starting motor armature shaft is made to revolve** by current from battery, then **D becomes the driving member** and turns in direction shown by arrow point on D, causing rollers (R) to roll outward and clutch against inner surface of sprocket (2), thus transmitting the power through D to R, to 2, then by the silent chain to crank-shaft of engine.

After engine is thus started and motor switch is off, then **engine drives sprocket (2), which becomes the driving member** instead of D. This reversed action causes rollers (R) to roll in opposite direction and against spring stops (S), thereby releasing the clutching action to the inside of 2. Result is, the double sprocket (2) **over-rides** clutch D. Therefore when engine is running, clutch D and gears A and B and starting motor, are idle.

CHART NO. 170.—1914 Gray and Davis Electric System, used in order to Explain the Principle of the **Roller Type Clutch. Mechanical Method of Regulating Output of a Generator by means of a Governor.** Now obsolete but shown in order to explain the principle.



Entz Motor-Generator.

Operation of Entz self-starter: The operation requires only one movement on the part of the driver—the movement of the starting switch.

Switch: Controls both the starting and the ignition; the same operation makes contact with the primary circuit of the battery, so that the regular cycles of the ignition system will be taken up when the engine begins rotating.

The starter switch is kept in charging position, except when driving for more than one quarter mile below eight miles per hour in high gear; in this case, the switch is set in neutral, throwing the switch back to charging immediately the car increases its speed to over eight miles per hour. Under all other running conditions, regardless of the speed, the switch is kept in charging position.

If the car is left standing for any length of time, the engine is stopped. If it is necessary to keep the engine running, the switch is set in neutral, while the car is standing still. After idling the engine or running slowly for a considerable length of time, the switch is put back in charging position, as soon as the speed of the car picks up.

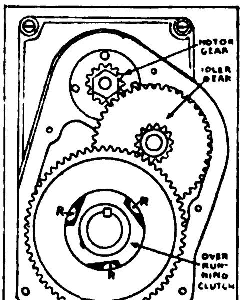
The combined motor and generator of the Entz electric system, is known as differentially wound motor-generator. The series and shunt field coils are connected so they operate **compounded as a motor, differentially as a generator.**

All automatic cutouts, regulators or controllers have been eliminated from the system. There is but **one armature** and one set of field **magnets**, but two field windings.

The motor-generator is a 4 pole "multi-polar" type of generator, with four brushes. The motor winding is the large wire. The other differential winding is small wire wrapped over the large wire and is the **generator winding.**

When starting engine with starting motor, switch is placed "on." It remains on until engine is stopped. When the switch is placed "on" position, the engine is revolved 80 revolutions per minute by the starting motor. (heavy winding of wire).

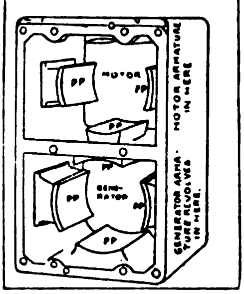
Above 600 revolutions, the motor is converted into a generator—as above this speed the small wire winding is generating enough current to overcome the 6 volts pressure of battery, hence it stores current into the battery. If, however, the engine is reduced to 80 revolutions or less, the generator again is transformed into a motor, and the generator not overcoming the pressure of the batteries; battery again turns armature as a motor—therefore, the engine is "non-stallable."



In other words, in any circumstances where engine would ordinarily be stalled, immediately upon releasing the clutch pedal the motor will turn engine crank and become operative.

Both the fine and coarse wire winding is wound in the same direction on the field, but current in the heavy wire winding travels in opposite direction, due to pressure from battery which tends to reverse the polarity of the fields or "buck the fields." **This tendency to reverse the poles of the field is governed by the amount of charge or amperage hours in the battery. That is,** if the battery is in a discharged condition the fields will build up, causing a greater flow of current through the fine wire, but as the battery becomes charged the fields will become weakened, which condition will cause less current to flow through the fine wire.

The electric light globes are 21 volts, although the battery is but 18. As there is always a slight excess of current from all generators this prevents lamps burning out rapidly. **The polarity switch** (used with the Atwater-Kent ignition system) is explained in chart 117.



Remy "Double Decker" Motor-Generator.

The Remy model 150 exemplifies how a generator and starting motor can be operated one over the other.

Employs two separate armatures and two separate fields, and may be termed a "double decker" since the motor armature is super-imposed over the generator armature.

The two armatures are connected together with a system of gearing and an over-running clutch. (R), see chart 170 for principle). **The motor armature** and the gearing are only in operation when the starting switch is pressed.

The generator armature is the only moving part under running conditions, as the over-running clutch of the roller type is provided to disengage motor armature and reduction gears, which remain idle and inoperative when engine is started and running under its own power. **Generator armature revolves in lower field.** Motor and generator are entirely separate—(armature is drum type). **A regulator and automatic cut-out** of usual type are provided.

CHART NO. 171—The Entz System—formerly used on the Chalmers. **Also similar to Entz system** formerly used on the White. **The Remy "Double Decker."**

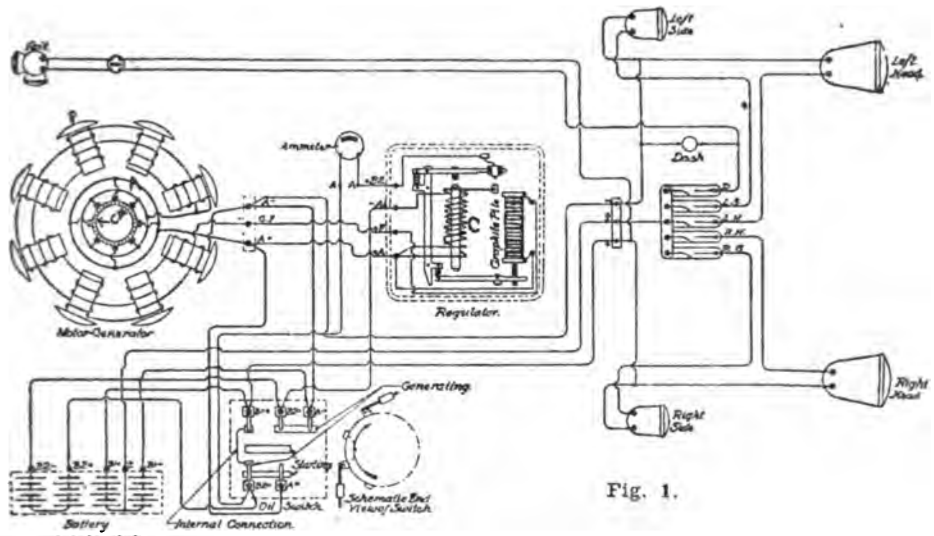


Fig. 1.

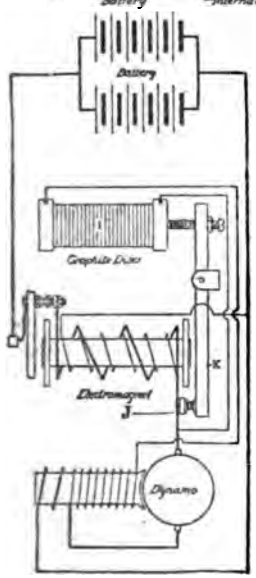

Fig. 2. The regulator of the U. S. L.

The regulation of constant voltage is maintained by pressure upon the graphite discs I, which are pressed together by lever K, by pressure of coil spring J. The less the pressure, the greater the resistance thrown into the field winding, for if the discs are not close and tight, resistance is offered to flow of current. Note the pressure upon these discs is also controlled by the electromagnet, the stronger the current flowing from generator, greater will be the magnetic pull on K and J, thereby taking pressure off of the graphite.

U. S. L. 1914 Flywheel Installation.

The U. S. L. 1914 is a two-unit system. In installing this system the armature of the motor-generator takes the place of the flywheel and performs its functions as well as those of the electric lighting and cranking systems.

The field has two windings, shunt and series. When machine operates as a motor, those windings are cumulatively compounded, that is, magnetic effect of series winding augments that of shunt so as to secure maximum torque. When machine operates as a generator, these windings are differentially compounded, that is, the magnetism of series winding is opposed to that of shunt, so as to assist in regulaton. The voltage of the motor is 24, while the charging voltage of the generator is 12.

The preferred disposition of the units is that shown in fig. 1. As will be seen, the added weight will be only that of the battery, fields, switches and controller as the flywheel is removed and replaced by the armature of equal weight.

When a foot switch is pressed the battery is connected to the motor and this turns over the engine at the rate of from 200 to 300 revolutions per minute.

As soon as the engine picks up to a speed giving 8 miles, the motor-generator becomes a shunt-wound generator and starts to charge the battery, restoring the current used at a 3-ampere rate.

In order that the output of the generator shall be uniform, a carbon or graphite pile regulator, operated by a series coil, C, is used. This keeps the output through the working range of from 600 to 1,200 revolutions per minute, practically constant.

1915 U. S. L. Electric System.

The improved system eliminates the carbon pile regulator and the "series parallel" switch. No regulator is used, as windings of generator are so proportioned, that the output of generator, cannot exceed the current demand of the storage battery and lamps.

A portion of the multi-polar field of the motor-generator is wound with a series coil for starting purposes. The other portion of the fields, are wound with shunt and compensating coils, for generating and regulating purposes. The brushes are so connected, that the entire number is used for starting, whereas but three are used for generating.

The storage battery is provided in some cases with two, and in some cases three, terminal posts. When two terminals are provided, a 14 volt lamp must be used. When three posts are provided, seven volt lamps are used.

The number of cells of battery are cut down from 12 to 6, giving 12 volts instead of 24.

CHART NO. 172—The U. S. L. (U. S. Light & Heat Corporation) Electric System. See also fig. 1 page 347 for construction of generator. **Note—The U. S. L. Co., Niagara Falls, N. Y. now use a differen principle of regulation. This is shown as a matter of information.**

Gray and Davis Motor-Generator.

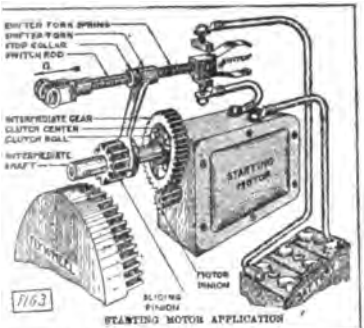

FIG3 STARTING MOTOR APPLICATION

The starting motor is a separate unit, and is constructed for fly wheel drive, or crank shaft drive. Fig. 3 illustrates the fly wheel drive principle.

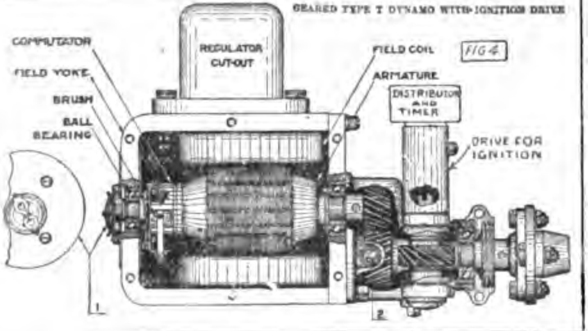
The starting motor switch is also shown—the action of which is clear in the illustration. The battery is a 6 volt battery.

The dynamo is a separate unit:. compound-wound instrument driven by the engine. The driving power is transmitted by chains or gears, according to the installation.

The dynamo (figs. 4, 1 and 2) has two principal parts: The "field," in which magnetism is induced, is stationary. The "armature," in which electrical current is generated, rotates.

The dynamo has the characteristics of a compound-wound machine; that is, the field strength, or magnetism automatically increases as additional work or load (lamp load) is applied, and vice versa. But it is of the shunt wound type, and is thus classified; because its field windings are connected in shunt with, or across the armature.

GEARED TYPE T DYNAMO WITH IGNITION DRIVE FIG4



Reference to Wiring Diagrams.

Chart 174, shows the shunt field winding in parallel; one side connected to the positive dynamo brush; the other passes through the regulator points and is connected to the negative dynamo brush.

Type "T, G & D" dynamo is rated at 6½ volts, 10 amperes, 1,000 r. p. m.; type "S" dynamo is rated at 6½ volts, 10 amperes, 650 r. p. m.

The dynamo is connected to the engine by chain or gears, so that it will rotate at rated speed when car speed is 10 miles per hour, at which speed it should deliver current.

The Regulator and Cutout.

The regulator and cutout performs two duties: One to "regulate" the dynamo for uniform output. The other to connect the dynamo into the system only when sufficient to charge battery and to disconnect dynamo from the system to prevent battery discharging through dynamo.

The shunt winding, series winding, cutout points, regulator points and field resistance, are shown in wiring diagrams.

The shunt winding is permanently connected across the dynamo armature. It attracts the cutout armature, thereby closing the cutout points.

The series winding, when the cutout points are closed assists the shunt winding in holding cutout points firmly together.

The cutout points, when closed, connect dynamo into the system..

The regulator points, when closed, short circuit or shunt the field resistance, and when drawn apart, insert the field resistance into the field circuit.

The field resistance retards the flow of current in the field.

When dynamo is at rest, cutout points are open and regulator points closed.

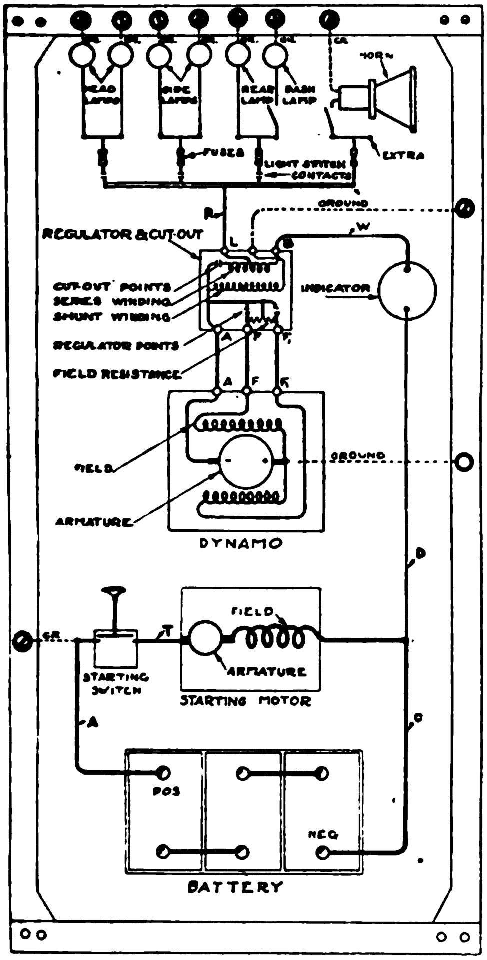
As dynamo first speeds up the regulator points remain closed. Thus, the field resistance is short circuited, permitting the dynamo to build up under full field strength. When the proper voltage is reached the points open, permitting current to flow through the series winding to the system.

As the dynamo speed increases beyond that necessary for full output the pull of the shunt winding attracts the regulator armatures. This reduces the pressure at the regulator points and inserts a resistance into the field circuit, which prevents further increase of output. The varying of the pressure at the points, which allows the resistance to be put into the circuit, is intermittent. The frequency is in proportion to the speed variation.

When lamps are turned on the frequency at the regulator points is reduced and the dynamo output is increased, giving the dynamo compound-wound characteristics. See A, chart 163, showing resistance in field circuit which gives an idea of the regulator.

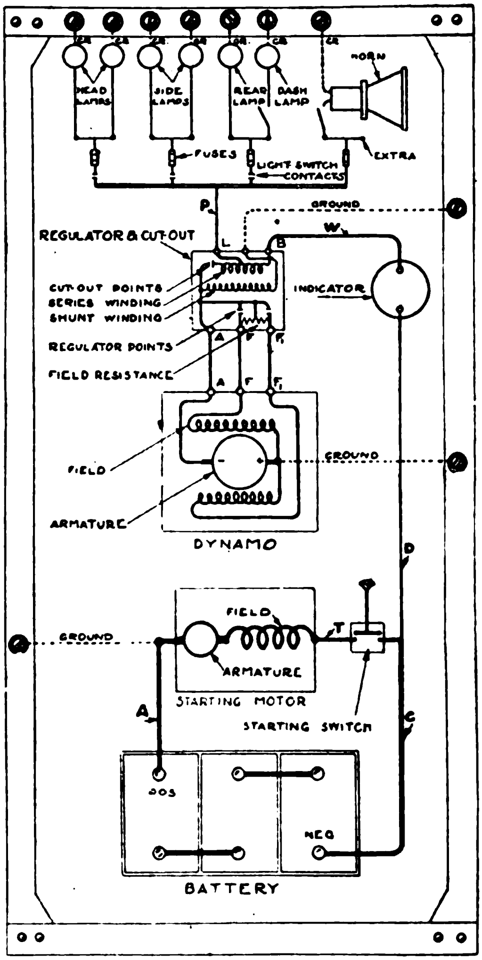
Ignition; is similar to Delco and other systems of this description. Note provision is made for driving timer and distributor on generator shaft (fig. 4).

IART NO. 173—One of Gray and Davis' Starting Motor and Generator. Fly Wheel Application of Starting Motor.



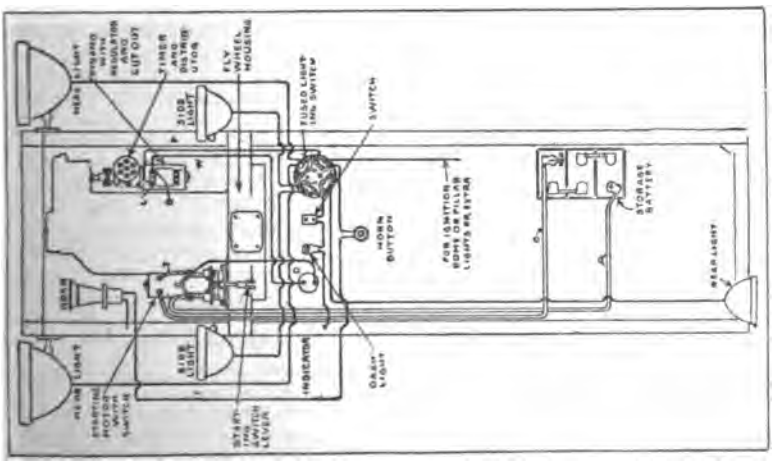
"Grounded Switch," system

Cable (A), instead of connecting directly to the starting switch, connects to frame of car. The car frame carries the current to the grounded terminal of starting switch.



"Grounded Motor" system

Cable (A), instead of connecting directly to the starting motor, connects to the frame of car. The car frame carries the current to the grounded terminal of starting motor.



To trace motor circuit, "grounded switch" circuit is traced from positive connection of battery through cable (A), starting switch, cable (T) starting motor and cable (C), to battery (NEG) terminal.

The "Grounded motor" circuit is traced; positive terminal, cable (A) to starting motor, cable (T), starting switch and cable (C), to battery (NEG) terminal.

CHART NO. 174 —Gray and Davis Wiring Plan of "Grounded Switch" and "Grounded Motor." There are two Wiring Systems in general use; "Grounded-Motor" and "Grounded-Switch." Size of wires; Starting Motor, No. 1 B & S gauge; Dynamo Battery and Lighting Switch, No. 12; To Headlight, No. 10. —see chart 173.

*A SUDY OF LEADING ELECTRIC STARTING AND GENERATING SYSTEMS: Chalmers, Overland, Hupmobile, Marmon, Franklin, Locomobile, Saxon, Chevrolet, Maxwell, Mitchell, Studebaker, Dodge, Reo, Haynes; as examples.

Pointers for Studying this Instruction.

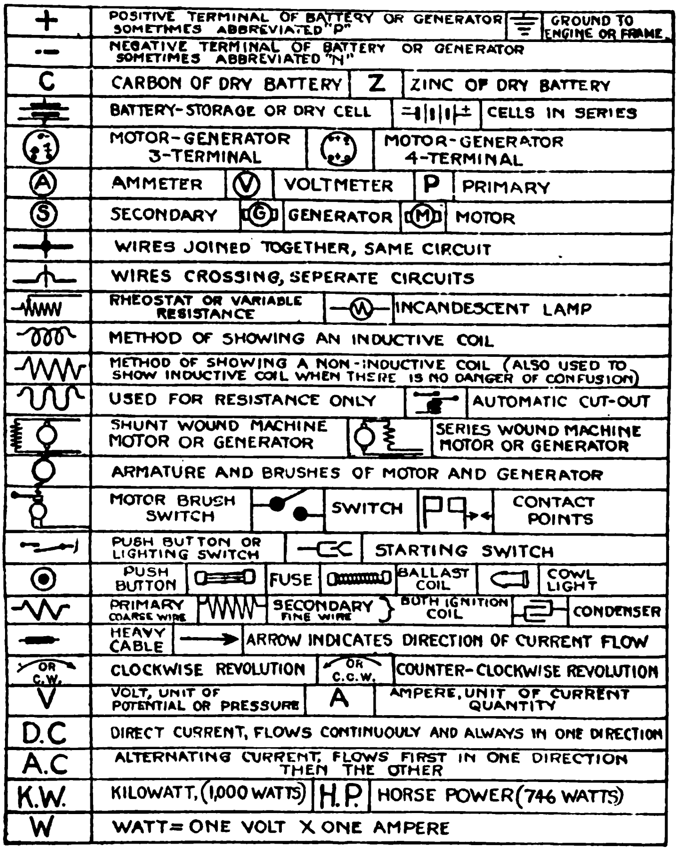
The fundamental principle of the starting and generating systems have been treated in the preceding instructions. If the reader will master the principles as laid out in the foregoing matter, it will not be a difficult matter to understand any and all systems, because each system embodies one or more of the principles explained. Although the methods of operation or construction may vary, the purpose remains the same.

****We will devote this instruction to diagrams of the leading electric systems.** With information gained from the preceding "**ignition**," "**electric starting**" and "**generator**" instructions, the reader ought to easily understand the various systems from these diagrams.

The Delco electric system will be treated under a separate instruction, also care of electric systems, wiring of electric systems troubles and tests.

‡**Electrical symbols:** before studying the different diagrams, learn the electrical symbols as illustrated on this page. For instance, the sign which denotes a "ground," "storage battery" or where "wires connect" or "pass over each other." They will be used quite freely in these instructions, as well as many of the other signs.

It is also advisable to refer to chart 181D, for the address of the leading manufacturers of electric systems and if the explanations are not clear, their catalogs will no doubt be of assistance.



Wiring principles: although this subject is treated under "wiring of electric starting and generating systems" it is well to know that there are two wiring principles; "single wire" and "two wire" systems.

The "single wire" system is where one insulated wire is used and the frame of car is used for the return circuit. This system is used most, as it will be noted in diagrams following.

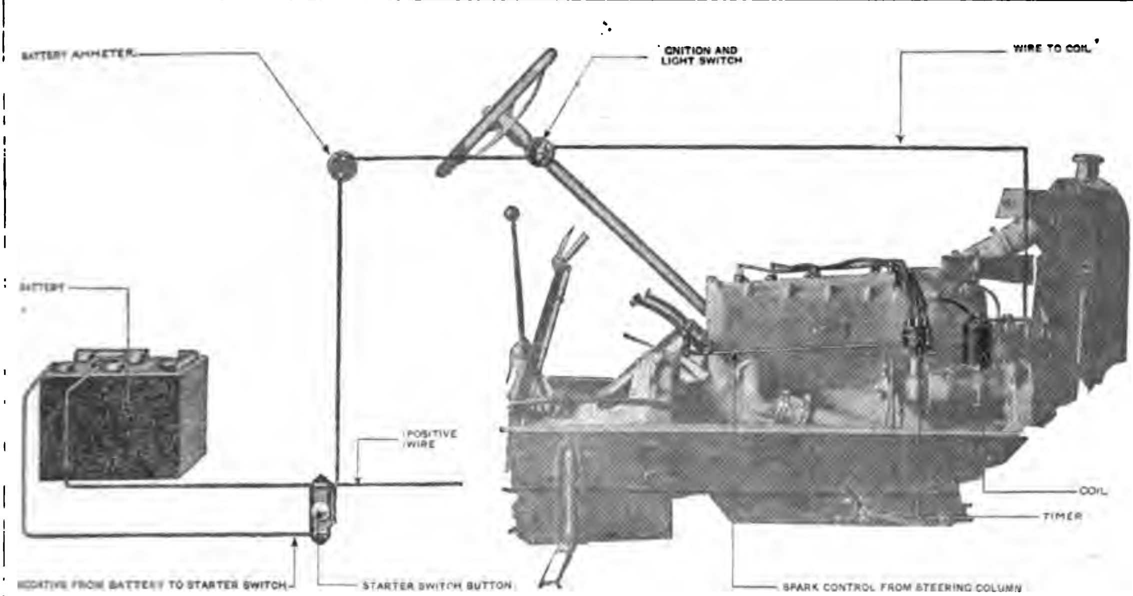
The "two wire" system is where there is no ground to the frame, but two insulated wires are used.

Another point to remember in studying the different electric systems: note the starting, generating, and ignition systems, are not always of one manufacturers' product. For instance, the Studebaker uses the Remy ignition and generator, and a Wagner starter. The King uses a Ward-Leonard starter and generator, and the Atwater-Kent ignition.

‡A storage battery plate is indicated by a long line as positive plate, and a short black line as negative plate. One pair of lines represent a cell, for instance, note symbol to designate a 3 cell battery—at lower left corner of fig. 1, page 391. See also, fourth symbol from top on above chart.

*See pages 544 to 546 for "Specifications of Leading Cars," which will give the make of starter, generator, ignition, carburetor, etc., used on all leading cars. See instruction No. 34, "Operating Cars," for lever movements, for gear shift, and control systems of different leading cars. See pages 484, 543 for "Lamp Voltages." See index, "Removing Battery." *See instruction No. 24 and page 548 for "Ignition Timing."

**We do not attempt to show the latest wiring diagrams in this book for two reasons: because the reader must master the early principles first; second, because most of the cars which need repairing are older models. See ad for Wiring Diagram Book for wiring of all cars.

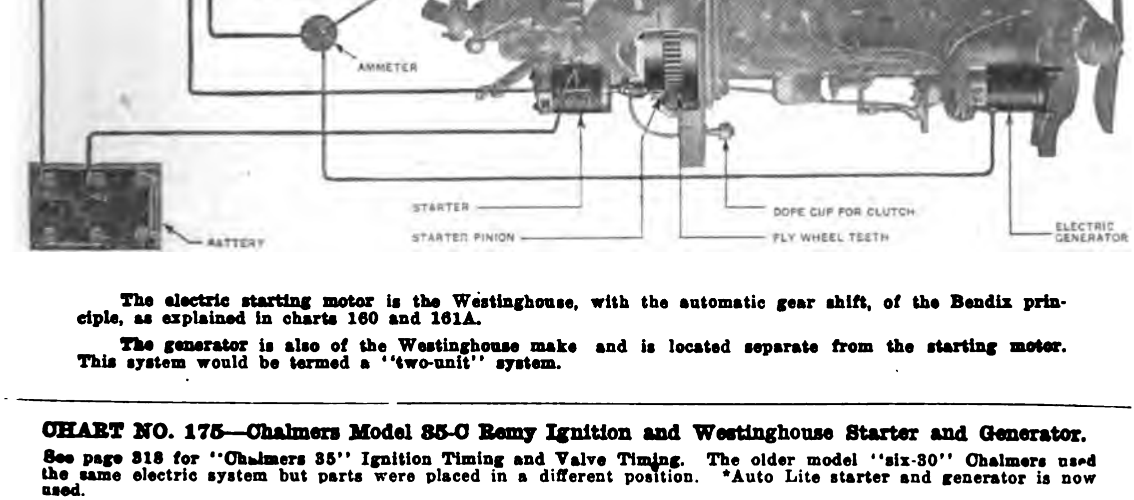


By referring to the "Specifications of Leading Cars," charts 229 to 234, it will be noted that the Chalmers use a Remy ignition system and a Westinghouse starter and generator.*

The ignition system: The timer and distributor are located on the generator and driven by spiral gears off the generator drive shaft. The connections are shown in diagram. The firing order is 1, 4, 2, 6, 3, 5. **The timing contact points** should be kept adjusted to .015 to .020 inches. Spark plug opening should be .025 inches.

Setting of timer. Place piston in No. 1 cylinder 1$\frac{5}{16}$" after top dead center, between power and compression stroke. Then the timer should be slowly and carefully turned backward (contrary to the direction of normal rotation) until the interrupter points just separate. At this point connect up levers so that with fully retarded spark lever on the steering gear quadrant, this interruption should have just taken place. The cam on timer is a hexagon six point cam. It is a taper fit on shaft and locked in position by a small nut screwed on the shaft over top of cam. Distributor should just be making connection with spark plug in cylinder number 1.

All upper dead centers are marked on rim of fly wheel thus—D. C. 1 & 6, D. C. 4 & 3 or D. C. 2 & 5, as the case may be.

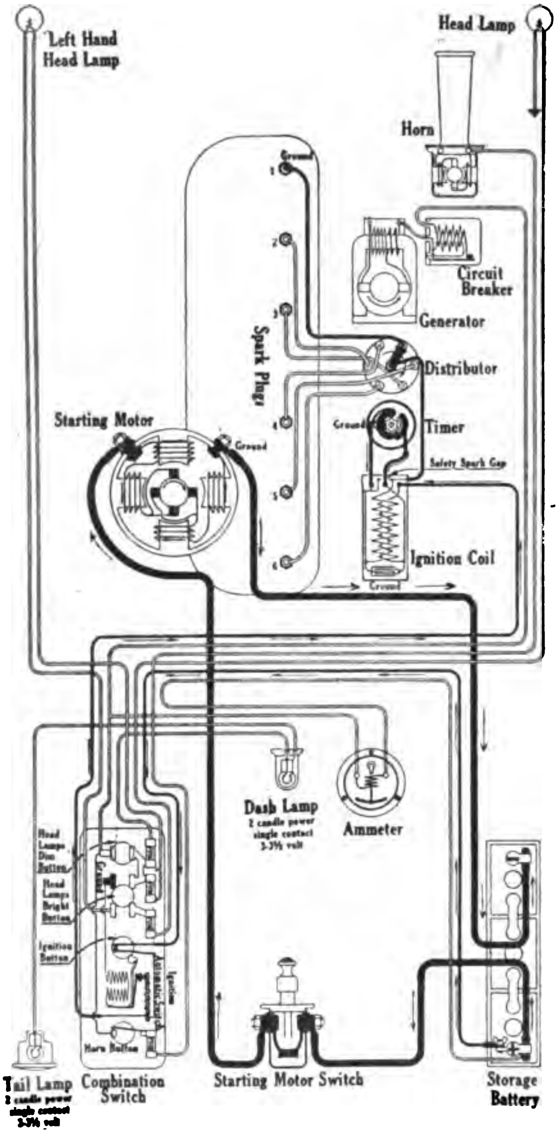


The electric starting motor is the Westinghouse, with the automatic gear shift, of the Bendix principle, as explained in charts 160 and 161A.

The generator is also of the Westinghouse make and is located separate from the starting motor. This system would be termed a "two-unit" system.

CHART NO. 175—Chalmers Model 35-C Remy Ignition and Westinghouse Starter and Generator.

See page 318 for "Chalmers 35" Ignition Timing and Valve Timing. The older model "six-30" Chalmers used the same electric system but parts were placed in a different position. *Auto Lite starter and generator is now used.



Wiring Diagram of Willys-Knight Six.

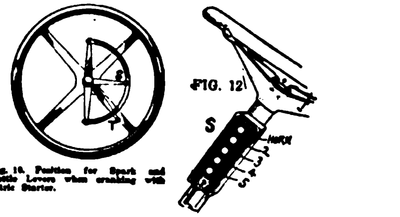


Fig. 10. Position for Spark and Throttle Levers when cranking with Electric Starter.

Fig. 12. Combination switch is placed on the steering column instead of the dash. There are four push button switches, as follows: **1st,** horn; **2nd, ignition;** 3rd, head lights; 4th, dim lights.

The rear and instrument lights are connected with 3 and 4. The Overland formerly used 5 switch buttons, the fifth was for a solenoid connection for starting.

Fig. 10. Position for the spark lever (S) and throttle lever (T) when cranking with electric starter.

If battery or generator is disconnected, do not operate engine unless a short piece of bare copper wire is connected from terminal post of generator, to brass screw in name plate.

Willys Six Model 89 Electric System.

Starting Motor: Auto-Lite 6 volt with a Bendix drive which starts engine through the fly-wheel. See heavy black lines for the circuit and note that the battery is grounded at one terminal of starting motor.

The starting motor like all others, is a series wound machine and has 4 brushes. Most all starting motors have 4 brushes because the current is very heavy.

Generator is driven by silent chain from crank shaft. **Regulation of generator** is the constant current or inherent method, consisting of a reversed series winding, similar to the method explained on page 845; "bucking series regulation", which cuts down the field strength, thus preventing an excess output when engine is running at high speeds. The generator begins to produce current at a car speed of about 7½ miles per hour and at which time the cut-out (circuit breaker) closes the circuit between battery and generator. The production climbs to about 14 amperes at 20 m. p. h. At this point the reversed series coil holds the output constant no matter how fast the car is driven.

The cut-out (also called circuit-breaker) is exactly the same principle as described on page 834 and 864B.

The generator circuit can be traced by starting at the right side terminal on generator, through cut-out to ammeter, through ammeter to battery (+), out (—) side of battery to ground (on starting motor), to ground through frame, to grounded terminal on generator.

Ignition system consists of the Connecticut closed-circuit timer, distributor, coil (see also, fig. 14 next page), and the automatic thermostat switch (different from one on page 859).

The combination switch is mounted on the steering post as per fig. 12.

To trace the primary ignition circuit, start at (+) side of battery, follow the dark wire to ignition button, thence through thermostat spring to primary winding on coil, thence to timer, back to grounded connection on coil, thence to (—) side of battery which is grounded to frame of car at starting motor.

The ignition secondary circuit is from secondary winding on ignition coil, to distributor, then through distributor arm to spark plug, through ground of engine to ground on coil. Note "safety spark gap," the purpose of which is explained on page 254.

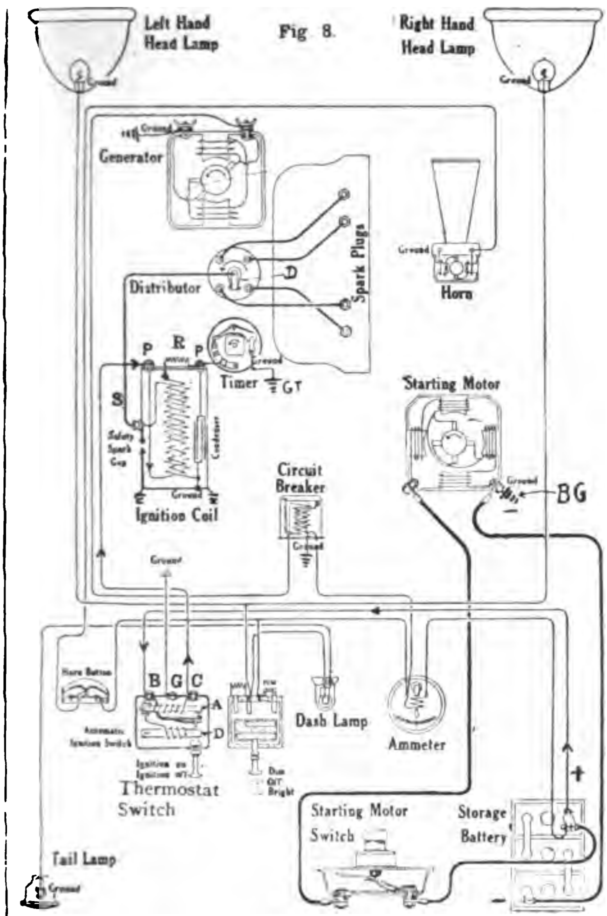
The purpose of the thermostat in the combination switch, is to open the circuit if switch is left on when engine is not running. The spring (below word "automatic switch"), heats when ignition switch is left "on" and engine not running. As long as engine is running the interrupter is intermittently opening and closing circuit and this blade does not heat, but when circuit is closed for any length of time (30 or 40 seconds), then it heats and bends down, making contact with magnet coils which causes switch button to release, as explained on page 254, thus opening circuit.

To time ignition: Retard timer. Turn fly-wheel slowly by hand until mark "1—6DC" on fly-wheel is 1 inch past the indicator on rear end of cylinder, just after the completion of *compression stroke in either No. 1 or No. 6 cylinder. Then so mesh the timing gears with the timer drive gear that the points of timer are just starting to separate and the distributor arm is making connection with the cylinder being timed. See also, page 258. **Firing order:** 1, 5, 3, 6, 2, 4.

To time Overland model 85-B: Turn fly-wheel until mark "1-4UP" on it, is 1¼" past indicator, in either No. 1 or 4 cylinder when just completing compression stroke. "Country Club" model; 1¾" past indicator; **Willys-Knight Eight;** place mark "1-4-TC-R," 1½" past indicator. **Model 90;** place mark "1-4UP," 1" past indicator. **Firing order** model 90, and 85B, 1, 3, 4, 2. **Timer gap .018"; plug gap .025".**

To raise ampere rate of Auto-Lite generator if below 14 amperes, remove small brass cover plate from side of generator where brush holders are fastened to a ring. Loosen screws and turn ring in direction of rotation.

CHART NO. 175A—Willys-Knight Six "Model 89" Electric System, Explaining the Combination Switch on the Steering Post. See pages 497-49 for Overland Gear Shift. See page 112, 113; meshing gears and silent chain adjustments. *See page 320 to tell when piston is on compression stroke.



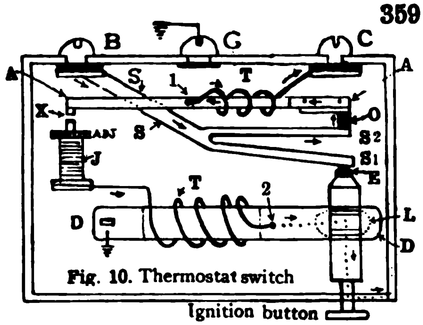


Fig. 10. Thermostat switch

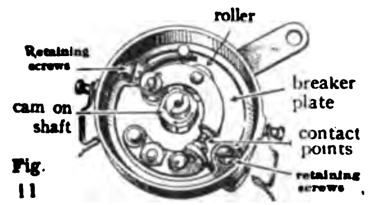

Fig. 11

Connecticut Timer—Top view

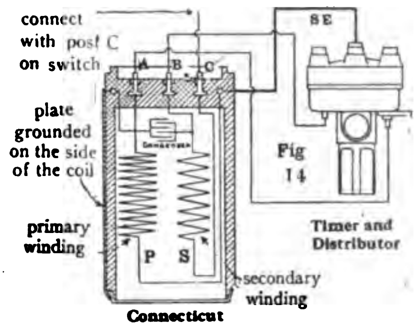

Fig 14

Connecticut Ignition Coil

The only cars manufactured by the Willys-Overland Co., Toledo, O., for 1920 are: "Overland 4", page 677 and the "Willys-Knight "model 20."

The model 90 electric system is explained, due to the fact that a great number are in use.

Starting motor is similiar to the description on page 358.

Generator is the Auto-Lite. **Regulation of current** by third-brush, (the principle of which is explained on page 389). Generator begins to produce current at 8 miles per hour car speed sufficient to close cut-out (circuit breaker) contact points, thus connecting battery with generator. At 20 m. p. h. output is 14 amperes; at 25 m. p. h., about 15 or 16 amperes. Maximum output of 17 amperes is produced at 32 m. p. h., after which speed the current decreases.

Ignition. The Splitdorf closed-circuit timer and ignition coil is shown in fig. 8.

Primary circuit. Start at battery (+) side, follow single arrow points to B on thermostat switch through A to C, thence to primary winding (P) on coil, thence through resistance R (see purpose of resistance unit on pages 246, 250, 878), to insulated contact on timer, through timer points to grounded timer contact, to ground connection to battery (—). Note (—) side of battery is grounded on starting motor at (BG) which grounds battery to frame of car.

Secondary circuit: From secondary winding on coil, through cable (S) to distributor arm (D), to spark plugs, through engine to ground of coil.

Safety spark gap is provided between ground connection to secondary winding, for reasons explained on page 254. **Condenser,** like all condensers, is shunted across primary circuit.

Connecticut model 16 timer (fig. 11) and coil (fig. 14) are used on some of the "model 90" Overland cars. Note this coil circuit is clearly shown. P is primary winding and S, secondary. The wire from C on coil connects with C on thermostat switch.

Connecticut thermostat switch, also called automatic switch is used on all "model 90" cars. This switch (fig. 10) is different from the thermostat switch shown on page 358 and 254, in that blade D, takes the place of the magnet coils on the thermostat switch shown on above pages.

Purpose of thermostat switch. It must be understood that this timer is a closed-circuit type, therefore if engine is not running and switch is left "on", a waste of current and heating of coil results, therefore this switch opens the circuit.

Thermostat action (see fig. 10 and 8). Battery current flows from battery (+), to B, then through insulated spring (S, fig. 10). If ignition button is pushed in, then an insulated plunger (E) on switch button, presses against spring (S1) causing spring (S2) to close points (O). Current then travels through (A) to (1), through resistance wire ribbon (T) (thermostat wire which is insulated from A, except where grounded to A at 1), to insulated connection (C), to (C) connection on coil.

So long as engine is running, the intermittent opening and closing of timer contact points prevents (T) from heating, blade (A).

If engine stops with ignition switch "in", then timer points are closed, and within for 30 or 40 seconds, the continuous current passing through resistance wire (T) heats spring blade (A), causing it to bend down, thus making contact with (J) at (X). Current then flows through (J) to (T) on blade (D), through (2) to ground connection of switch box at (G).

Blade (D) then becomes heated and bends up, releasing a wedge shaped lug (L) which is attached to under part of D, from a groove in ignition button shaft. The spring (S1) then easily forces ignition button "out", thus opening circuit at O and X. See also, page 365.

Ignition timing, and firing order, see page 358.

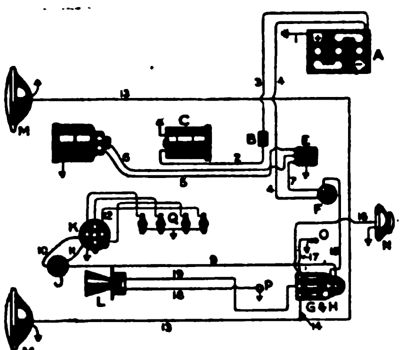
If battery is disconnected, short circuit between the two terminal posts on front end of generator.

CHART NO. 175AA. Overland "Model 90" Electric System, Explaining the Principle of the Connecticut Thermostat Switch. See also, pages 365, 254.

Hupmobile Series "N"—1916-17 Electric System.

The Hupmobile formerly used a Bijur starter and generator. The system now used is a Westinghouse starter and generator and the Atwater-Kent Ignition.

Westinghouse generator—driven by chain front end right side. Charges battery at 8 miles per hour, at which point the cut-out connects with battery. At 20 miles per hour, generator reaches its maximum. Charging rate 14 to 18 amperes if battery is low, and 6 to 9 amperes if battery is well charged.



Wiring Diagram of Westinghouse Equipped Cars After 71,800

A—Storage Battery	J—Spark Coil
B—Starting Switch	K—Atwater-Kent Ignition
C—Starting Motor	L—Horn
D—Generator	M—Head Lamps
E—Voltage Regulator	N—Tail Lamp
F—Ammeter	O—Instrument Lamp
G—Ignition Switch	P—Horn Push Button
H—Lighting Switch	Q—Spark Plugs

The regulator performs two functions. It acts as a cutout, which connects and disconnects generator from the battery at a certain predetermined speed. It also acts as an automatic voltage regulator which, after the cutout has made connection between the generator and battery, automatically keeps the generator voltage below a certain fixed value, and thereby controls the output of the generator.

Wiring: There are two wires leading from the generator to the regulator. The larger of these two wires connects the generator terminal nearest to the engine with the regulator terminal, which is at the extreme right as viewed from the driver's seat. The other wire connects the generator terminal nearest the car frame with the middle terminal on the regulator. (See illustration above.)

To adjust generator chain tension proceed as follows: slightly loosen the three nuts holding the generator to the crank case, remove the shield over the front of the generator, then with the lower bolt as pivot, the generator can be swung to either side until the proper tension is obtained.

The chain can only operate in one direction. Arrows stamped on each link show the direction in which the chain should run. **The proper chain tension** or adjustment is when a very slight motion can be felt in the chain.

Starting motor is located on right side of engine and drives through a gear on the flywheel operated by a foot pedal. **Starter pedal** is located to right of foot accelerator pedal.

Ignition—Atwater-Kent (see page 248). Firing order 1, 2, 4, 3.

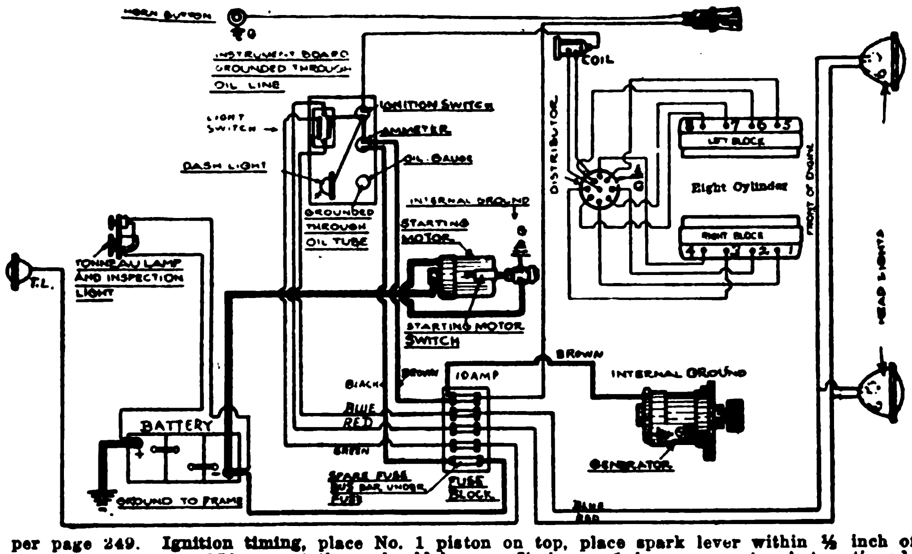
Setting the ignition: Set the hand spark lever in a horizontal or mid position on the sector, and loosen the two nuts on the control rod at either side of the small swivel block at the igniter.

The piston in No. 1 cylinder should be raised to top dead center, which should be at a time when the mark "1 and 4 CL" on the flywheel registers with the dead center, which can be ascertained by removing the flywheel cover. Turn on past dead center about two inches. Then the distributor unit should be turned so that the lug, to which the swivel connects, points directly away from the carburetor and then carefully turn back about 1/6 of a turn contrary to the direction of normal rotation of the distributor shaft, until a click is heard; then clamp the adjustment in place.

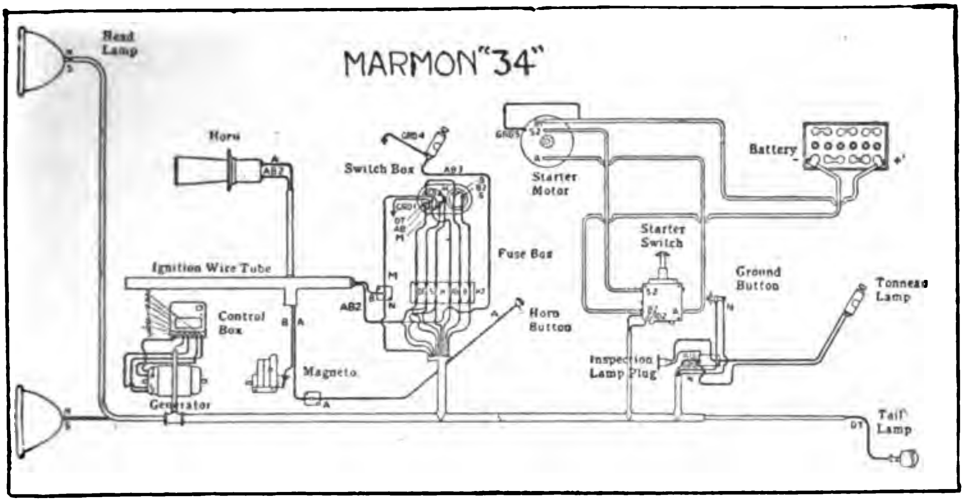
If the distributor unit has been properly installed, the metal edge of the distributor block, should be pointing toward the radiator.

King Eight-Cylinder Model "EE & F" Electric System.

Wiring, single wire, grounded return; **Lamps,** single contact. All are 6-8 volt. Head lights are 18 c. p. and 4 c. p. Instrument and tail light 2 c. p. **Fuse,** 10 amp.; Generator, Bijur constant current type, page 925; **Starting** motor, Bijur with Bendix drive, page 881; **Ignition,** Atwater-Kent, type "CC" closed cir-



cuit per page 249. **Ignition timing,** place No. 1 piston on top, place spark lever within ½ inch of full retard and time per page 250, except timer should have a ⅞ in. or 1 in. movement. Automatic advance not used. **Firing order,** 1, 8, 3, 6, 4 5, 2, 7. **Cut-out** is mounted within generator housing. **Regulation;** third brush.



Bosch starting, generator and ignition system. Three unit type. Ignition: Bosch DU6, independent magneto, driven from the generator shaft, by means of a flexible coupling. A grounded, "one wire" system is used.

Ignition timing; the magneto should be so timed, that with a fully retarded spark, the interrupter platinum points will just begin to separate. when the line marked "top center" on the flywheel has still one inch to go before passing under the flywheel pointer. On the magneto coupling. there is an adjustment by which the magneto timing may be advanced or retarded, in its fixed relation to the engine piston, as desired. For valve timing, see page 113. Firing order, 1, 5, 3, 6, 2, 4.

Starting motor—Is series wound with a displacement type armature, called the "automatic electro magnetic gear shift" type. It is located on the right hand side of engine. See chart No. 161.

The Bosch dynamo, type "DSR-3," is a shunt wound machine, having an iron ballast coil working in parallel with a bucking field coil, (see illustration B, chart 163,) these serving to keep the dynamo output within the proper limits.

At low dynamo speeds the current on the line passes through the ballast, which, when cold, has a high conductivity.

At higher dynamo speeds, however, when the current output is liable to rise excessively, the ballast heats up, and its higher resistance forces a high proportion of line current through the bucking coil mounted on the field, thus reducing the dynamo output automatically, see fig. 2, chart 166.

The control box, is mounted above the generator, convenient for inspection. Incorporated in the control box are the automatic cut-out, the field fuse and the iron ballast coil. The automatic cut-out is provided for the purpose of automatically connecting the dynamo to the battery, when the dynamo voltage is at a value sufficient to cause the battery to charge, and automatically disconnecting the dynamo from the battery, when the dynamo voltage drops below that necessary for charging.

Voltage—The Bosch system here described, is of the 12 volt type, using Willard 6 cell storage battery.

Dynamo lubrication—Each oil cup should receive two or three drops of oil every 500 miles. Light machine oil and not cylinder oil should be used.

Trouble Finding.

Trouble finding: If the ammeter registers on the discharge side when all the lights are off, particularly when the engine is running; or if a heavy reading is noted on the discharge side when the lights are on and the engine is standing, either a ground or a short circuit is indicated. If with lights off and engine operating at normal speed, the ammeter shows zero and at the same time the proper battery discharge reading is obtained when the engine is stopped and the lights are on, the generator is not working.

If the lights are obtainable with the engine at a standstill proceed as follows: Inspect the main fuse in the control box; see whether battery is badly run down; loose or broken battery connections; loose, broken or disconnected wire between battery and the OB (marked on switch) terminal of the switch that is, either between the negative terminal of the battery and the B terminal of the control box and the OB terminal of the switch, or between the positive terminal of the battery and ground.

If the fuse is blown the trouble should be located by testing the various lamp circuits before a new fuse is put in.

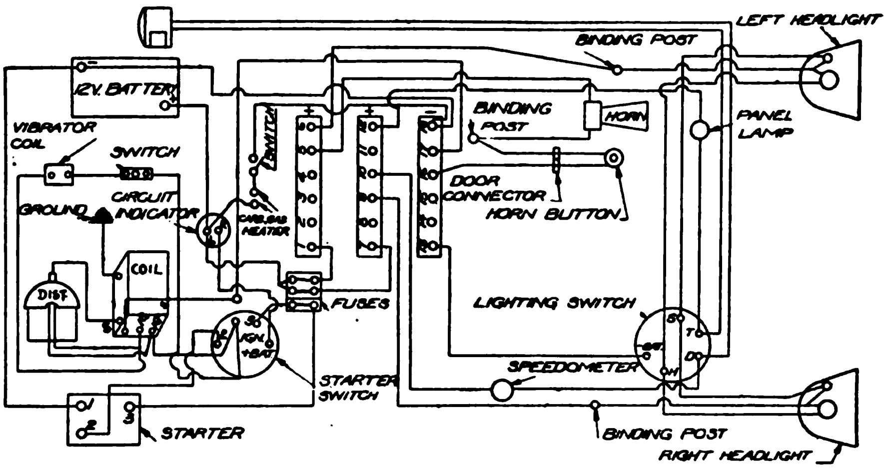
If lights are obtainable only when the engine is running, it is likely that the battery has become disconnected. If this is so, the ammeter will show zero with all lights off instead of reading charge when the engine is running. Also when the lights are switched on with the engine running, the intensity of the lights will vary with the speed of the engine. The engine must not be operated under these conditions, as there is danger of burning out the windings of the generator.

If all lights are dim with the engine off, the trouble may be due to a weak battery; poor connection at the battery, or at some point in the circuit, between the battery and the terminal OB of the lighting switch; a deteriorated main fuse; a partial short circuit as mentioned above.

Battery polarity reversed: If, when making the installation or at any other time, the battery should be incorrectly connected to the system, the cut-out will vibrate rapidly; this must be remedied by interchanging the wires which connect to the battery terminals at the battery.

CHART NO. 176—Marmon "34" (1916-17): Bosch Starting Motor, Generator and Ignition System.

On the 1918-19 Marmon the Bijur starting motor and generator were used together with the Bosch DU-6 magneto in connection with a 6 volt Prest-O-Lite battery. On the 1920 Marmon the Delco starting, lighting and ignition equipment and a 6 volt Willard battery is used.



Wiring Diagram Franklin Series 9-B Touring, Four-Passenger Roadster, Two-Passenger Runabout. NOTE:—This Wiring Diagram to be used after 17200 Cars only.

*Franklin Electric System.

The Dyneto starting and lighting system on the Franklin, is a combined generator and starting motor, in one unit. The complete electrical system therefore, is of the two unit type. (Starter and generator form one unit and Atwater-Kent ignition the other.) The starter is driven by a silent chain.

This system requires neither a voltage regulator or cut-out, automatically changing from a motor to a dynamo as engine speeds up.

The starter switch has three positions: "off", "neutral" and start". When the switch is thrown to **start position,** the starting motor turns engine over until engine begins to fire. Then at an engine speed, corresponding to a car speed of 8 to 9 miles per hour, the starter automatically begins to generate. The generating current on both series 8 and 9 cars is controlled by thrid-brush regulation. This gives a maximum charging current of 12 to 14 amperes at a car speed of approximately 20 miles per hour. At higher speeds the charging rate decreases so that at 40 miles per hour the charging rate is approximately 9 amperes. The **neutral position** of switch should be used when the car is being driven for long periods or when the battery is fully charged. When the switch is set on neutral the charging of the generator is discontinued.

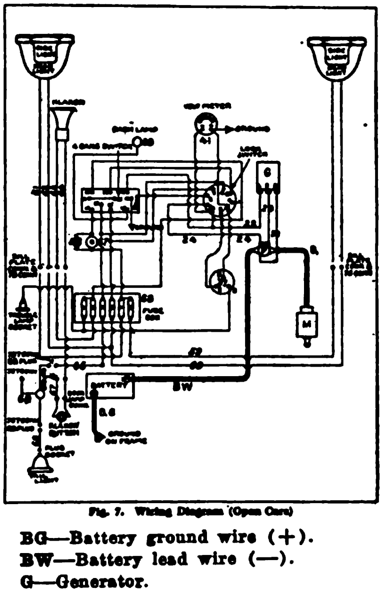


Fig. 7. Wiring Diagram (Open Cars)

BG—Battery ground wire (+).
BW—Battery lead wire (—).
G—Generator.
M—Starting Motor.
P—Primary relay or cut-out switch.
4—Gang switch.
16—Tail-light connection.
19—Ground connection.
37—Ignition switch.
41—Volt meter.
57—Dimmer switch.

Ignition: The Atwater-Kent system of ignition used, is the K-2 type, with automatic spark advance (see chart 117). This system uses very little current and in case of a dead battery, it can be operated on dry cells. The breaker points should be set .010 inch apart.

Wiring: The lighting system is wired independent of the starting system. The head and dimmer lamps are 14-volt and are wired in parallel so that the burning out of one lamp will not affect any other. The tail and dash lamps are 7-volt and are wired in series so that if either one burns out, the other will not burn. The dash light is therefore a tell-tale for the tail light. The horn is a 14-volt one.

Locomobile Electric System.

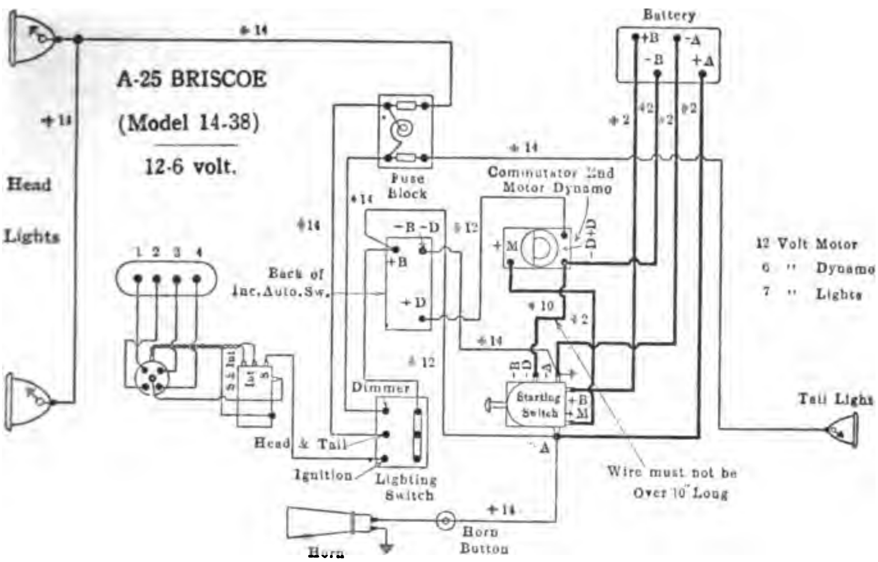
Westinghouse generator and starting system. Three unit type. **Generator** is placed on right side. Regulation: by a differential winding of the field, and is magnetic—no moving parts. **Starter:** on left side of engine and works upon the flywheel ring-gear from below. **Ignition:** separate Eisemann magneto—high tension dual system—similar to the Bosch, as explained in charts 134 to 136. **Firing order:** 1, 5, 3, 6, 2, 4. **Magneto setting:** with spark full advanced, spark occurs while piston is 7/16 inch from top (on the "48") and 5/16 inch from top on the model "38." **Battery and coil setting:** with spark lever retarded, spark will occur, after piston has just started down—this is to make hand-cranking safe.

Battery: 6-volt—used for starting, lighting, and ignition. **Wiring:** Single-wire, grounded return.—Positive terminal of battery (BG.) is grounded. Negative side (BW.) goes to primary relay or cut-out—switch (P). **Lighting:** current is taken through wire (21) from switch (P) to the terminal (B) of the generator (G.) passing through field winding of generator, and out at terminal (L) to lead (22) thence to terminal (1) of lock-switch.

Starting Motor: Wire (23) runs to magnetic coil in switch (P) from here lead (24) goes to terminal (9) on lock switch—out terminal (8) to terminal (20) on "gang dash-switch," then to ground via terminal (19.) When starting button is pressed,—current flows along wires (23 and 24), lock switch (P) closing switch and thus permitting current to flow through (B) to the starting motor magnetic switch. The magnetic pinion shift, is an electro-magnetic affair, which automatically throws the armature shaft with its pinion, in mesh with fly-wheel gear.

CHART NO. 177—Franklin: The Dyneto Starting Motor and Generator and Atwater-Kent Ignition. The Locomobile Model "38" & "48:" Eisemann Magneto Ignition and Westinghouse Starter and Dynamo. (see pages 500 and 497—Loco gear shift and spark control.)

*Wiring diagram is that of series 9. The series 8, manufactured in 1915, 1916, used the Eisemann magneto with automatic advance.



Splitdorf-Apelco.

The Splitdorf-Apelco starting and lighting, system as a single unit, consists of a motor-generator, indicating automatic switch and starting switch, together with a 12-volt storage battery.

Generator: By connecting the motor dynamo across the terminals of the battery, through the starting switch, the motor-dynamo acts as a motor, spinning the engine until it picks up on its own power. The motor-dynamo is then driven by the engine as a generator, furnishing current for charging the battery.

Acting as a motor, the unit has sufficient power to spin the engine at a good rate of speed. As a generator, it has capacity to keep the battery fully charged insuring ample current for starting, lights, ignition, horn, etc.

The armature of the machine has but one set of windings, one commutator and one set of brushes. No gears or clutches are employed in the construction of the motor-dynamo, the armature being the only revolving part. Sprockets and silent chain are used for driving the starting and lighting unit, no additional reduction being necessary than that secured through the sprockets.

The current output of the dynamo is controlled by means of the special field windings. This **inherent regulation** feature makes it impossible to charge the battery at too high a rate, and at the same time makes the use of any regulators unnecessary.

The indicating automatic switch, is mounted in the circuit between dynamo and battery. Its function is to make connection between these two units when the voltage of the dynamo exceeds that of the battery—as well as break connection when the battery voltage exceeds that of the dynamo. In other words, the switch automatically closes when the dynamo is being driven at sufficient speed to charge the battery allowing current to flow from the dynamo into the storage battery. When the dynamo is not running at sufficient speed to charge the battery, however, or is stopped, the switch automatically opens, preventing a discharge of current from the battery back through the dynamo.

The Indicating Automatic Switch is equipped with an Indicating Dial which is mounted on the dash and shows at a glance whether or not the battery is being charged. When current is flowing into the battery the words "Charge On" show on the dial and when the battery is not being charged the words "Charge Off" appear.

The Starting Switch is one built especially for use with this system. Its design is such as to make arcing of the contact impossible.

A 12-6 volt Storage Battery is used in connection with the Splitdorf-Apelco starting and lighting system for motor cars. The battery is divided into two individual 6-volt units which are enclosed in one case.

At the time of starting, when the starting switch is pressed down, the two 6-volt units of the battery are then connected in series through the switch, furnishing 12-volt current to the motor-dynamo. This, however, does not affect the voltage to the lamps, as 6-volt current is supplied for lighting and ignition at all times. As soon as the starting switch is released, however, the two battery units are connected in parallel and charged as a 6-volt-battery.

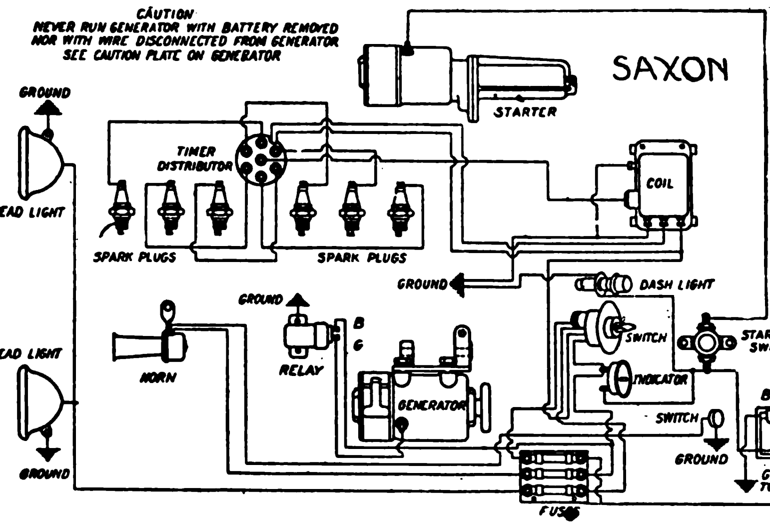
The use of 12 volts for starting, insures sufficient power to spin the engine under normal conditions, as well as cuts down the current drawn from the battery. At the same time, 6 volts for charging makes it posible for the generator to begin charging at very low car speeds, as well as makes the use of 7-volt bulbs possible for the various lamps on the car.

General circuit: The current flows from + D on generator to + D on indicating switch, through the winding in the coil, coming out at + B, then to + A on starting switch, where it divides, one side leading to + A on battery through battery to —A on starting switch. The other half of the current flows through jumper in the switch to + B on starting switch, through to + B in battery through battery to —D on generator thence to —B—D on starting switch —B-D are the common return points of the current on starting switch, from there to —D on generator.

Starting switch: When the switch is depressed the current flows from the battery at + A to + A on starting switch, through switch to + M on switch, then to + M on motor dynamo, through motor-dynamo to —B—D on starting switch, then to —B on battery, through battery to + B on battery then to + B in starting switch, through switch to —A on switch to —A on battery, through battery, to + A completing the circuit.

If battery is removed: connect a wire across posts —D and + D of motor-generator.

CHART NO. 178—Splitdorf-Apelco Electric System as an Example of a 12 volt Motor-Generator—as formerly used on Briscoe. The Ignition is Connecticut.



Saxon Six. Wagner starting motor with Bendix drive. Wagner dynamo, chain driven. Remy-battery and coil ignition. Wiring, 6-volt single wire, three unit system.

To set timer on Saxon, crank engine until piston No. 1 has passed its uppermost position, on compression stroke one inch on the fly wheel. This position can be determined by dead center mark (DC) on fly wheel. Move to position one inch past the fly wheel pointer. No. 1 post on timer cap must now be in position to make contact with wiper. Rotate body of timer until contact breaker opens. Now connect timer to spark control lever. Set above with spark lever full retard. Firing order is 1, 5, 3, 6, 2, 4. Breaker point gaps are set .015 and spark plug gap, .025". Above is the 1916-17 model car.

Chevrolet "490" Electric System.

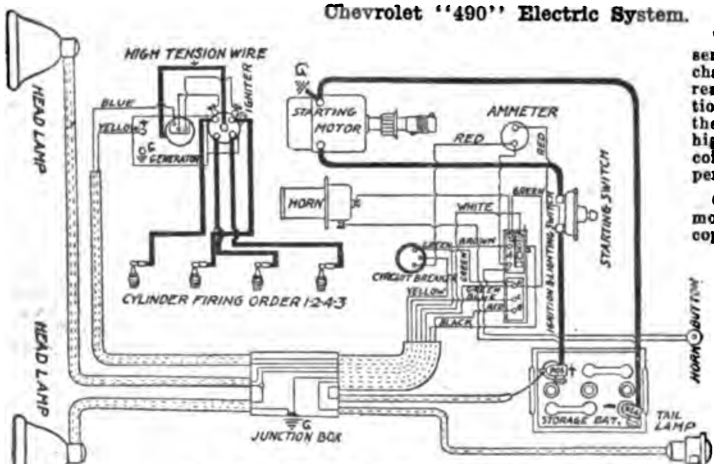


Fig. 2—Wiring diagram of Chevrolet "490."

The generator is a "reversed series wound" dynamo. Begins charging at 7 miles per hour, and reaches maximum current production at 20 miles, at which speed the amperage is about 14. At higher speeds the reversed series coil holds the output at this amperage.

Cutout or circuit-breaker—if removed, connect a short piece of copper-wire between terminal posts on generator, see chart 175AA for type cut-out used.

Ignition is the Connecticut, as explained on page 254.

To time the ignition: Rotate the fly wheel until the No. 1 intake valve begins to open. Piston No. 1 is then at "top center."

After removing the spark plug and inserting a screw driver or rod as illustrated on page 636 continue to rotate the fly wheel until the piston again reaches top of its compression stroke.

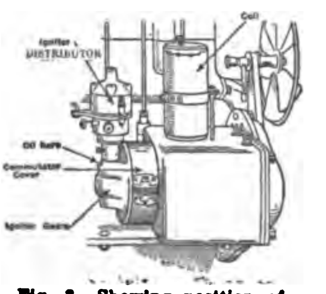

Fig. 3—Showing position of generator and ignition system. Also see pages 254 and 636.

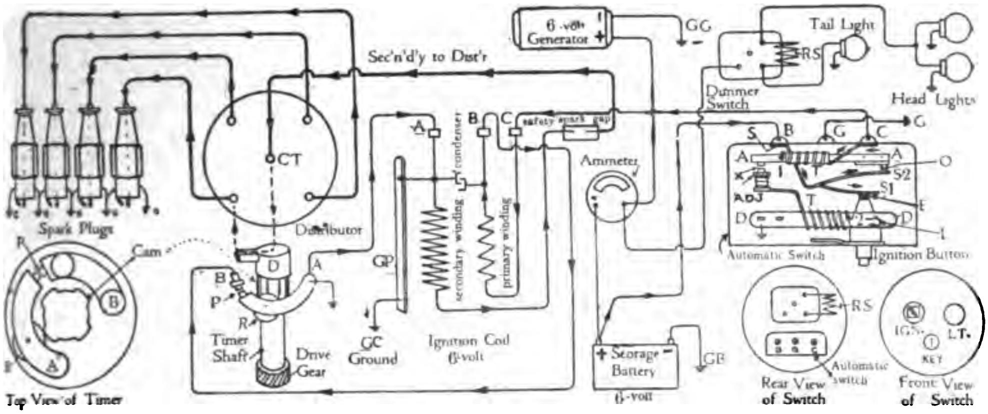
Fig. 4.

Turn switch on and as in starting, slip the igniter on the shaft and connect the wires to their proper plugs, then remove the No. 1 wire from the terminal socket on the distributor case and hold it about one-quarter inch away from the brass ring of the socket, as in fig. 4.

Rotate the entire igniter assembly on the shaft in a clockwise direction, until a spark jumps from the end of the spark plug wire to the brass ring of the terminal. The igniter set screws should then be tightened, and the No. 1 wire inserted in its socket. Setting is made with spark lever retarded. Firing order, 1, 2, 4, 3.

On "490" Chevrolet no adjustment of brushes on generator is provided. If generator fails to give its full output—see page 409. Later "Auto-Lite" generators have third brush regulation.

CHART NO. 179—Saxon "6:" Wagner Starter and Dynamo and Remy Ignition. Chevrolet "490:" Auto-Lite Starter with Bendix Drive and Auto-Lite Generator and Connecticut Ignition.



Dort Electric System Explaining The *Connecticut Thermostat Ignition Switch.

The Connecticut ignition system using the Connecticut automatic thermostat switch, which is similar to the one shown in fig. 10, page 359, is clearly shown in this illustration.

The purpose and action of this automatic switch is explained on pages 359 and 358. Also note that there are two types of Connecticut automatic thermostat switches; the type using magnets and one thermal blade, per pages 254 and 358, and the type where magnets are dispensed with and two thermal blades A and D are used, as per fig. 10, page 359 and this page.

Primary ignition circuit can be traced by starting at + of battery to thermostat connection B, through spring S, to connection C, (when ignition button is "in"), thence to primary winding of coil C, through coil out coil terminal B to stationary contact B on model 16 timer, through points P to movable contact A (which is grounded), to grounded terminal of coil primary winding at A, through ground plate (GP) to ground (—) of battery.

Secondary ignition circuit is from secondary winding through safety gap, to center terminal (CT) of distributor, to distributor arm (D) which passes the secondary current as it revolves, to spark plugs, thence through center terminals of spark plugs across spark plug gaps to shell of spark plug to engine frame thence back to ground plate (GP) on coil to grounded terminal of secondary winding.

Generator is the Westinghouse, using a third-brush regulation with a cut-out switch (reverse current type) contained in generator. Note one terminal of generator is grounded, likewise the (—) terminal of battery. **When starting,** ignition current is taken from battery. **After starting,** and generator gains sufficient speed (8 or 9 miles per hour car speed), then the generator supplies current for ignition and charges battery. The generator produces 12 to 15 amperes at 18 miles per hour. At higher speeds the charging rate decreases slightly.

The starting motor (not shown) is located on the left side of the engine, at the rear. It is fitted with a Bendix drive which automatically engages and disengages the flywheel gear as explained on page 331. One terminal of starting motor is grounded, other terminal connects with starter switch, from starter switch to battery (+), through battery to ground.

The lighting and ignition switch is combined with the Connecticut automatic thermostat ignition switch, a front and rear view is shown above. It has two buttons.

When button to left is pushed in, the ignition is "on". When it is **pulled out** the ignition is "off".

When button to the right is pushed all the way in, the head-lights will burn "dim", as the dimmer resistance (RS) is in series with the circuit. When **pulled all the way** out the head-lights will burn "bright" as the resistance (RS) is then cut out of the circuit. When **placed in the center,** the lights are "out".

Fuse for lights is under hood on right side and a fuse for the horn is on the left side. If **all** lights fail to burn or horn **fails** to operate see if the **fuse** is blown. The fuses are 7 volt, 10 ampere enclosed No. 1 type, di. ¼"x⅝" glass tube.

Timing ignition. Open priming cocks. Turn starting crank until 1 and 4DC (cylinders No. 1 and 4 are on dead center of compression stroke) appears on flywheel and is in line with center mark on crank case, then turn flywheel 1 inch past this dead center line.

Retard spark lever and loosen set screw on distributor shaft.

Push in the ignition switch button. Disconnect the spark plug wire on cylinder No. 1, and place it so that the terminal may be about 1/16" from the metallic part of the spark plug.

Turn the distributor shaft very slowly, in a clockwise direction till a spark is seen between the spark plug and the wire terminal, and stop.

Screw securely the set screw on the distributor shaft, put the handles of the priming cups in a vertical position and the spark is correctly timed.

Firing order is 1, 3, 4, 2 and wires to spark plugs should be so attached to distributor in this order. No. 1 cylinder is the one next to fan. Spark plug is ⅞-18 thread and gap should be .025". **Timer gap,** see page 254.

CHART NO. 180—Dort Electric System Explaining the Connecticut Automatic Ignition Switch—See also, pages 359, 358, 254.

*The Connecticut ignition system consists of model 16 timer, type GA coil and K. V. B. switch.

Maxwell 25 Electric Systems.

1915-16-17 cars used Simms-Huff motor-generator combined in one unit. As a starting motor it operated at 12 volts from the 12 volt battery (per fig. 20, page 367). As a generator, it delivered current at 6 volts to battery in two halves, or in parallel, (fig. 21, page 367). A Simms magneto was used for ignition.

1918 Car used the same system, except the Atwater Kent 6 volt ignition was used instead of a magneto. In Aug. 1918 the system was changed to a straight 12 volt battery and 12 volt ignition.

1919 Cars used the same system (changed in Aug. 1918).

1920 Cars use an Auto-Lite 6 volt generator, third-brush regulation. 6 volt Atwater Kent ignition and a separate starting motor with a Bendix drive and 6 volt battery.

1919 Maxwell (Aug. 1918).

Starting Motor (see fig. 1, page 367) current from (+) or 13 connection on 12 volt battery, through starting switch to terminal 11 on starter-generator, through brush support to starter brushes 2, 4 and 6, through commutator bars, through armature windings to brushes 1, 3 and 5, through series (heavy) windings on field poles 1, 3 and 5, to starter yoke and ground through starter-generator frame and engine back to (—) or 15 terminal of battery.

The shunt field windings assists the series field windings when used as a motor, thus the starter motor is known as a "cummulative compound" machine. See term explained on page 847. Path of shunt circuit would be from (+) or No. 2 terminal on starter to post No. 2 (DYN) on back of fuse block, to regulator and cut-out bus bar, through regulator arm, across regulator points (which at this time makes contact), through wire to terminal post No. 3 (FIELD) on fuse block, through circuit No. 3 to field terminal 3 on starter frame, through the 6 shunt field windings to ground on pole pieces No. 3, thence to ground 15 on storage battery.

Generator uses the same armature and fields. It is driven by the fan belt. The belt being adjusted so that it is taut enough to drive generator and charge battery, at the same time loose enough to allow it to slip on the generator drive pulley when used as a starting motor.

When releasing starting switch after starting engine, and engine runs under its own power, the motor action is converted into a generator which, when up to speed will close cut-out points and generates 14 volts to charge battery, and supply current for lights and ignition.

When used as a generator the series and shunt field windings oppose each other instead of assisting, thus it is known as a "differential compound" machine; the term being explained on page 845. The opposition of the series field to the shunt field together with the effects of the regulator prevents current becoming excessive at high speeds.

Generator, Cut-Out and Regulator Action

is explained on page 367. When studying the diagram, first trace the generator circuit and note that there are two circuits from the generator; the "main charging circuit" from 2 to battery, and the "shunt circuit" from 2 to 3 generator terminals, which control the strength of the field poles.

Don't confuse the action of the cut-out with that of the regulator. A similar device is shown on page 842, 834. If engine slows down to less than 11 miles per hour car speed, then cut-out points will open as the shunt coil on cut-out will not have sufficient energy to hold cut-out armature (2).

Dash panel is a very important part of this electric system and is placed on the instrument board. It consists of "lighting" and "ignition" switch, "fuses," "cut-out," "regulator" and "current indicator"

The dash panel is grounded to the instrument board cover because cut-out and regulator windings are grounded and a good ground should be made at all times.

An indicator instead of an ampere meter is used on the Maxwell 1915-1919 model cars and shows "Charge" when cut-out points are closed and "off" when open. See page 410 for principle of an indicator.

To Test Generator, Regulator and Cut-Out. All Models.

Generator: Remove all wires from generator. Connect large positive terminal on end of generator to small field terminal on side of generator with short piece of insulated wire. Speed engine up and connect between metal part of car and large terminal on end of generator. If an arc occurs, generator is O. K.

Caution—Make sure that fan belt is not slipping by grasping generator shaft with one hand while motor is speeded up.

To test cut-out 1916-17-18 models: Ground terminal marked "Dyn." "Bat."—on fuse block. If ammeter shows charge, trouble is usually caused by shunt contact on starting switch (not illustrated) not making connections to ground. On 1918 models which do not have this terminal, connection must be made between frame of dash panel and any metal of the car. Cut-out winding is grounded to panel on dash, be sure it is well grounded.

To Test Regulator—All Models: Connect between Dyn. + and field terminal on fuse block with pliers. If ammeter shows high rate of charge, trouble will be found in regulator, usually caused by points being dirty or spring tension too weak, although loose soldered connections on back of panel may cause same trouble.

All these tests should be made on an engine running at a speed not less than twenty-five miles per hour.

Adjusting Cut-Out and Increasing Output.

The cut-out on the 1915-16-17 model cars can be adjusted to "cut-in" at 11 to 13 m. p. h. by bending adjusting hook (1) on cut-out armature (2) back so as to decrease the tension of spring (3).

If cut-out points stick it will be indicated by indicator showing "charge" and generator continuing to run after engine is stopped.

The charging rate can be increased to between 13 and 15 amperes (if brushes are in good order), by bending downward the hook (4). **This requires careful and painstaking effort.**

Ignition.

Atwater Kent closed-circuit system is the system used and is fully explained on pages 249. The ignition circuit is closed by inserting and turning switch key in the lighting and ignition switch, which connects terminals 5 and 1 on back of switch.

Current for ignition is taken from terminal marked (BAT) 6 on switch, thus current is supplied from battery when starting, or generator when running over 11 m. p. h. See page 367 for primary and secondary circuit.

Ignition Timing.

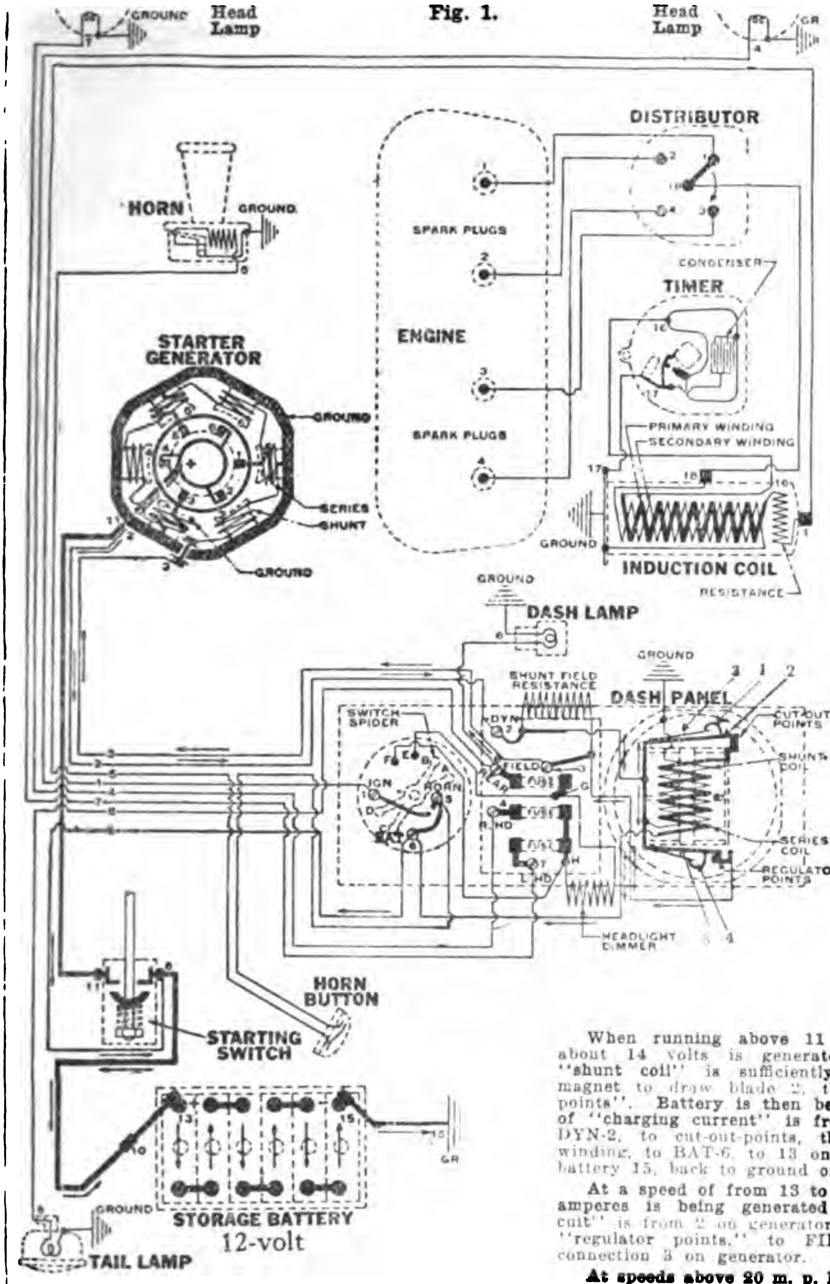
Timing ignition when ignition driving mechanism has been removed. A punch mark and slot in timer drive shaft coupling should be assembled in line. Timer drive gear and cam shaft gear should have the double punch marks together. No. 1 piston should be in firing or compression stroke position and slot in timer drive shaft should be up.

If timer coupling shaft has not been loosened. Turn crank until No. 1 piston is $\frac{1}{16}$" past top d. c., or 1¼" past on flywheel, on compression stroke. Turn timer shaft coupling until distributor arm is on No. 1 segment. Turn timer coupling shaft to left or right until coupling pin is in position to engage drive shaft coupling notch. Couple to engine, bolt to bracket and connect cables to plugs to fire 1, 3, 4, 2.

If timer coupling shaft has been removed. Place No. 1 piston and distributor arm in position as explained above. Retard timer. Turn timer coupling shaft by knurled collar until timer points just separate. Hold coupling shaft in this position, turn coupling on its shaft until coupling pin is opposite the notch in drive shaft of coupling, then tighten and couple timer to engine and connect terminals to plugs.

Timer point adjustment .006". **Spark plug gap .027" to .030," or slightly less than $\frac{1}{32}$".**

Fig. 1.



1919 Maxwell Ignition.

Primary coil circuit takes current (12 volts) from ignition switch at IGN-1. When switch key is turned, connection is made through terminal 5 from BAT-6. Current is taken from battery below 11 m. p. h. car speed and from generator above this speed.

Current path is from IGN-1, to 1 on coil, through resistance to 16, through timer-points to 17, to 17 ground on coil.

Secondary circuit: From 18 to distributor arm 18, to spark plugs, to engine frame, to ground 17. See also, page 249.

1919 Generator Circuit

(See arrow points)

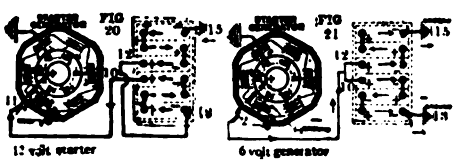
When engine is started, generator current begins to flow from 2 on generator to DYN-2 on fuse-block, through "shunt coil" winding of cut-out to ground (above it), back to ground on generator. Out-out-points are supposed to be open, therefore ignition is from battery.

When running above 11 m. p. h. car speed, about 14 volts is generated, therefore cut-out "shunt coil" is sufficiently energized to cause magnet to draw blade 2, thus closing "cut-out-points". Battery is then being charged and path of "charging current" is from 2 on generator to DYN-2, to cut-out-points, through "series coil" winding, to BAT-6, to 13 on battery to ground of battery 15, back to ground of generator.

At a speed of from 13 to 20 m. p. h., 13 to 15 amperes is being generated and "shunt-field-circuit" is from 2 on generator, to DYN-2, to closed "regulator points," to FIELD-3, to shunt-field connection 3 on generator.

At speeds above 20 m. p. h.; in order to prevent generator output increasing, the increased current flow through regulator "series coil," causes magnet (lower end), to draw regulator blade 5 to it, thus opening "regulator points". The path must then be through the "shunt-field resistance", which cuts down magnetism of field poles, thus decreasing output. This action is repeated over and over as speed of car increases and decreases.

The cut-out-points through which the main charging current flows, remains closed and cut-out only opens when speed drops below 11 m. p. h., therefore, battery is being charged during the time the regulator-points are closed or open. See also, page 342 for a similar principle.



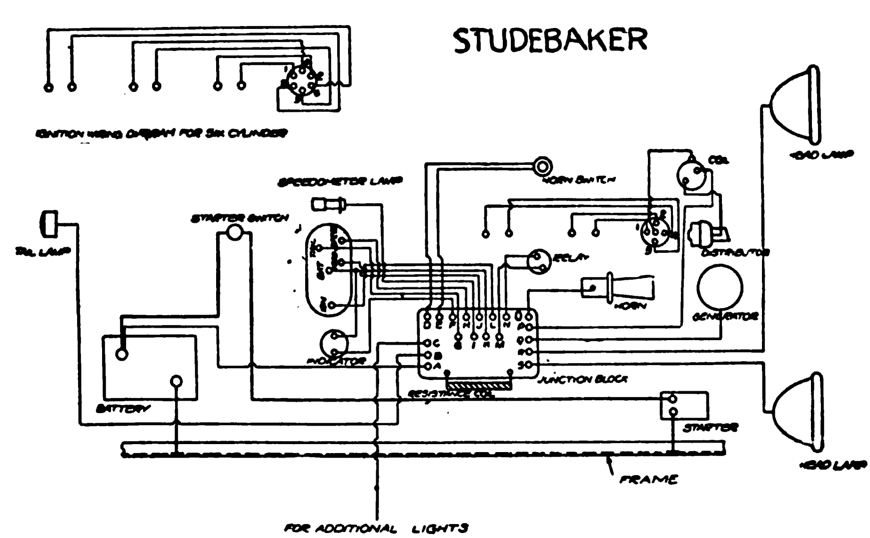
1915-16-17.

Fig. 20: Two halves connected in series by starting switch (not shown). + 12 cell connects with — 13; + 10 with + 11 on motor, to motor ground, to battery ground — 15.

Fig. 21: The parallel connection is made in starter switch when released after starting. Path from + 2 on generator, to + 12 and 10; out grounds — 15 and 13, to — ground on generator.

1915-16-17 Battery Connections.

1915, 16, 17 motor operated at 12 volts. As a generator it delivered 6-volts to same battery. Imagine two three-cell 6-volt batteries, end to end, and note how connected in figs. 20, 21.



Studebaker Electric System.

The starting motor is connected to engine by gears integral with the starting motor (see fig. 1, chart 164). A roller chain transmits the power to a sprocket on the crank shaft. The latter sprocket operates through an "over-running clutch" on the crank shaft.

***The generator** is mounted in a vertical position on the right side of engine (G, page 204), and is operated by a spiral gear from timing gears. It begins to deliver current to the battery at a car speed of about 10 miles per hour and reaches a maximum rate of flow at about 18 miles per hour.

Generater is oiled at bearings every 2000 miles with light machine oil. (See page 204 for lubrication of entire car.)

Cut-out—also called a relay, is of the usual type, and is attached to the dash.

The relay will require no attention unless the battery indicator shows **discharging** when no current is being used for lights, horn, or ignition. If this should happen, remove the relay cover and examine the contact points to see if they are stuck together. If they are, they should be separated and dressed if rough.

The method of wiring used throughout, is the grounded return, or so-called one-wire system. In this system there is but one insulated wire circuit from the battery to each electrical unit. **If any of the wires should be removed in making repairs**, make connections as shown under car wiring diagram above. When repairing wiring or electrical parts, first disconnect wires from battery to prevent possibility of short circuit.

If it is desired to operate the car without a storage battery a set of four dry cells may be installed in the place of the battery, connecting them to the terminal of the large cable riveted to the frame, and to the terminal of the smaller of the two cables disconnected from the negative storage battery terminal. Any use of the lights or horn under these conditions will serve to discharge the dry cells rapidly. If the storage battery is removed it is vitally necessary, to take the following precaution.

If for any reason the engine is to be operated with the generator disconnected from the storage battery, be sure to connect the terminal of the generator to some point on the metal frame of the generator or engine, using a piece of copper wire. This precaution is for the protection of the generator and is essential. This "ground" wire should be removed when the generator is again connected to the storage battery.

Lamps: For headlamps use 7-volt 12-candle-power bulbs, and for tail and speedometer lamps use 7-volt 2-candle-power bulbs.

Ignition: is the Remy—see page 251. **The ignition unit**, is mounted to the front of the engine, and driven by gears at half crank shaft speed. Coil is mounted to the side of the distributor.

Adjustments: contact points should be .015 of an inch. Spark plugs .025 inch gap.

Timing the spark: Open the pet-cock on top of the cylinders and turn the engine over by hand until the piston in No. 1 cylinder has begun its compression stroke. The beginning of the compression stroke may be detected by holding the thumb over the open pet-cock until compression is felt. The exact upper dead center position is indicated by the mark "UP-D-C-1" on the flywheel coming under the pointer at the top of flywheel. Turn over the engine until this mark has 4 inches to travel (for the four) or 5⅛ inches to travel (for the six) before reaching the pointer. The engine is now in the proper position for the fully advanced spark in No. 1 cylinder.

Turn the spark lever on the steering wheel to its extreme advanced position. The timer control lever should then be in its extreme forward position.

Remove the distributor cover without disconnecting the wires, lift off the distributing segment holder, and loosen the nut which holds the cam on the tapered shaft.

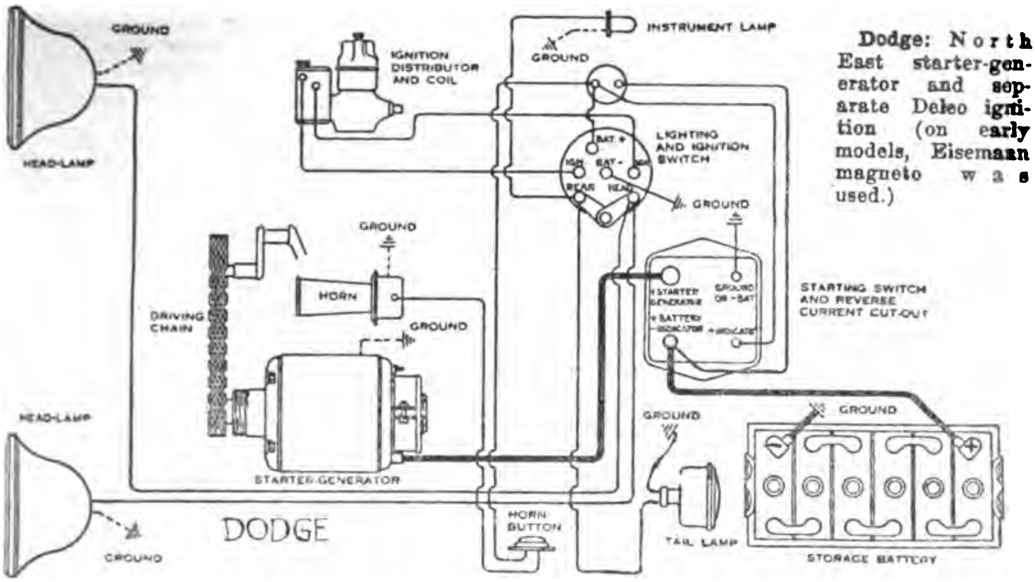
Pry the cam from its seat on the shaft, using the special tool which will be found in the regular tool kit.

Turn the cam in a anti-clockwise direction until it reaches a position such that when all parts are replaced the edge of the distributing segment will come directly under No. 1 distributor terminal. Then continue turning until the breaker points are just in the act of separating.

Tighten the lock nut to hold the cam in this position and replace the distributing segment holder and cover.

*See chart 116 and 164 for the 1915-16 Studebaker electric drive principle.

HART NO. 180C—Studebaker Electric System: Wagner Starter and Generator—Remy Ignition.
bove is 1916-17 Studebaker. 1918 system similar.



Dodge: North East starter-generator and separate Delco ignition (on early models, Eisemann magneto was used.)

***Dodge Electric System.**

Starter—Generator: position, front left hand side of engine. 12 volts.

One armature and two sets of field windings. Operating both as a starter and as a generator. Driven by means of a silent chain. Ratio of 3 to 1. (Also see chart 181A.)

‡Ignition: Delco, distributor on right side of engine, driven by water pump shaft. Distributor of course is driven at ½ crank shaft speed. The system is similar to other Delco ignition systems. **Firing order** is 1, 3, 4, 2. **Spark plug** gaps are separated 1/32 inch, or about thickness of a smooth dime. **Wiring**—grounded or single wire system.

To time the ignition: Open all the priming cups. and crank the engine until the compression stroke begins in cylinder No. 1.

This can be ascertained by holding the thumb tightly over the priming cup of this cylinder and observing that both the valves remain closed at the top of the stroke.

Slowly continue to turn over the crank until piston No. 1 has passed the top of this stroke about 5°, which is ⅝ inch past dead center measured on the flywheel. This position can be determined without removing the cylinder head, by turning the starting crank handle until the exhaust valve in cylinder No. 4 just closes.

Remove the distributor head and distributor rotor. and loosen the breaker cam adjusting screw on the top of the vertical shaft.

Then set the breaker cam in such a position that the rotor button will come under the position of No. 1 cylinder high tension terminal in the distributor head when it is replaced on the breaker cam, and so that the timing contacts are just starting to open with the spark lever in the fully retarded position.

Set the breaker cam carefully so that when the slack in the distributor gears is rocked forward, the timing contacts will open, and when the slack is rocked backward, these contacts will just close.

With the vertical shaft in the proper position in reference to the engine, and the breaker cam and distributor rotor both set as instructed, the timing adjusting screw should be screwed down tightly. Then replace the rotor and distributor head. See that the rotor button spring allows the button to be fully depressed, and that the distributor head is located properly by the locating tongue which snaps onto it.

Chain Adjustment of Starter-Generator.

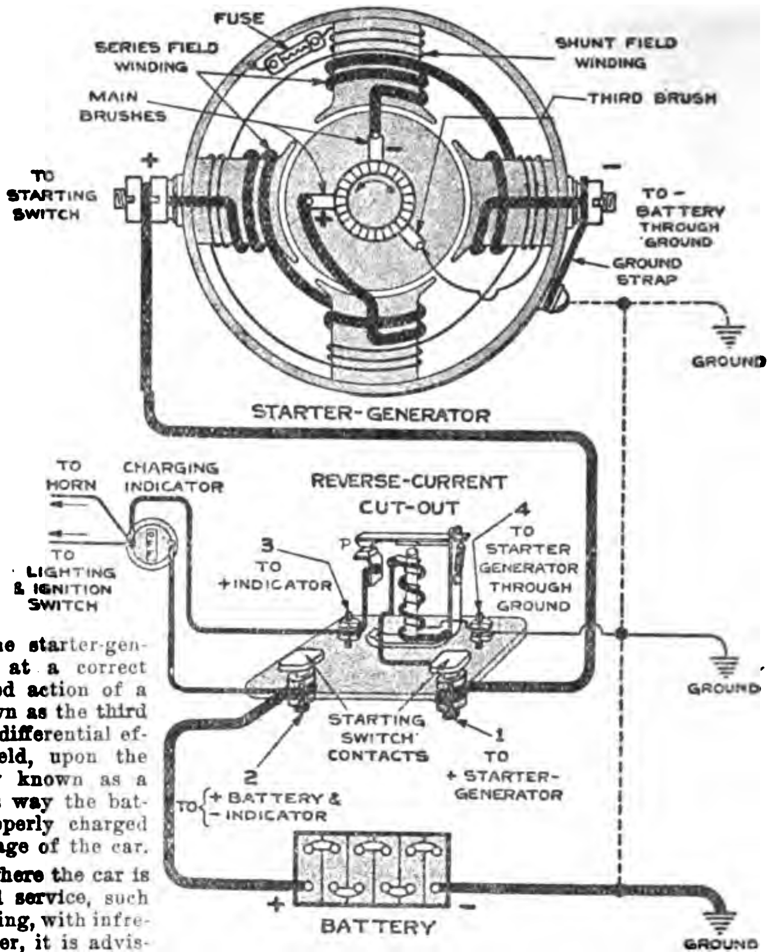
To obtain the proper adjustment for quiet running of the chain, proceed as follows: (see also pages 411 and 733.)

Loosen the set screw and lock nut on the edge of the front flange of the cylinder block. and back off the starter binding nut, just enough to remove the pressure from the adjusting ring. Loosen the "V" blocks and strap to allow the starter-generator to move. This will allow the eccentric adjusting ring. to be turned until the required play in the chain is obtained. There should be about one-half inch up and down movement in the chain. After the proper adjustment has been made, be sure that the set screw, lock nut, and binding nut are screwed up tightly. See that the chain tension has not been disturbed while performing this last operation.

Carefully adjust "V" blocks up snug between engine and starter-generator, and then tighten holding strap. After the inspection cover has been replaced the chain should run without perceptible noise. It is lubricated by dipping into the oil in the bottom of the front gear compartment; thus needing no further attention after it has been properly adjusted. —continued in chart 181A.

CHART NO. 181—Dodge Electric System.

*See also pages 733, 923, 924. †See page 878 for adjusting Delco closed-circuit timer. On some of the 1919 and 1920 models there is one wire running to coil and ground on timer. Ignition, as well as entire system is 12 volt. ‡See page 924, fig. 7, for the Northeast model O ignition system used on the Dodge since March 1918. See page 923 for explanation.



Generating: As soon as the car attains a speed of approximately 10 miles per hour the automatic cut-out located in the starting-switch housing automatically closes the circuit between the starter-generator and the battery, thus allowing a charging current to be conducted from the starter-generator to the battery. Whenever the car speed falls below 9 to 10 miles per hour the cut-out automatically opens the generating circuit and prevents the battery from discharging through the starter-generator, except, of course, when the starting switch is operated.

The output from the starter-generator is maintained at a correct value by the combined action of a **regulating** device known as the **third brush system,** and the **differential** effect of the series field, upon the shunt field, commonly known as a bucking field. In this way the battery is kept in a properly charged state under normal usage of the car.

In cases, however, where the car is subjected to abnormal service, such as continuous day driving, with infrequent use of the starter, it is advisable ocasionally to allow the lights to burn dimmed over night. This will compensate for the abnormal charge given the battery. The same results may be obtained by allowing the starter-generator to run the engine with the ignition turned off for a period of five to fifteen minutes.

Under extreme conditions it may be necessary to have the charging rate of the starter-generator changed slightly, so as either to decrease or increase the charge given the battery, to meet the special requirements of the case. This alteration of the charging rate can be quickly made by **adjusting the third brush,** as explained on page 733.

The current indicator is located on the left hand side of the instrument board, and is inserted in the charging circuit, between the automatic cut-out and the positive battery connection of the starting switch. To the positive terminal on the current indicator are connected the wires which conduct the current for the ignition and lighting switch and for the horn.

This indicator registers "charge" when the starter-generator is charging the battery, and "Discharge" when the battery is supplying current for the ignition or lighting systems. Whenever the starter-generator is supplying normal current to the battery however, the indicator will show "charge" even if al the lamps are burning. "Discharge" will appear on the indicator whenever the lights are being used while the car is standing, or running on direct drive at a speed of less than 10 to 12 miles per hour.

If at any time the current indicator fails to register properly, inspect its terminal posts to see that the wires leading thereto are tightly attached. Also, make sure that there are no short circuits in the wiring system.

The showing of "Discharge" instead of "charge" when the latter should be indicated, is an almost certain sign that a short circuit has developed in the wiring system unless, of course, the wires attached to the current indicator, have been connected to its terminals in such a way as to reverse the direction of flow of the current through the indicator.

If no short circuit in the car wiring is to be found remove the current indicator, and inspect it for internal difficulties. Be sure to replace properly all connections before again running the engine.

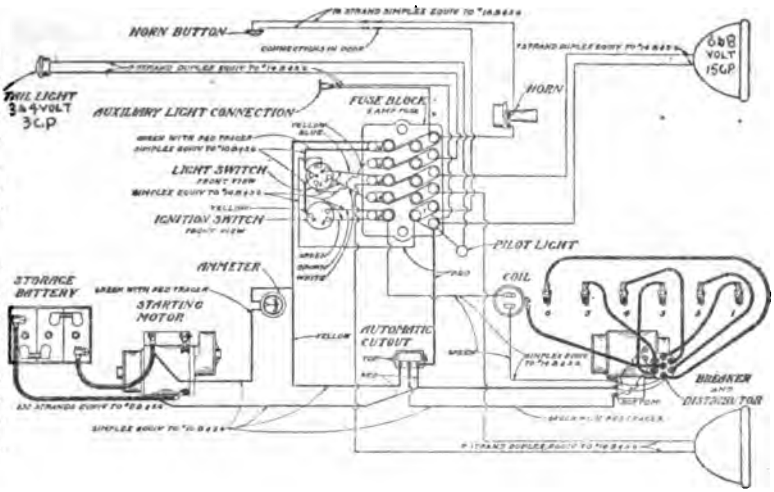
Lighting system: single grounded return system is used, see chart 197 for size lamps used. Lighting switch has three positions; "off," "dim" and "on." For disconnecting battery or generator—see index "disconnecting battery" and "disconnecting generator."

CHART NO. 181A—North East Electric System on the Dodge—continued.

Reo Electric System.

The Remy electric starter, generator, and ignition system is used on both the four, and six, cylinder Reo. The construction is similar on both cars. (see this chart and chart 181C.)

The starting motor has a gear reduction built integral with starting-motor. The power is transmitted to transmission main shaft by means of a roller chain and sprocket. (see fig. 8, page 336.)



When the starting button is depressed, a lever tightens the friction cable, which passes around a sheave mounted beside the starting motor chain sprocket on the transmission. This cable holds the sheave until a slot in it engages a trip pin connected to a pawl on this sprocket. When this trip pin makes contact with the side of the slot it twists the pawl and brings it into mesh with the teeth of a ratchet on the universal shaft. The universal shaft and the sprocket then turn as a unit until the starting button is released, freeing the sheave and permitting a spring to disengage the pawl from the ratchet.

Generator, is a low speed 6 volt, machine, with the Remy ignition unit, as explained in chart 118, and page 251, also in chart 169. The thermostatic control is mounted on the generator.

The automatic cut-out is located on the dash beneath the hood. and is for the purpose of preventing current from the storage battery. flowing back through the generator when it is standing still, or running at a speed lower than 300 R. P. M. or about five miles per hour in high gear. The cut-out requires no adjustment other than to keep the points clean and smooth with contact the full width. Do not under any condition alter the spring tension. Do not close the cut-out points when the engine is not running as they will stick together and allow the battery to be discharged in a few hours time as well as ruining the cut-out coil.

Regulation of output.—This generator is equipped with "third brush regulation" and means are provided for varying the maximum output. A small screw which is located in the rear end of the generator is connected to the third brush by a rack and pinion movement, which allows the position of the brush on the commutator to be changed slightly. Turning this screw in a clockwise direction increases the output for a given speed while turning it in the opposite direction decreases it.

Thermostatic control.—In order to provide against a shortage of current in winter weather or on short runs where starts are numerous and at the same time to insure against overheating the generator in the summer or on long runs a thermostat is arranged to cut down the charging rate as soon as the temperature of the generator reaches a certain point. This thermostat can be seen by removing the cover from the rear of the generator. and since it requires no adjustment should not be tampered with, (see chart 169.)

Amount of charge.—The generator is in normal working condition if the ammeter shows a charge of about 18 amperes, when running 15 miles per hour on first starting and reduces this charge to about 10 amperes on becoming warmed up.

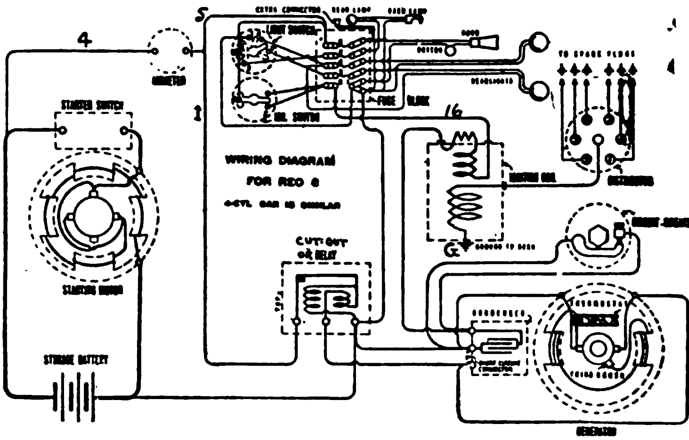
Condenser.—The condenser is contained in the metal box mounted on the side of the generator. This places it within a few inches of the breaker points which is very desirable. The condenser terminals are the two upper ones on the end of the box. The two lower terminals are connected to the armature, and the clip marked "Short Circuit Connector" is for the purpose of connecting these terminals. if it is desired, at any time, to run the engine without generating current.

Brushes.—The brushes are of special copper carbon composition and should last indefinitely. If replacement should be necessary from any cause, do not use carbon substitutes, but obtain the special brushes furnished by the Remy factory, branch house or service stations. Brushes should be kept tight on the holders and in perfect contact with the commutator.

—continued in charts 181C and 181D.

CHART NO. 181B—Reo 1917 Electric System—The Remy.

—Reo continued.



The ammeter is for the purpose of indicating the amount of current passing into and out of the storage battery. The indicator or hand should point to zero at the center of the scale when the engine is standing still and all lighting or ignition switches are in the "off" position. If it does not, it is almost conclusive proof that there is a leakage of current tending to run down the battery, but in order to make certain that the ammeter is not at fault, disconnect one of the battery terminals at the battery. This prevents any current from flowing and the ammeter will, if it is all right, indicate zero or very closely to it.

If the ammeter indicator is off from this zero position, then the difficulty is in the ammeter and it may be corrected by removing the ammeter from the case and resetting by bending the hand. There is very little chance of this type of ammeter reading incorrectly as ordinary short circuits have little or no detrimental effect, since only a small part of the current is shunted through the coil attached to the indicator and this current does not affect the permanent magnet. However, an unsually heavy short circuit will burn the coil or balancing springs.

Leakage.—If the ammeter shows zero reading with the battery disconnected and shows a discharge reading with battery connected, engine standing still and all switches in the off position, then there is a leakage of current.

This leak should be found and stopped at once or the storage battery will become discharged and if allowed to remain in this condition for any length of time, cause injury to the battery.

These leaks are most likely to be found in the lighting wires, sockets, and connections and in the ignition wires. Leaks in that section of wires between ammeter and battery are not registered on the ammeter, which should be borne in mind when looking for battery trouble.

The ammeter does not show the amount of current used by the starting motor. The starting motor takes about 95 amperes to turn the engine over at approximately 125 revolutions per minute. This current is used, of course, only for a few seconds and it is not considered necessary or advisable to try to pass it through the ammeter.

The ammeter does not show the amount of current in the battery. A hydrometer is the only instrument that will show this.

Generator disconnected: if wires running to the generator should be disconnected for any cause, great care should be used in replacing them—generator will reverse its polarity if wires are reversed—no serious injury would result, but ignition current might be interfered with.

Fuse block—If a fuse burns out—find the cause. Replace with 5 ampere fuses. **Bulbs:** headlight, 6 to 8 volt, 15 c. p. Dash and tail lights, 3 to 4 volt, 3 c. p.

Disconnecting storage battery: If the storage battery (3 cell, 6 volt) should become discharged to such an extent that it fails to supply ignition current it should be recharged from an outside source of current. If absolutely necessary to use the car with battery removed place five dry cells, connected in series, in place of the storage battery, connecting to the same terminals. Connect the two lower terminals on the condenser box (located on the side of the generator), together by the short circuit clip which should be found attached to the lower terminal or by a piece of wire and the car can be used until storage battery is recharged; it, of course, being necessary to crank the engine by hand. It should be remembered that it is often possible to start an engine by hand cranking even after the storage battery is too weak to drive the starting motor.

If battery is removed, be sure and replace it as it was originally—same connections and be sure they are tight.

Ignition—the Remy battery and coil system is explained in chart 118 and page 251.

Adjustments: maximum opening of breaker points .012 to .015 inch. The re-bound spring should be .020 inch, from the breaker arm, when points are at maximum opening. Spark plug gap .025 to .030 inch.

—continued in chart 181D.

CHART NO. 181C—Reo Electric System—The Remy—continued.

—continued from chart 181C.

If the engine misses when running idle or pulling light, the spark plug gaps should be made wider. If the engine misses at high speed or when pulling heavy, at low speed, the gaps should be made closer. It should be borne in mind however that there are many other things which will cause the engine to miss and act like ignition trouble, viz.: carburetor being out of adjustment, leaky valves, incorrect valve timing, air leaks in intake manifold or around valve stem, engine not oiling properly, lack of compression, etc.

To set ignition: Turn fly-wheel until piston of No. 1 cylinder is at top of compression stroke. Then turn ¼ turn more until marks on fly-wheel (U. D. C. 1 & 6) are opposite reference mark on base of rear cylinder. At this point, turn armature shaft (ignition timer is connected to it) until cam on interrupter, is just starting to break. Put lever in full retard position.

To check point of firing.—Open cylinder pet cocks, retard spark control lever, turn on ignition switch, and notice that the ammeter shows a discharge. Then while one person turns the engine over very slowly with the hand crank, a second person can watch the ammeter. The instant at which the ammeter pointer starts to return to zero, is the time at which the spark occurs. At this instant one of the U. D. C. marks on the fly wheel, should be from 1 to 1½ inches past the dead center reference point. Firing order is 1, 4, 2, 6, 3, 5.

Haynes Electric System (per diagram below).

Haynes car uses the Leece-Neville starter and generator system. A two-unit system.

Starting motor drives the crank shaft in front, by a chain and an over running clutch. Starter is mounted on the left side.

Generator—driven by gears from crank shaft of engine and is mounted on right side. A circuit-breaker or cut-out is mounted on generator.

Regulation—by third brush. **Ignition**—on the Haynes "12-40" and "12-41" is Delco. On the "6-37" and "6-36" Remy is used. The distributor and timer are mounted on the generator.

To time the ignition: spark occurs in cylinder No. 1 when mark "IN—CL" (inlet, closes) on fly wheel, comes under pointer—at end of compression stroke and spark lever fully retarded. This causes spark to occur ¾ inch past dead center, as measured on fly wheel. See index for Delco and Remy coil and battery ignition system for further detailed description.

Wiring diagram of the Haynes.

CHART NO. 181D—Reo Electric System—continued. **The Haynes 1916-17 Electric System using the Leece-Neville Starter and Generator, Remy Ignition** (also see chart 169.)

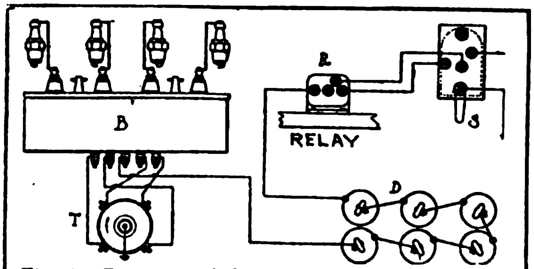

Fig. 1. Diagram of the "Delco" Ignition System

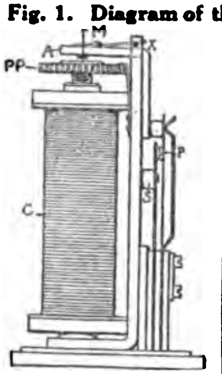

Fig. 2. The Controlling Relay.

The Delco "relay" ignition system consists of: (1) a coil box containing four non-vibrating high tension coils (B); (2) a relay (R) used in the circuit of the commutator or timer; (3) switch (S); timer (T).

The principle of this system is similar to the master vibrator system explained in chart 110, and is used in connection with the old style commutator or a timer.

The master vibrator in this instance is called the controlling relay. The ignition or controlling relay will be explained as follows:

This relay is for the purpose of breaking the primary circuit and thereby producing a spark from the secondary windings of the induction coil. It takes the place of the four vibrators on an ordinary coil unit, as it acts, for each coil in turn as the commutator makes connection. In this way, it replaces what is commonly known as a master vibrator as explained in chart 110. It differs from the ordinary vibrator, however, in that it uses but one spark for each contact of the commutator.

But in starting, when the button at the top of the switch is pushed in, it opens the auxiliary or holding coil and permits the armature (A) to vibrate the same as any vibrator, sending a shower of sparks to the cylinder for starting. This is one of the features of this system. After engine starts a "single" spark is supplied.

Operation of relay. C is the magnet coil, composed of two windings; one heavy winding through which the primary circuit passes when the timer makes contact, thus drawing down the armature A, and opens contact P. This contact opens the circuit and the armature would again return to its first position, making contact and breaking it again as an ordinary vibrator if it were not for a second fine winding, wound on the same coil, but shunted around P. The current flowing through this holds the armature A against pole piece PP until the timer slips off contact, when this auxiliary circuit is opened, thus releasing the armature and allowing the platinum iridium contacts P to come together and be ready to break the circuit when the timer makes the next contact.

A hard rubber spacing support holds the lower contact spring in a definite position. The hard rubber insulating stud on the armature pushes the center spring out and opens the contacts "P" when the armature "A" is drawn down against the pole piece "PP."

PP is a pole piece which screws in or out as desired by means of a ratchet. This is the only adjustment on the entire system and is only used to get the proper opening of the contacts P.

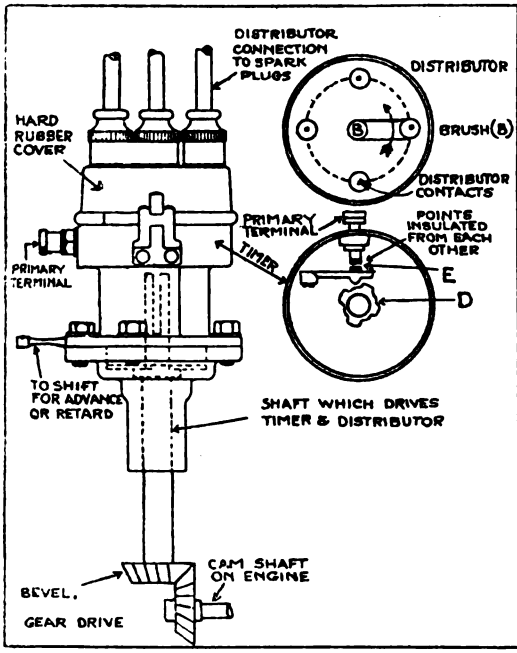

Fig. 3. The distributor and timer arranged in this manner dispenses with the multiple coil, only one non-vibrating coil is now necessary. The relay is not shown with this system. This was the next improved Delco ignition system.

Note diagram; when timer makes contact at E and breaks, the distributor brush (B) makes contact also. Above is an open circuit type timer.

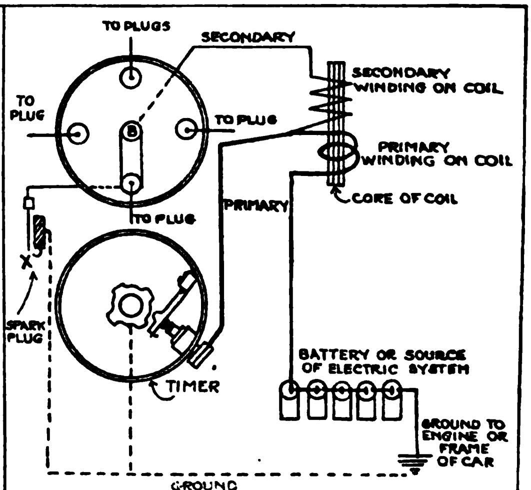

Fig. 4. A wiring diagram of fig. 3. The distributor and timer principle showing how the two are combined in one unit and driven from one shaft. A later development is shown in chart 184.

The timer cam (D) and distributor brush (B) are driven at engine camshaft speed. If engine crankshaft turned 720° or two revolutions, the timer-distributor shaft would revolve one-half the speed or 360°, or one revolution. Note on a four cylinder engine ignition system, there are 4 lobes on cam (D) and 4 points on distributor.

On a magneto, as explained on page 295, there are usually 2 lobes on cam, therefore on a four cylinder engine the magneto armature would revolve at engine crankshaft speed.

CHART NO. 183—Delco Ignition System. The Relay System: one of the first Delco Ignition Systems. **The next Improved Ignition System was the Delco Distributor and Open Circuit Timer System,** figs. 3 and 4. The later improvement is the system shown on pages 377, 378.

INSTRUCTION No. 28-A.

†DELCO IGNITION SYSTEM: Early Form of Relay System. Distributor and Timer Development. Automatic Advance of Spark. The Modern Delco Ignition. Circuit Breaker. Resistance Unit.

We will not attempt to show all of the Delco systems, but will first explain the original Delco ignition system, then the different "regulation" systems used with the Delco generator.

Delco "Relay" Ignition.

In order to note the development of the Delco ignition systems, it will be necessary to start at the beginning, therefore we will briefly describe the Delco relay ignition system which is similar in a manner to the master vibrator, except a "single" spark is used to run on instead of a "succession" of sparks, although a succession of sparks are given to start on.

This relay system was one of the early forms of ignition used for automobile work before the development of the present "distributor and timer" system now used so extensively.

This Delco "relay" system is still used on marine engines and many four cylinder engines using the old style commutator and vibrating coil. For example, suppose you had a four cylinder engine with four vibrator coils and commutator, then you could better this ignition system by using the relay to take the place of the vibrators. The same timer would be employed. A diagram of this system is shown in chart 183.

Delco Distributor and Timer Development.

The old style commutator faults are explained on page 242. This device was usually placed in front of the engine and run from the end of the cam shaft, just as the principle is now employed on the Ford car. There are many objections to this old style commutator and vibrating coil system, some of the objections are the current consumption, lag in spark timing, sticking vibrator points and the constant moving of wires in advancing and retarding the spark, by shifting the commutator and last but not least, the great amount of wiring necessary.

To overcome these objections the commutator was arranged as a "timer" so it would give a single spark instead of a succession of sparks, see fig. 2, page 242. The several coils were dispensed with and one non-vibrating coil was used instead. To accomplish this, the timer and a distributor were combined and operated from cam shaft. This principle is explained on page 230, but in this instance, a "timer" making a single contact, is used instead of a commutator as on page 230. A diagram illustrating this timer and distributor development is shown in chart 183 and page 378.

A Later Delco Ignition.

Is the system illustrated in chart 184. **This system** combines the distributor and timer, but instead of the spark being advanced by hand it is advanced *automatically. The distributor and timer, together with the ignition coil, spark plugs and wiring constitute the ignition system. The source of supply can be from storage battery, dry cells or generator.

The Delco timer is made in two **types**; **open** and **closed** circuit type—see **page 378**.

Parts of the Delco Ignition System.

The combination switch (fig. 5) is for the purpose of controlling the lights, ignition and the circuit between the generator and the storage battery. A later type page 378.

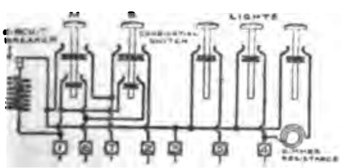

Fig. 5. Diagram of combination switch.

The button M controls both the ignition and the circuit between the generator **and** storage battery.

The button B controls ignition current from dry cells. (now eliminated).

This is shown on the circuit diagram, **fig.** 2 chart 184. The button next to (B) controls the cowl and tail lights. The next button controls the head lights. The button on the right controls the dimmer.

*An automatic principle is explained on page 248, although the construction is different in chart 117, the principle or idea will be made clear by a study of same. The Delco Co. also produce the non-automatic system, which is used on small four cylinder cars. Dayton Engineering Laboratories. Dayton, Ohio is address of the manufacturers.

†See pages 544 to 546 for "Specifications of Leading Cars" for those using the Delco system.

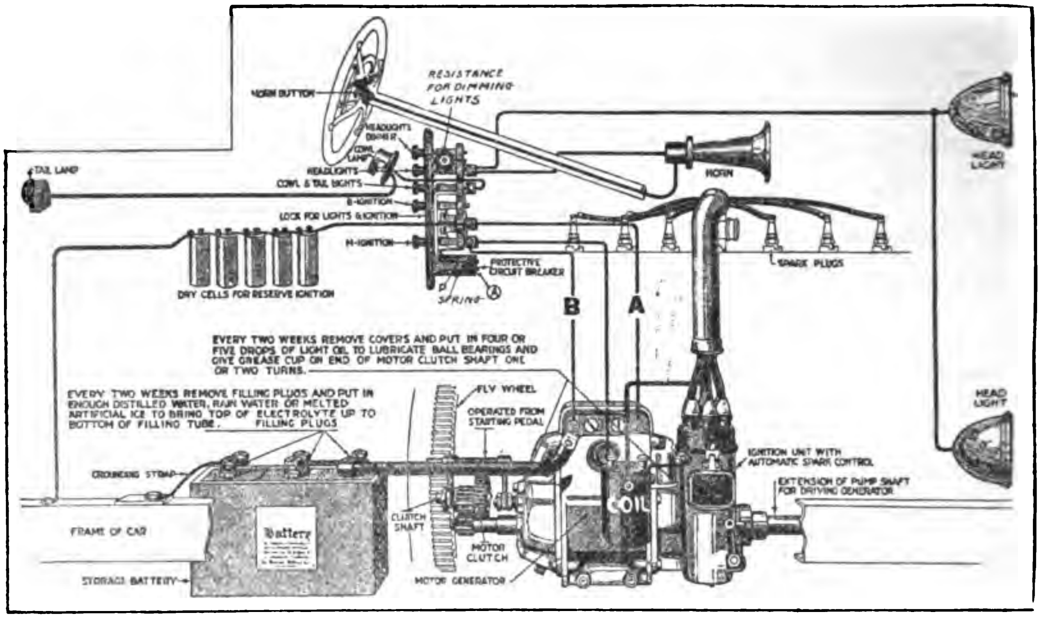

Fig. 1. Illustrating the Delco ignition system. The distributor and timer are mounted on the side of the motor-generator. The timer and distributor shaft is driven from the pump shaft, which is driven by gear from crankshaft. This distributor and timer could be mounted separate from the motor-generator. The ignition coil (see fig. 4, page 378), in this instance is mounted on the distributor, it could also be mounted separate on the dash or elsewhere.

When either the ignition switch M or B is pulled out, on the combination switch it closes the circuit between the generator and the storage battery at the contact (X) below, and starts the armature of the generator turning over slowly so that the gears can be meshed. In other words, the generator acts, for the time being as a motor.

The (M) button on switch closes the ignition circuit at (XI).

***The (B) button** closes the dry cell ignition circuit at (X2).

"M" is intended to mean "magneto" side for ignition but in reality the source of electric supply is not from magneto at all. The current for ignition is usually given by the storage battery to start with. After engine is started, the generator (not magneto) supplies current, after certain speed (see pages 244 and 341, why called "magneto ignition")

The letter "M" was not intended by Delco to mean "magneto." It was intended for the car driver to use this system as he formerly used the magneto system.

If button "B" is pulled out, note the "dry cells" are used for ignition. The dry cells are seldom used except for auxiliary or emergency.

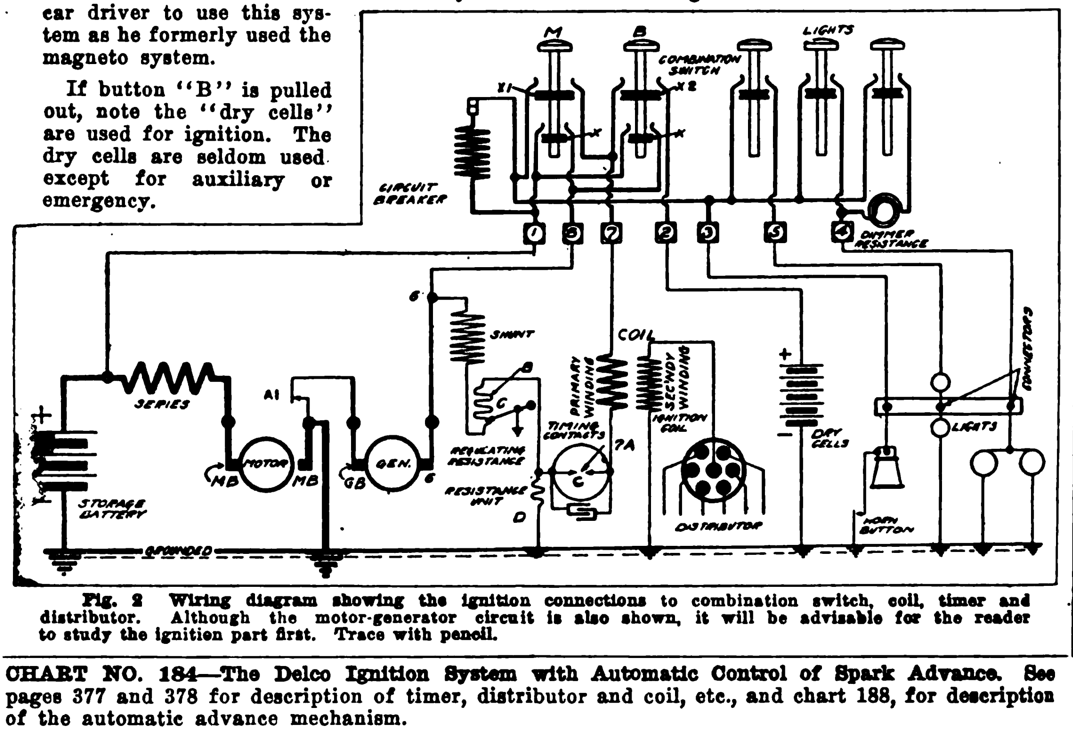

Fig. 2 Wiring diagram showing the ignition connections to combination switch, coil, timer and distributor. Although the motor-generator circuit is also shown, it will be advisable for the reader to study the ignition part first. **Trace with pencil.**

CHART NO. 184—The Delco Ignition System with Automatic Control of Spark Advance. See pages 377 and 378 for description of timer, distributor and coil, etc., and chart 188, for description of the automatic advance mechanism.

*On the latter Delco ignition systems (pages 377 and 378) the "B" switch has been eliminated

Delco Circuit Breaker.

The circuit breaker is mounted on the combination switch as shown in fig. 1, chart 184. This unit is a protective device, which takes the place of a fuse block and fuses. It prevents the discharging of the battery or damage to the wiring to the lamps, horn, or ignition, in case any of the wires leading to these parts become "grounded." As long as the lamps, horn and ignition are using the normal amount of current the circuit breaker is not affected. But in the event of any of the wires becoming grounded, an abnormally heavy current is conducted through the circuit breaker, thus producing a strong magnetism, which attracts the pole piece and opens the contact. This cuts off the flow of current which allows the contacts to close again and the operation is repeated, causing the circuit breaker to pass an intermittent current and give forth a vibrating sound.

It requires 25 amperes to start the circuit breaker vibrating, but once vibrating, a current of three to five amperes will cause it to continue to operate.

In case the circuit breaker vibrates repeatedly, do not attempt to increase the tension of the springs, as the vibration is an indication of a ground in the system. Remove the ground and the vibration will stop.

Circuit Breaker Troubles.

If the circuit breaker indicates a grounded wire, the cover of the junction box on the dash should be removed, and the line which is grounded should be opened at the terminal on the junction block. If the circuit breaker stops vibrating when this is done, the ground must be in the line after it leaves the junction box. If it continues to vibrate, however, the ground is in the switch or ignition circuits.

In case the circuit breaker continues to vibrate when all buttons on the combination switch are depressed, the trouble is almost sure to be in the horn or its connections.

†The Ammeter.

Purpose: The ammeter on the right side of the combination switch (page 388, 378), is to indicate the current that is going to or coming from the storage battery, with the exception of the cranking current. When the engine is not running and current is being used for lights, the ammeter shows the amount of current that is being used, and the ammeter hand points to the **discharge** side, as the current is being discharged from the battery.

When the engine is running above generating speeds, and no current is being used for lights or horn, the ammeter will show **charge.** This is the amount of current that is being charged into the battery. If current is being used for lights, ignition and horn, in excess of the amount that is being generated, the ammeter will show a **discharge,** as the excess current must be discharged from the battery, but at all ordinary speeds the ammeter will read **charge.**

The approximate charging rate for different car speeds when no current is being used for lights or horn, is given in the curve on page 390.

Location. The ammeter would be placed in the line from connection (1), fig. 2, chart 184—to the (+) or positive terminal of battery. The ammeter is not shown connected up in this drawing, but by referring to the upper illustration on page 388 and 391 the location is clearly shown.

*Delco Distributor and Timer.

The distributor and timer, together with the ignition coil, spark plugs and wiring constitute the ignition system—see page 245.

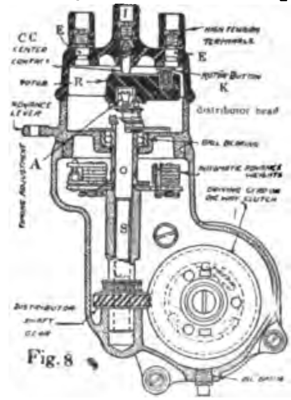

Fig. 8—Illustrates the modern Delco distributor and timer. Note the distributor is above the timer—Buick six as an example.

The distributor and timer shaft (S) is driven by a gear, shown to the right, which is driven by an extension of the pump shaft.

The pump shaft, although it revolves 1⅓ times crank shaft speed, the vertical distributor and timer shaft (S) is driven at **one-half crank shaft speed.**

Although there is a "clutch" in the driving gear which operates gear on distributor shaft, both are driven at a fixed speed by pump shaft. To understand this, see "generator clutch," page 386.

The distribution of the high tension or secondary current from "rotor-button" (K), fig. 8, to spark plug terminals (E) is similar to other systems as Atwater-Kent, Connecticut and others, pages 248, 254, 245.

Distributor rotor (R), **fig.** 8 distributes the high tension current from the center of distributor (CC), to the spark plug terminals (E). The high tension current is brought from coil to distributor center at top (1), thence carried through (CC), through rotor (R) to spark plug terminals (E). Rotor button (K) should be kept clean.

Distributor-head if removed, must be put back in proper position, otherwise the rotor brush (K) will not be in correct contact with spark plug terminal (E) at the time the spark occurs. Lubrication of this device, see page 397. Distributor head can be removed for cleaning.

*Automatic Advance of Spark.

Advance and retard is obtained by shifting by hand that part of mechanism as shown attached to the "advance lever" fig. 8, in addition to the automatic advance.

An explanation of the automatic advance of spark and the advantages of same are given on pages 246, 249, 307 and 248.

Why Hand Control Also.

The reason is explained on pages 246 and 249 see also page 307.

**Position of Spark Lever.

With the spark lever set at the running position, which is about ⅓ way down (Buick, page 497 as example), the automatic feature of timer will give the proper spark for all speeds; except a wide open throttle at low speed, at which time spark should be slightly retarded.

*All Delco systems are not automatic—see pages 394 and 395. †See also page 415.

**When the ignition is too far advanced, it causes loss of power and a knocking, due to too early ignition.

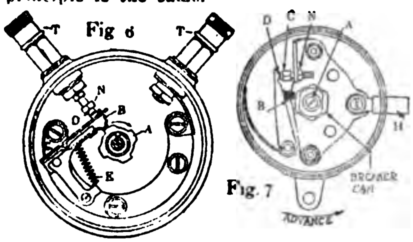
When ignition is too late or retarded there is a loss of power (which is usually not noticed excepting by an experienced driver or one very familiar with the car) and heating of the engine and excessive consumption of fuel is the result.

Delco Timer.

****Also termed "interrupter," or "contact breaker" is mounted directly under the distributor** and operated from the same shaft which drives the distributor—see fig. 8.

The governor advances the cam as the speed increases. By referring to page 248 the governor principle will be made clear.

Although construction may vary, the purpose or principle is the same.



***Delco timers are made on both open and closed-circuit principle.** The latter being used most since 1915.

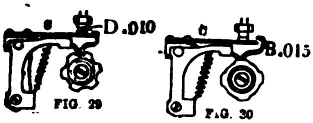
Fig. 6.—Open-circuit type; D—stationary contact; **C—movable** spring blade with other contact—both insulated; **A**—cam which raises (B) and closes contact on (C) with (D); **T**—primary terminals (one is sometimes grounded). Points are normally **open.**

Fig. 7.—Closed-circuit type; D and **C** are normally **closed;** movement of projections on breaker cam **opens** the contact (DC); **H**—is insulated terminal from primary coil winding, connected with point (C); **D**—is arm with other contact point and is grounded (on some of the Delco timers this is just the reverse); **B**—projection on arm (D) which is raised or lowered by lobes on cam.

Adjusting Delco Contact Points.

Closed circuit type: Loosen lock nut (N) and raise or lower screw (C), fig. 7. To do this crank engine by hand, until (B) is on top of cam lobe or projection. Space between points D and C should be .018 or .020" (see also, pages 132 and 245).

Open circuit type: Crank engine until (B) is off cam lobe as per fig. 29. Then loosen lock nut (N, fig. 6) and adjust clearance to .010" as at (D), fig. 29.



In addition to adjusting the clearance of points to .010" as per fig. 29, there should be a clearance of .015" between end of blade (C) and pigtail (B, fig. 30, which hangs over C), when (B) is directly on top of cam lobe—see also, fig. 37, page 392.

To Time Delco Ignition.

See instructions given on pages 132 and 729 (Cadillac) and pages 390 and 245.

Spark Plug Gap

is .025 to .030". If too wide, missing will occur when accelerating at very low speeds and hard pulls; if too close will miss at idling and high speeds.

Delco Ignition Coil

Is a regular double-wound high tension coil without a vibrator, per fig. 4, page 245. It is usually round and is sometimes mounted to the side of the motor-generator, per page 376. Also termed a **transformer coil.**

A condenser is incorporated in it, per page 245, fig. 4. All high tension coils must have condensers.

An **ignition resistance unit** is mounted on rear end of coil, sometimes it is mounted on timer, per page 392, fig. 37.

Primary Current.

The primary current is supplied through the combination switch and resistance unit on the coil, through the primary winding, to the interrupter contacts. This is plainly shown on the circuit diagram, chart 184.

It is the **interrupting** of this primary current by the timer contacts, together with the action of the condenser, which causes rapid demagnetization of the iron core of the coil that **induces** the high tension current in the secondary winding.

Secondary.

Secondary winding; one end terminates at the high tension terminal midway of coil, (see fig. 4, page 245)—thence conducted to distributor at point (I), fig. 8, page 377.

Condenser

principle is explained on page 228. **A defective condenser will cause excess sparking** at contact points and missing at low speeds. (see page 245.)

Ignition Resistance Unit.

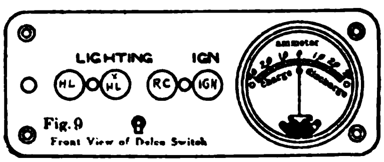
The ignition resistance unit which is shown on the coil in fig. 4, page 245, is for the purpose of obtaining a more nearly uniform current through the primary winding of the ignition coil, at the time the breaker points open. (see also page 246.)

It consists of a number of turns of iron wire, the resistance of which is considerably more than the resistance of the primary winding of the ignition coil. **If the ignition resistance unit was not in the circuit and the coil was so constructed to give the proper spark at high speeds, the primary current at low speeds would be several times its normal value with serious results to the timer contact.** This is evident from the fact that the primary current is limited by the resistance of the coil and resistance unit and by the **impedence** of the coil.

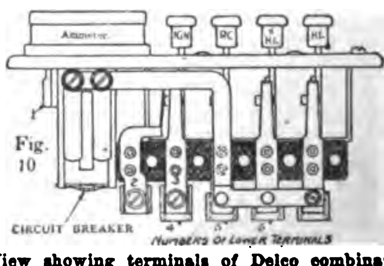
(Impedence is the choking effect which opposes any alternating or pulsating current magnetizing the iron core.) The impedence increases as the speed of pulsations increase. At low speeds resistance of the unit increases, due to the slight increase of current heating the resistance wire.

Delco Combination Switch.

The Delco switch used on D55 Buick-six is shown below. Note "B" switch, referred to on page 385 has been eliminated.



HL—headlight switch; **X-HL**—auxiliary head lights; **RC**—rear and cowl or instrument lights; **IGN**—ignition switch which controls the ignition circuit and also closes the circuit between generator and storage battery. **Note:** on **ammeter** "discharge" side is to the right. **On page 415, 410** it is to the left—this varies.



View showing terminals of Delco combination switch. See also page 388.

*Whenever the spring (which is always present on breaker arm) forces the arm **against the cam,** it is an "open circuit" type; when spring forces contact parts together, it is of the "closed circuit" **type. **To distinguish the difference, suppose we term fig. 6 a timer and fig. 7 an interrupter.**

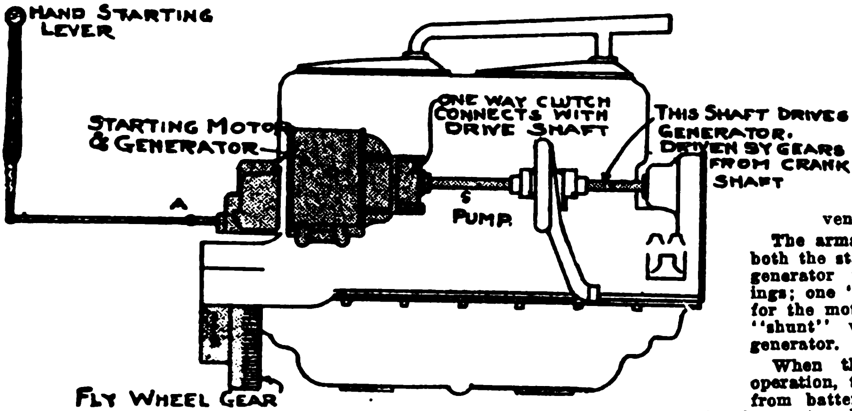


Fig. 1. The mounting of the 1914 Delco motor-generator is similar to the later models.

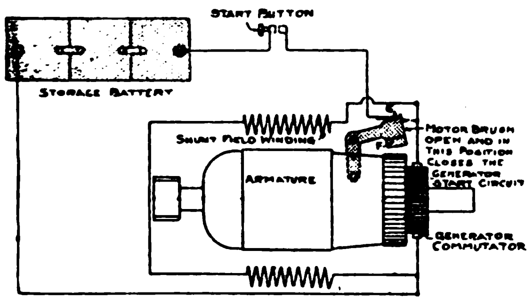

Fig. 2. When starting, push "start button," this sends current from the battery to the generator (not motor) armature, through the field and it revolves slowly. Note: Motor brush is up and makes contact at G for the generator.

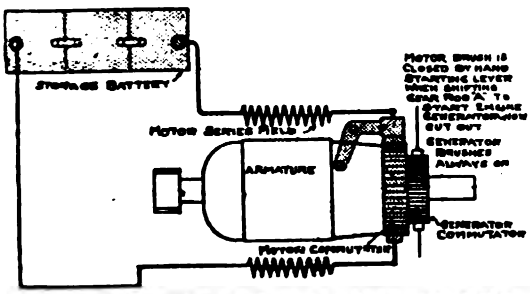

Fig. 3. The motor brush is now down and starting motor is working. Generator is cut out.

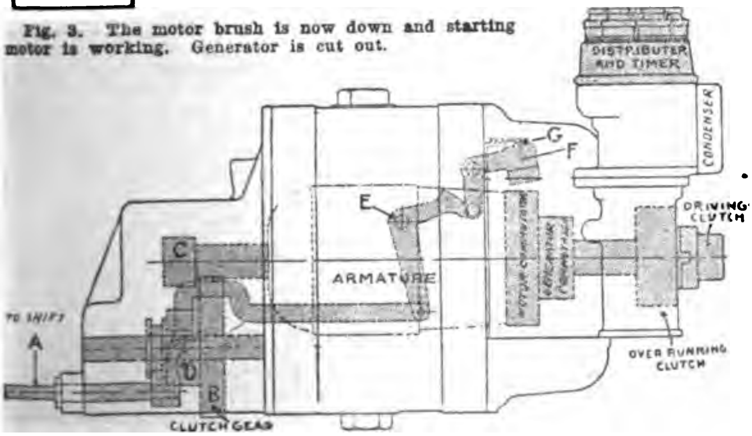

Fig. 4. Phantom view of motor-generator.

The 1914 Cadillac and 1914 Hudson "6-40," Delco motor-generator is located along side of the engine driven by pump shaft.

The armature is used for both the starting motor and generator with two windings; one "series" winding for the motor, fig. 3, and a "shunt" winding for the generator.

When the motor is in operation, the current flows from battery to the series winding through the motor brush and commutator.

When the generator is in operation, the motor brush is raised at (F) fig. 2. The generator brushes remain on commutator at all times. The current then flows through the "shunt" winding.

The starting motor drives the flywheel gear through the gears C, D and B (fig. 4). A roller type clutch is provided on the front part of armature shaft, so that the armature is free from the pump shaft which drives the generator.

The armature is driven by connection with pump shaft by engine, after engine is started and starting gears are out of mesh.

A one-way clutch connects the pump shaft with armature shaft to drive generator. This clutch will permit the pump shaft to drive generator, but generator armature when running as a motor cannot drive the shaft (see index "generator clutch" explaining action of a one-way clutch).

Starting Operation.

First: Place ignition switch on battery side. Next; depress starting button on dash (see fig. 2). This sends current from the storage battery to the generator (not the motor) and in passing through the generator field shunt winding, and armature winding, the armature slowly revolves.

The purpose in using the generator as a motor is to revolve the armature slowly, so that gears will mesh with flywheel gears when the starting lever throws them in mesh. It must be remembered that the brush on starting motor commutator is not in contact, but being in the position as shown in fig. 2, the generator circuit it closed at G, but not the motor circuit.

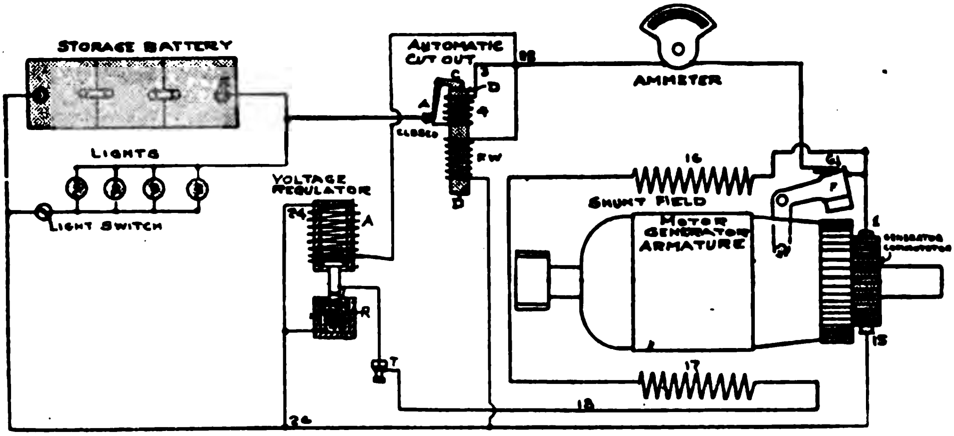
Next, after generator armature is revolving slowly, pull back on starting lever.

This causes rod "A" to be pushed forward, causing gear "B" of the starting clutch to mesh with motor pinion "C." Immediately after gears "B" and "C" are meshed, the gear "D" which is integral with "B," meshes with the gear teeth on the fly wheel, and at the same time, the extension of the rod "A" to the bell crank "E" allows the motor brush "F" to travel toward the motor commutator, opening the generator circuit and shunt field at "G" and closing the motor circuit.

The generator would then be cut out and the starting motor is revolving engine through the fly wheel. (fig. 8.)

—continued on next page.

CHART NO. 185—The 1914 Delco Starting and Generating System, explaining the first principles of the Delco system and how the one Armature serves for both the Motor and Generator.



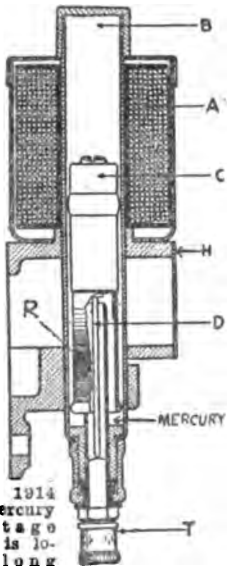


Fig. 2. 1914 Delco mercury type voltage regulator is located along side of the cut out, both in the battery box or on the inside of dash under hood.

Purpose; to control the amount of current flowing from generator to the storage battery. (See chart 168 explaining purpose of regulator.)

Description: A magnet coil (A) surrounds the upper half of the mercury tube (B). Within this mercury tube is a plunger (C) comprising an iron tube with a coil of resistance wire (R), wrapped around the lower portion on top of mica insulation. One end of this coil is attached to the lower end of the tube, the other end being connected to a needle (D) carried in the center of the plunger.

The lower portion of the mercury tube is divided by an insulation tube into two concentric wells, the plunger tube being partly immersed in the outer well, and the needle in the inner well. The space in the mercury tube above the body of the mercury is filled with an especially treated oil, which serves to protect the mercury from oxidization, and to lubricate the plunger. A bracket (H) serves to support the parts described.

—continued from page 379.

Generating Current.

When the starting lever is released, the spring throws the gears out of mesh, and at the same time raises the brush (F) from the motor commutator and closes the generator circuit again. The "start" button having been released in the first operation, the generator is now generating current, as the engine is running and driving the armature as a generator through pump shaft.

The starting motor has served its purpose and is now cut out of operation, as the brush "F" is away from motor commutator.

The principle of this mercury type of voltage regulator is as follows: The generator, as stated previously, is driven from the pump shaft which is driven by gears in front of engine from crank shaft.

After engine is started and hand starting lever disengages the gears out of flywheel, and motor brush "F" is lifted off of motor commutator, the motor is cut out and the generator is now in action as it must run when engine runs, as the pump shaft is connected with armature through a one-way clutch (see fig. 1, chart 185), which permits the engine to drive armature, but the armature, when revolving as a motor, cannot drive the engine only through the gears to flywheel. This clutch permits the armature to run ahead of the driving shaft during the cranking operation.

The generator now begins to generate current; but until engine is running at a speed which will turn generator armature fast enough to generate a pressure of 6 volts, or required amount to overcome the pressure or voltage of the storage battery, the current will pass from generator commutator 1, to 2, around the fine wire winding of cut out core (D), thence back to the other commutator brush 15. This current will continue to travel in this path until it has sufficient pressure, which is slightly over 6 volts, to magnetize the core (D) so that it will draw the magnet armature of cut out (C) down—when circuit is closed to battery. Battery will then be charged from generator, or generator will also supply current for light. At other times, the storage battery supplies current for lights.

If engine is speeded up, the pressure increases and lights would be burnt out, therefore, the mecury regulator is brought into action.

As the voltage increases with speed, the intensity of the magnetic pull exerted by the magnet coil "A" upon plunger "C" causes the plunger (C) to move up out of the mercury.

Now the current to the shunt field (17) of the generator must follow a path leading into the outer well of mercury, through the resistance coil (R) wound on the plunger tube, to the needle carried at the center of the plunger, into the center well of mercury and out of the regulator.

It will be seen that as the plunger is withdrawn from the mercury, more resistance is thrown into this circuit, due to the fact that the current must pass through a greater length of resistance wire. This **greater resistance in the field of the generator** causes the amount of current flowing to the battery to be gradually reduced as the battery nears a state of complete charge, until finally the plunger is almost completely withdrawn from the mercury, throwing the entire length of resistance coil into the shunt field circuit, thus causing a condition of practical electric balance between the battery and generator, and obviating any possibility of over charging the battery. **As the speed decreases,** the magnetic pull of the core (A) is weaker and plunger "C" assumes a lower position.

The late Delco system does not use the automatic "cut-out" or "mercury type" regulator.

CHART NO. 186—The 1914 Delco Generating System. Action of the Mercury Voltage Regulator. This regulator is not now used but shown in order to explain the principle.

INSTRUCTION No. 28-B.

*DELCO ELECTRIC STARTING, GENERATING, LIGHTING AND IGNITION SYSTEM: Generators. Motor Generators. Early System. Regulation Methods; mercury, variable resistance and third brush. Principle and Theory of Delco Systems. Examples Delco Systems: Hudson, Buick, Cole, Oldsmobile, Cadillac. Motoring the Generator. Motor and Generator Clutches. Charging Rate Curve.

Early Delco Electric Systems.

In order that the reader will understand the later Delco systems, it will be necessary to begin with the early models. A study of chart 185 and 186 is advised before proceeding.

One Armature Serves for Motor and Generator.

It is well to note, that Delco employs one armature, but two commutators on their motor-generators in the later Delco systems as well as the early systems. The motor commutator and the generator commutator can be placed both at one end of armature, which is the method employed on the Buick model D-44, also in 1914 model as per charts 185 and 186, or the commutators can be at opposite ends of armatures, as per chart 188.

Windings.

Armature winding. There are two regular "drum" type windings on the armature, one for the generator and one for the motor.

Field windings. There are two windings on the plain two pole (bi-polar) fields; a "series" for the motor and a "shunt" winding for the generator (see chart 187,) with the exception of the types that are regulated by the "reverse series" method, employing a third field winding.

The motor series field winding is wound from strip copper. The **generator shunt** field winding is separated from it entirely, and is brought out to the terminals on one end of the field coil. One of these is connected to the generator brush lead and the other to the bottom of the regulating resistance (B). See chart 187 and 188.

Delco Regulation Methods.

The "mercury" voltage regulator was used on the 1913 and 1914 models of the Delco system, as explained in charts 185 and 186. This regulation system is now seldom used.

***__The "third brush" regulation method,__ **is the popular Delco principle** now employed and will be explained further on.

The "variable resistance" regulation is also used at the present time on some of the Delco systems. An example of this principle is shown in charts 187, 188, and 188D. The Hudson "six-40," Buick models "38 and 54," Cole "6-50" page 392, used this system. As an example we will use the Hudson "Six-40."

Principle of the Delco "Variable Resistance" Regulation—Hudson "Six-40" as an example.

The object or purpose of "regulation" of the output is explained in instruction twenty-seven, therefore we will not deal with the principle here but will take up the general construction.

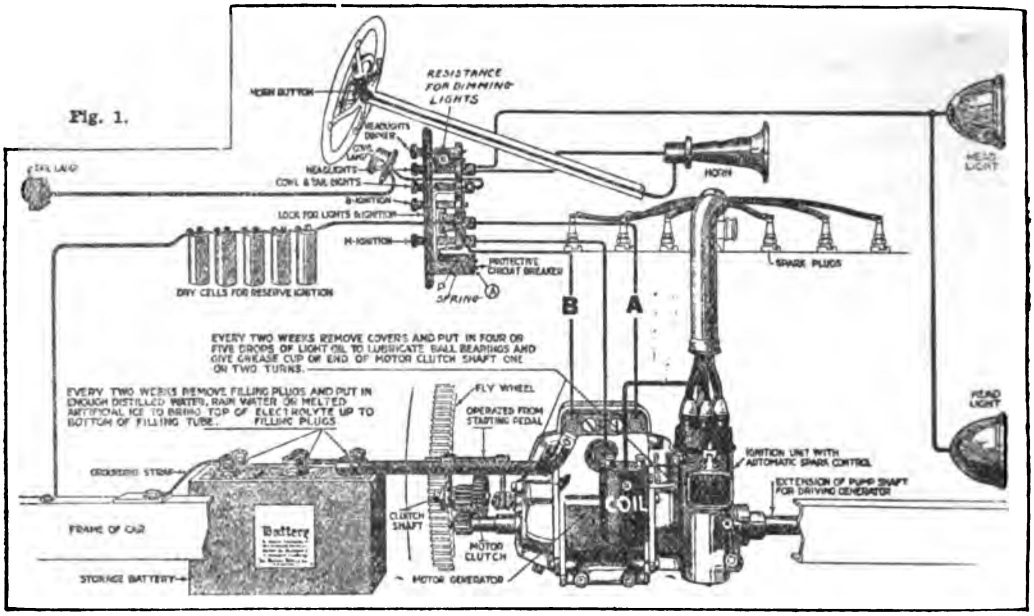
The variable resistance regulation is accomplished through a special resistance wire wound on a spool of non-inflammable material and mounted in the distributor housing just back of the condenser as shown at B fig. 3, chart 188.

**__By inserting some of this regulating resistance on spool (B) in the shunt field circuit at the higher speeds,__ the output is controlled automatically by the lever (C) and the same mechanism that advances the spark. The circuit can be readily understood by referring to the circuit diagram, chart 187, and from this circuit diagram it can be seen that all of this resistance is in the shunt field circuit when the arm C is at the top position; that is, at maximum speed (also see fig. 3, page 384).

The "ignition resistance unit" (D) is grounded through the output resistance and is cut out of the ignition circuit when the arm it at the top position. This increases the intensity of the spark at high speeds. Note however, that it is distinct and separate from the "regulating resistance unit."

*See charts 229 to 232 for users of Delco electric systems.
**See page 387 for different sizes of resistance units to use.
***See also page 370.

Fig. 1.



The starting motor and generator, use the same armature. The starting motor is explained in these charts. Therefore we will deal with the generator and winding and the circuits of wiring in this chart.

When the generator is supplying the current, it comes from the forward terminals on the side of the generator through the wire "A" to No. 6 terminal on the switch (see below), and since Nos. 1 and 6 terminals are connected (when either the "B" or "M" button on the switch is pulled out), it can be seen that there will always be current supplied to this switch for the lights, horn and ignition. The excess current flows through the switch wire "B" to the rear terminals on the generator and the heavy lead wire to the battery, thus charging the storage battery.

An ammeter inserted in the "A" line would indicate the amount of current coming from the storage battery to the generator, in case the engine was not running, or the current being generated when the engine is running.

The primary ignition current is an intermittent current—it flows only when the timer contacts are closed. This current can be readily traced on the diagram. A high voltage is induced in the secondary winding of the ignition coil when the flow of primary current at the timer contact is broken. This causes a spark to occur at the plugs when the breaker contacts open.

When the dry battery ignition is being used, the current is supplied in exactly the same manner as though it was coming from the storage battery; the "B" button on the combination switch closing the circuit between terminals No. 1 and No. 6, in order that the generator may be connected to the storage battery for charging purposes.

The regulation of the output of generator in this particular system, is controlled automatically by the lever C (see below and fig. 3, chart 188), which is raised and lowered by the action of the governor which cuts resistance into the shunt field winding at higher speeds; thereby weakening the strength of the fields, consequently the output of generator. This is called "variable resistance" method of regulation.

Fig. 2.

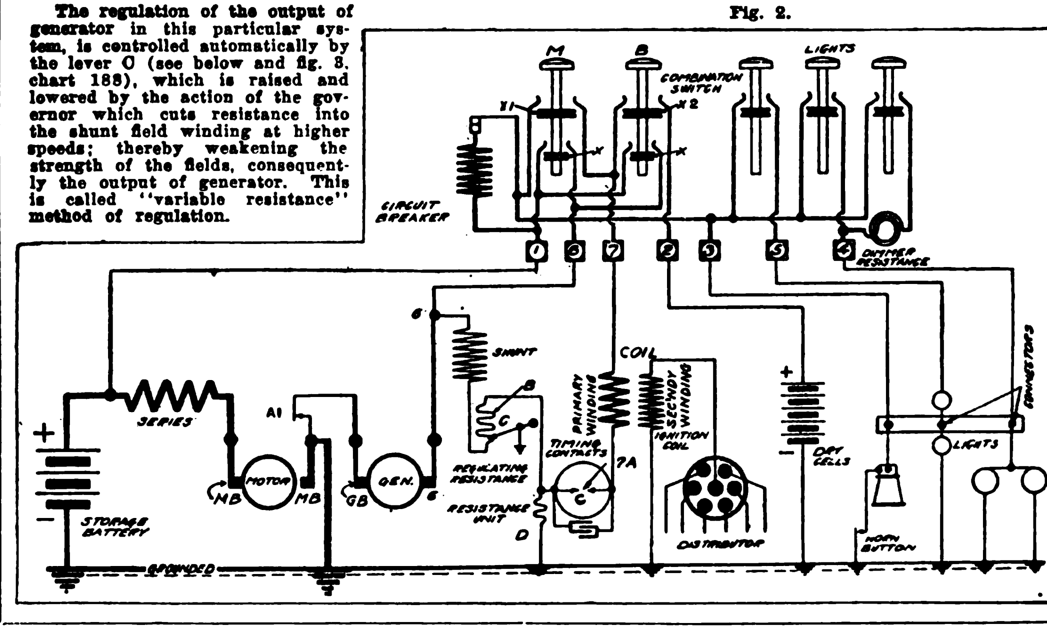


CHART 187—The Delco Electric System with "Variable Resistance Regulation" of Output of Generator and "Automatic Control of Spark" as used on the Hudson "Six-40." **A "single-unit" "single wire" system.**

The Control of the "Variable" Regulating Resistance—by governor action.

Note the action of the governor which controls the cutting in and out of this resistance. (See fig. 3, chart 188). The spiral gear (SG) is attached to the timer shaft (TS), this gear is operated by the pump shaft independent of the armature shaft. This gear being a part of the clutch which connects with the pump shaft. If distributor was driven from armature shaft the timing would be affected during the starting operation, during which time the armature operates at a different speed than pump shaft. The pump shaft runs at one and one half times crankshaft speed, but the six lobe cam, and the shaft, operate at one half engine crank-shaft speed.

As the timer shaft revolves the governor weights (G) assume a rising position which raises the arm (A), thereby raising the lever (C) which makes contact with the bare resistance wire (B), wound on an insulated spool. The principle is that as the speed of the engine increases the speed of the timer shaft increases and the governor arms (G) raise higher as the speed increases, thereby raising the arm (C) higher.

The higher arm (C) is raised, the more of this resistance wire is thrown into the field circuit, thereby weakening the output and keeping the current from gaining as the charging rate increases at the higher speeds.

The Automatic Advance of Ignition Controlled by Governor Action.

At the same time the timer cam on the end of the timer shaft is automatically "advanced." (As the speed is increased the action of the governor turns the timer cam in the direction of rotation) thereby causing earlier contact.

The ignition system is practically the same Delco principle described in previous instruction.

The resistance unit shown at (D) fig. 3, chart 188, is a coil of resistance wire, the purpose of which was explained in a previous instruction. See page 246.

This ignition resistance unit has connected in parallel with it, the regulating resistance (B), fig. 3, chart 188, see also diagram, chart 187.

When the arm "C," is in the lower position, the resistance of this path greatly exceeds that through the resistance unit, and practically all the ignition current passes through the ignition resistance unit.

But as the arm raises, as at high speed, this resistance is decreased, and when the arm is at the top position the full voltage is applied to the ignition coil.

In the event of the ignition resistance unit (D) being disconnected or burned out, it is impossible to get sufficient current through the regulating resistance, unless the arm "C" is held near the top.

The Automatic "Cut-Out" in this System not Used.

On the early Delco system (chart 186), the "cut-out" served the purpose of disconnecting the generator circuit from the storage battery, when the generator was running at slow speed and generating less than 6 volts. The principle being the same magnetic principle as described previously.

On the system now being explained (chart 187), and later systems, the "cut-out" is eliminated—The ignition buttons "M and B" in a way, takes the place of this cutout. The operation of either button controls the circuit between the generator and the storage battery. Should the engine stop and the ignition button (M or B) remained pulled out, the amount of current that comes from the storage battery is that which is required to operate the generator as a motor when first starting, and is about five amperes.

When the engine is not running, or when it is running below 300 R. P. M. and the circuit between the generator and the storage battery is closed by either the "M" or "B" button on the combination switch, the direction or flow of the current is from the battery to the generator and if the speed is very low indeed, as when throttled down to three miles per hour, the generator will over-run and the clutch will be heard in operation, as before stated.

A warning is given when the ignition button is pulled out or left pulled out (and engine were to stop) by the clicking of the ratchet type of driving clutch (see fig. 16, page 398), with which all these generators are equipped.

When the engine is running below 300 revolutions, then this clicking of ratchet will take place again, because the current from the battery is running back into generator slowly revolving it. This indicates that the generator is not running fast enough to overcome the pressure of battery. The amount of current that flows from the battery back to the generator at this slow engine speed is so small that it is negligible, therefore the automatic "cutout" can be eliminated.

Over 300 revolutions, the generator is **running fast enough to overcome the battery pressure.**

Single Wire or Grounded System.

The Delco wiring of the different parts are shown in figs. 1 and 2, charts 187. Note the single wire system is used in the illustration—the frame of the car being used to carry the return circuit.

The generator, storage battery, motor, lamps, horn and ignition apparatus each have a connection "grounded" to some part of the frame of the car or engine. The other connections are made with copper wires or cables.

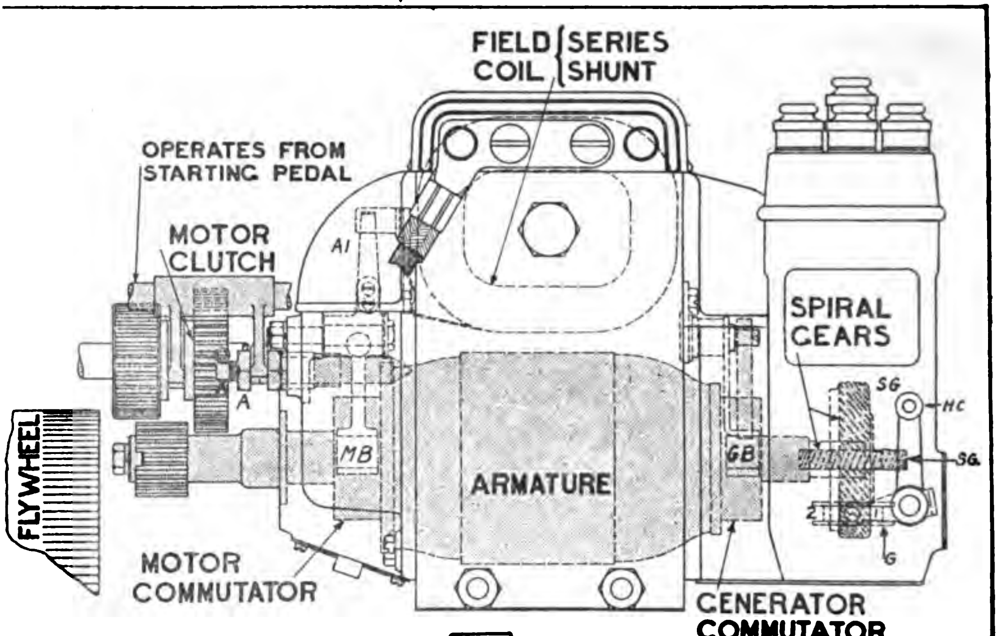

Fig. 1

The armature winding; there are two regular "drum" type windings on the armature. One for he generator and one for the motor. But only one armature. There are two commutators on the No. 1 ystem, one at each end; one for the generator circuit and one for the motor circuit.

The generator brush (GB), remains on the generator communitator, but the generator circuit (A1, g. 2), is opened when the motor brush (MB), is in action starting the motor.

The motor brush is raised and lowered to the motor commutator, by the motor brush switch (A). When the engine is started and starting pedal is released, the motor brush switch (rod A), raises the motor brush and opens the motor circuit and closes the circuit to generator at (A1).

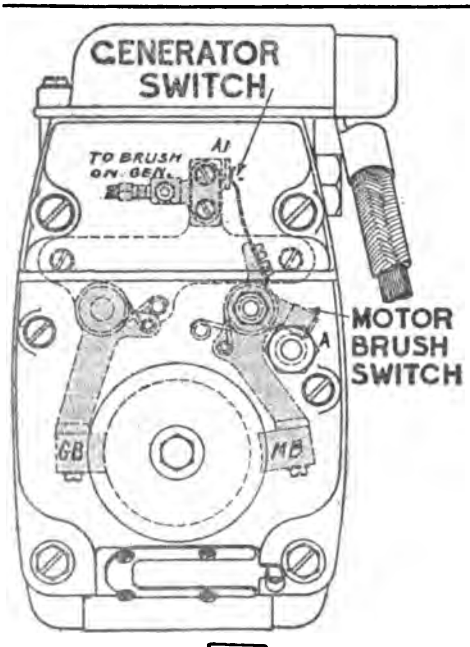

Fig. 2

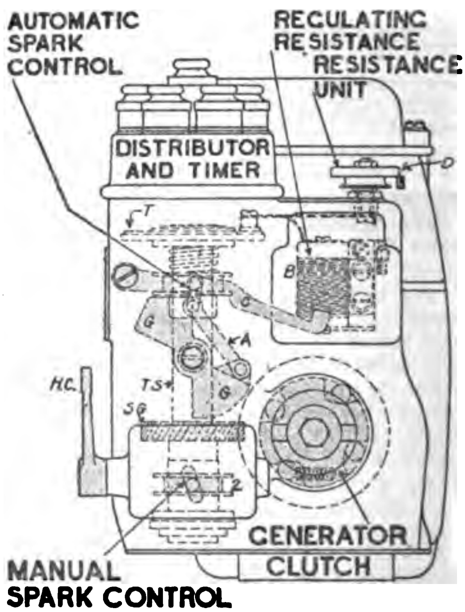

Fig. 3

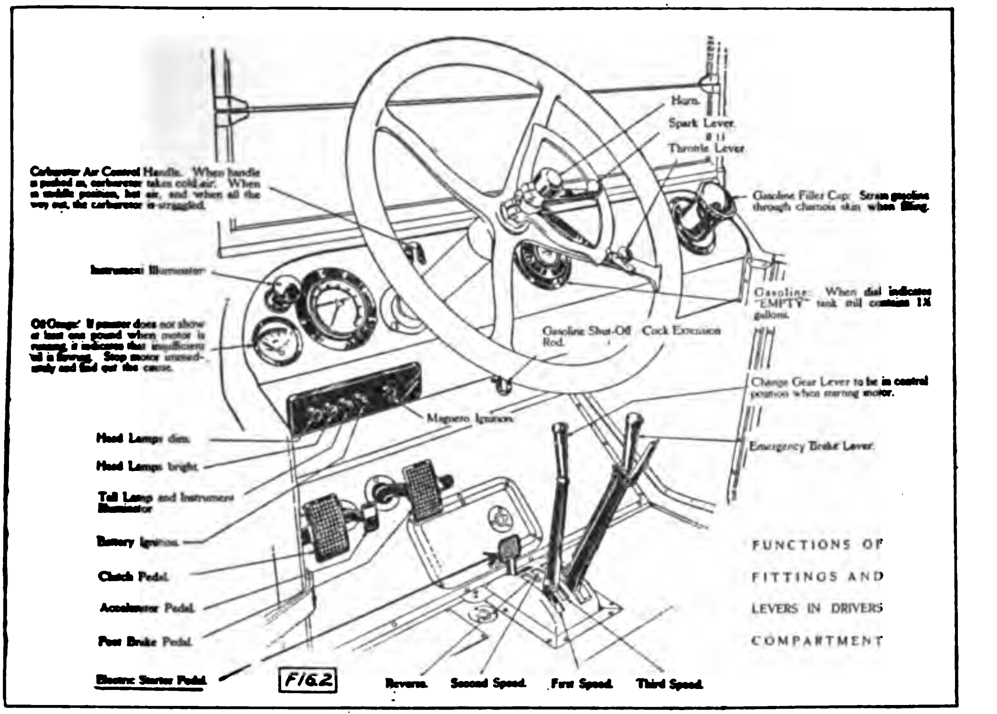
Generator brush (GB), remains on generator commutator. Generator circuit is opened and closed y action of switch (A1), raising motor brush (MB).

(HC), connects with steering post spark lever nd is called the manual control of spark.

(G), Governor on the timer shaft—operates utting in resistance wire at (B), by centrifugal action as speed increases it raises and actuates lever (C), through rod (A). At the same time the timer contact on end of shaft is made to break earlier, thereby advancing time of ignition. Spiral gear (SG), drives timer shaft from another spiral gear (see fig. 1), on outer shell of generator driving clutch.

ART NO. 188—The Delco Motor-Generator with Automatic Spark Advance and "Variable Resistance Regulation" of Field Current or Output of Generator. (See chart 187 for wiring diagram.) Note commutator on each end of armature.



Starting Operation, to Explain Diagram Page 382.

"Hudson" Six-40 as an Example.

(1) **Pull out ignition switch *M or B.** If M, current for ignition is taken from circuit (1), storage battery (page 382). If B, switch is pulled out, ignition is taken from dry cells (2). In both instances the generator circuit is closed at (X), and generator armature (now acting as a slow running motor), turns over slowly so that starting gears (fig. 1, chart 188), can be meshed. See page 399—"motoring the generator."

(2) **Depress "electric starter pedal"** (fig. 2 above); this action lowers motor brush (MB) and opens the generator circuit at (A1—fig. 2, page 382)—see figs. 1 and 2, page 384 and note rod (A), which operates this brush (MB) on "motor" commutator, when gear is shifted into fly wheel gear.

(3) **After engine is started**—starting pedal is released—gears are then thrown out of mesh—the motor brush (MB) is raised and generator circuit closed at (A1). Therefore the starting motor is cut out by brush (MB) being raised and generator is in action. The generator brush (GB) remains on its commutator at all times. The opening and closing of its circuit being at (A1).

Note—When either the "M" or "B" button is pulled out and the armature is revolving, a clicking sound will be heard. This is the operation of the generator clutch. This clicking sound will serve as a reminder that the ignition circuit is closed. When the engine is stopped or stalled, do not leave either the "M" or "B" button pulled out, as the battery will discharge through the generator.

1918 Hudson Starting Operation.

By referring to page 391, the 1918 electric system is shown. Note there is but one ignition switch (IGN). The dash board is similar except—a different gasoline regulator and air control is used (fig. 3). The gasoline tank is also on the rear (page 204). A Stewart vacuum system is used.

(1) See that the "gasoline feed regulator lever" is in the center position.

(2) See that the gasoline "air control lever" is in the "hot" position.

Note that the gasoline regulator lever should be moved over to the "rich" position to facilitate starting in cold weather. When this is necessary, the air control lever should be moved over to the "choke" position for a moment when cranking, and should be moved back to a position midway between "choke" and "hot" as soon as the engine starts. If this is not done, the engine will draw too rich a mixture. This applies only when the engine is cold.

Fig. 3

(3) Have the throttle lever an inch from the bottom of the quadrant and the spark lever about three inches from the top of the quadrant. (In cold weather it may be necessary to open the hand throttle a little farther than in warm weather.)

(4) **Pull out the ignition button** (IGN) on the combination switch as far as it will come.

(5) Have the left foot ready to use on the accelerator when the engine starts, and with the right foot press down gently on the starting pedal.

(6) After engine starts release starting pedal.

CHART NO. 188A—Starting Operation Delco Electric System—on the Hudson "Six-40" as an example. **Also 1918 Hudson Starting Operation.** *M—on the early Delco system means ignition through storage battery or generator (not magneto); B—through dry cells or an auxiliary battery for starting.

Delco Starting and Generating System Using a "Third Brush" Regulation.

This system is similar to previous Delco system described, except in the "regulation" of current and miner details. We will use this system, to more completely describe the generator and it's functions. The Delco system on the Buick D 54 and D 55 will be used as examples.

*Delco Motor-Generator Principle.

The motor-generator is located on the right side of the engine (chart 188-B).

This consists essentially of a dynamo with two field windings, and two windings on the armature, with two commutators and corresponding sets of brushes, in order that the machine may work both as a starting motor, and as a generator for charging the battery and supplying current for the lights, horn, and ignition.

The ignition apparatus is incorporated in the forward end of the motor-generator. This in no way affects the working of the generator, it being mounted in this manner simply as a convenient and accessible mounting.

The motor-generator has three distinct functions to perform, which are as follows: **1—motoring the generator. 2—cranking the engine. 3—generating electrical energy.**

**"Motoring" the Generator.

"Motoring" the generator means to use the generator armature temporarily as a motor. The purpose of using the generator as a motor is to revolve the armature slowly, so that the gears will mesh with fly wheel gears when starting. If the current was immediately applied to starting motor, it would revolve at full speed immediately. By "motoring the generator" however, the armature revolves slowly until gears are meshed, then the full current is applied to starting motor.

This operation is accomplished when the ignition button on the switch is pulled out. This allows current to come from the storage battery through the ammeter on the combination switch, causing it to show a discharge. The first reading of the meter will be much more than the reading after the armature is turning freely. The current discharging through the ammeter during this operation is the current required to slowly revolve the armature and what is used for the ignition.

Meshing gears. This motoring of the generator is necessary in order that the starting gears may be brought into mesh, and should trouble be experienced in meshing these gears, do not try to force them, simply allow the starting pedal to come back, giving the gears time to change their relative position.

Generator Clutch.

A clicking sound will be heard during the "motoring of the generator." This is caused by the "over-running of the clutch" in the forward end of the generator which is shown in (fig. 1, chart 188-B and fig. 16, page 398).

The purpose of the generator clutch is to allow the armature to revolve at a higher speed than the pump shaft during the cranking operation and permitting the pump shaft to drive the armature when the engine is running on its own power. Spiral teeth are cut on the outer face of this clutch for driving the distributor. This portion of the clutch is connected by an Oldham coupling to the pump shaft. Therefore, its relation to the pump shaft is always the same and does not throw the ignition out of time during the cranking operation.

Lubrication of clutch is from the oil that in contained in the front end of the generator which is put in at B (fig. 1, chart 188-B.) This is to receive oil each week sufficient to bring the oil up to the level of the oiler.

Cranking Operation.

The cranking (engine starting) operation, takes place when the starting pedal is fully depressed. The starting pedal brings the motor clutch gears, (fig. 1, chart 188-B) into mesh and withdraws the pin P, (figs. 1 and 2) allowing the motor brush switch to make contact on the motor commutator. At the same time the generator switch breaks contact. This cuts out the generator element during the cranking operation.

As soon as the motor brush makes contact on the commutator, a heavy current from the storage battery flows through the series field winding and the motor winding on the armature. This rotates the armature and performs the cranking operation. The cranking circuit is shown in the heavy lines on the circuit diagram (lower illustration.)

This cranking operation requires a heavy current from the storage battery. If the lights are on during the cranking operation, the heavy discharge from the battery, causes the voltage of the battery to decrease enough to cause the lights to grow dim.

*When the word "motor-generator" appears coupled together this indicates they are combined in one unit.

**See page 399 for principle, troubles and tests.

Cranking current. This is noticed especially when the battery is nearly discharged; also will be more apparent with a stiff engine or with a loose or poor connection in the battery circuit or a nearly discharged battery. It is on account of this heavy discharge current that the cranking should not be continued any longer than is necessary, although a fully charged battery will crank the engine for several minutes.

Ammeter readings during cranking operation: During the cranking operation the ammeter will show a discharge. This is the current that is used both in the shunt field winding and the ignition current; the ignition current being an intermittent current of comparatively low frequency, will cause the ammeter to vibrate during the cranking operation. If the lights are on, the meter will show a heavier discharge.

The main cranking current is not conducted through the ammeter, as this is a very heavy current and it would be impossible to conduct this heavy current through the ammeter and still have an ammeter that is sensitive enough to indicate accurately the charging current and the current for lights and ignition.

As soon as the engine fires the starting pedal should be released immediately, as the overrunning motor clutch is operating from the time the engine fires until the starting gears are out of mesh. They operate at a very high speed and if they are held in mesh for any length of time, there is enough friction in this clutch to cause it to heat and burn out the lubricant. There is no necessity for holding the gears in mesh.

Motor Clutch.

The "motor" clutch operates between the fly wheel and the armature pinion and is for the purpose of getting a suitable gear reduction between the motor generator and the fly wheel. It also prevents the armature from being driven at an excessively high speed during the short time the gears are meshed after the engine is running on its own power.

This clutch is lubricated by the grease cup D, shown in (fig. 1, chart 188-B.) This forces grease through the hollow shaft to the inside of the clutch. This cup should be given a turn or two every week.

How One Armature is Used for Starting Motor also Generator.

When the cranking operation is finished the motor brush switch is raised off the commutator by the pin (P) when the starting pedal is released. This throws the starting motor out of action. As the motor brush is raised off the commutator the generator switch makes contact and completes the charging circuit. The armature is then driven by the extension of the pump shaft and the charging begins.

Charging current: At speeds above, approximately 7 miles per hour, the generator voltage is higher than the voltage of the storage battery, this causes current to flow from the generator in the charge direction to the storage battery. As the speed increases, up to approximately 20 miles per hour, this charging current increases also, but at the higher speeds the charging current decreases.

The curve on page 390 shows approximately, the charging current that should be received for different speeds of the car. There will be slight variations from this, due to temperature changes and conditions of the battery which will amount to as much as from 2 to 3 amperes. The regulation of the generator current is explained on page 389. Which in this particular instance is the "third brush regulation."

Generating Electrical Energy.

If we have a generator in which the magnetic field remains constant and the generator produces 7 volts at 400 R. P. M., the voltage at 800 R. P. M. would be 14 volts, and it is on account of this variable speed of generator for automobile purposes that they must be equipped with some means of regulation for holding the voltage very nearly constant. The regulation of this generator is by what is known as **third brush excitation, the theory of which is as follows:**

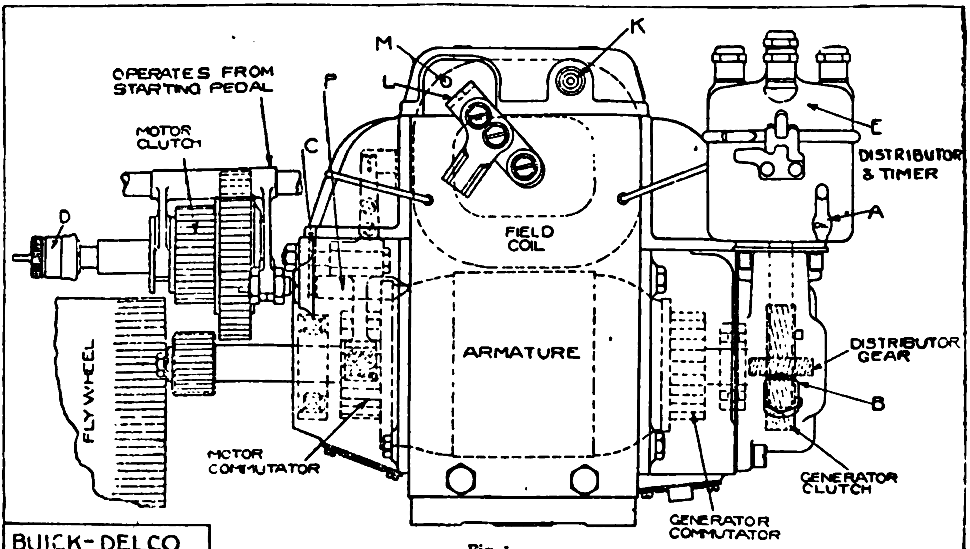
*The motor-generator consists essentially, of an iron frame and two field windings for magnetizing the pole pieces. The armature, which is the revolving element, has wound in slots on its iron core, a motor winding and a generator winding, connected to corresponding commutators. Each commutator has a corresponding set of brushes which are for the purpose of collecting current from, or delivering current to the armature windings while it is revolving.

When cranking, current from the storage battery flows through the motor winding, magnetizing the armature core and coils, and also the fields. This being acted upon by the magnetism of the pole pieces or the "field of force" between them causes the turning effort.

When generating, the voltage is induced in the generator winding and when the circuit is completed to the storage battery this causes the charging current to flow into the battery.

How "direct" current is obtained: The current flows in one direction in a given coil while under the influence of one pole piece, and in the other direction when under the influence of the opposite pole. If these cur-

*The motor generator serves both as a generator and as an electric motor for cranking the engine when starting. There are two windings on the armature and two in the field—one on the armature and one on the field are used when the motor generator is used as a generator and the other windings when it is used as a motor. See Cadillac-Delco wiring diagram, page 396.



BUICK-DELCO
BUICK D54-D55

Fig. 1

NOTE.—On the later models a change has been made in the oiler at B.

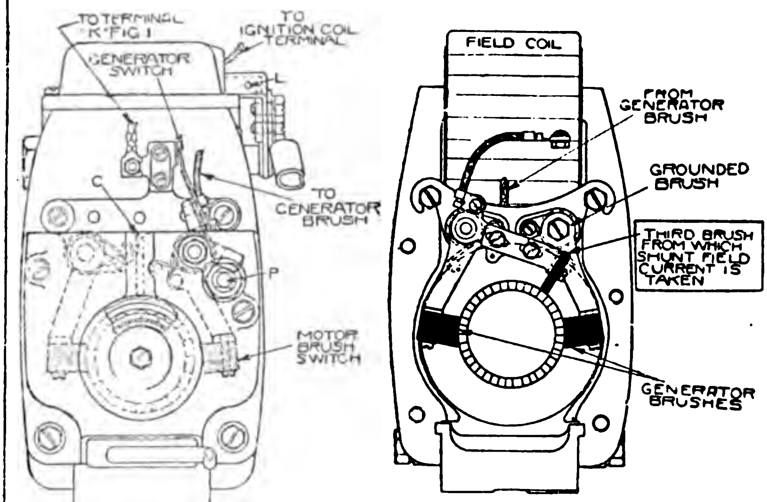


Fig. 2

The output of these generators can be increased or decreased by changing the position of the "third brush." Each time the position of the brush is changed it is necessary to sandpaper it so that it fits the commutator per page 404. Otherwise the charging rate will be very low, due to the poor contact.

The charging current should be carefully checked, and in no case should the maximum current on this generator exceed 22 amperes. Careful watch should be kept on machine on which the charging rate has been increased, to see that commutator is not being overloaded.

Note generator clutch connects with pump shaft not shown (see page 377 how distributor shaft is driven).

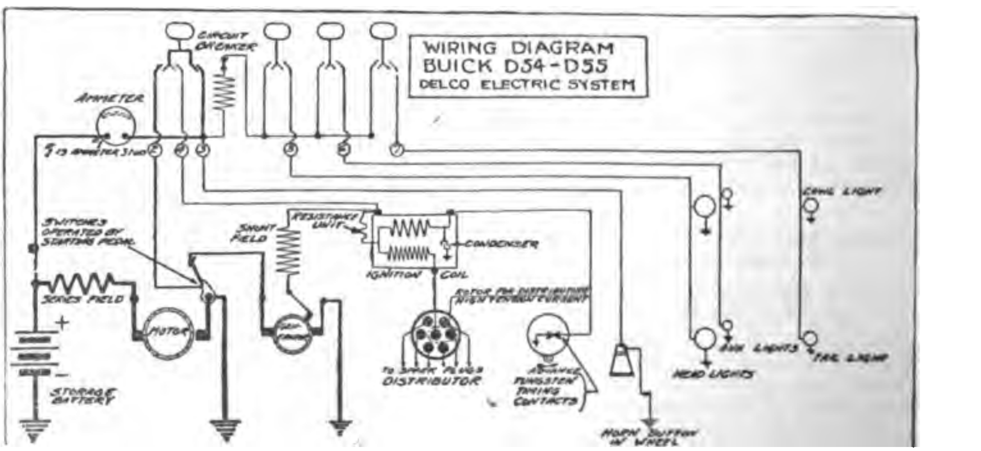

CHART NO. 188B—The Delco "Single Unit" System with "Third Brush Regulation" of the Shunt Field Winding—system used on the Buick D54-D55. The cut-out is not used.

On the "Buick-six" 1918 model—the generator and motor commutators are at front end of armature. The ignition coil (fig. 4, page 245), is placed on top of motor generator. Wiring etc. otherwise is similar.
***See page 497 for dash board and control of the Buick.**

rents were collected through "slip rings" instead of a commutator, they would be true alternating currents. But as we want "direct" current, we commute them (or turn them in one direction) through the medium of a commutator. Each segment on the commutator represents one end of a coil or set of coils, dependent on the way it is wound. There are many ways of winding and connecting armature coils, but the principle is as outlined above.

When the ignition button on the combination switch is first pulled out the current flows from the storage battery through the generator armature winding, also through the shunt field winding. This causes the "motoring of the generator."

After the engine is started and is running on its own power this current still has a tendency to flow in this direction, but is opposed by the voltage generated. At very low speeds a slight discharge is obtained. At approximately 7 miles per hour the generated voltage exceeds that of the battery and charging commences. As the speed increases above this point the charging rate increases as shown by the curve (fig. 15, page 390).

The ignition current flows only when the contacts are closed, it being an intermittent current. The maximum ignition current is obtained when the circuit is first closed and the resistance unit on the rear end of the coil is cold. The current at this time is approximately 6 amperes, but soon decreases to approximately 3½ amperes. Then as the engine is running, it further decreases until at 1000 revolutions of the engine it is approximately 1 ampere.

**Third Brush Regulation.

The regulation of this generator is effected by what is known as third brush excitation. From the foregoing explanation of the generating of electricity and from the fact that the voltage generated varies directly with the speed, **it is evident in order to maintain a nearly constant voltage with a variable speed, it becomes necessary to decrease the magnetic field as the speed increases.**

Since the magnetic field of the generator is produced by the current in the shunt field winding it is evident that should the shunt field current decrease, as the speed of the engine increases the regulation would be affected. In order to fully understand this explanation it must be borne in mind that a current of electricity always has a magnetic effect whether this is desirable or not.

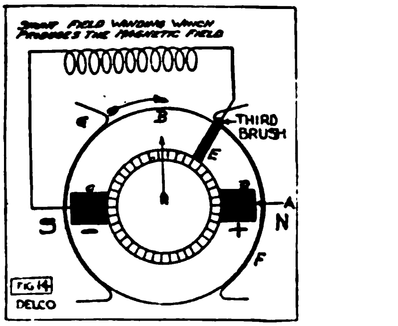

Fig. 14. The Delco third brush regulation: The third brush (E) is adjustable. On the "single unit" Delco systems this brush is exposed when the front end cover of generator is removed. On all "two unit" systems the third brush is located on the lower side of commutator.

Moving this brush in direction of rotation, increases the charging rate to battery.

Moving brush in opposite direction decreases the charging rate.

Referring to (fig. 14) the theory of this regulation is as follows: The full voltage of the generator is obtained from the large brushes marked "C" and "D." When the magnetic field from the pole pieces N and S is not disturbed by any other influence each coil is generating uniformly as it passes under the pole pieces.

***The voltage from one commutator bar to the next one gradually increases,** from zero to full voltage (dependent on position of coil to which commutator bar is attached).

The voltage from brush C to brush E is about 5 volts when the total voltage from brush C to brush D is 6½ volts and 5 volts is applied to the shunt field winding. This 5 volts is sufficient to cause approximately 1¼ amperes to flow in shunt field windings.

As the speed of the generator is increased, the voltage increases, causing the current to be charged to the storage battery.

The charging current flows through the armature winding, producing a magnetic effect in the direction of the arrow B. This magnetic effect acts upon the main magnetic field which is in the direction of the arrow A with the result that the magnetic field is twisted out of its original position in very much the same manner as two streams of water coming together are each deflected from their original directions. This deflection causes the magnetic field to be **strong** at the pole tips marked G and F, and **weak** at the opposite pole tips, with the result that the coils generate a very low voltage while passing from the brush E to the brush D (the coils at this time are under the pole tips having a weak field) and generates a greater part of their voltage while passing from the brush C to E. The amount of this variation depends upon the speed that the generator is driven; with the result that the shunt field current decreases as the speed increases as shown in the curve (fig. 15.)

***Roughly speaking, zero potential** is midway between the pole pieces and at maximum when leaving pole horns, as at points G and F. ****See also page 925** for **explanation of the Bijur third brush system** and pages 343 and 345 for different generator regulation systems. See also, page 864C.

By this form of regulation it is possible to get a high charging rate between the speeds of 12 and 25 miles per hour, and it is with drivers whose average driving speed comes between these limits that more trouble is experienced in keeping the battery charged. At the higher speeds the charging current is decreased. The driver who drives his car at the higher speeds requires less current, as experience has taught that this type of driver makes fewer stops in proportion to the amount the car is driven than the slower driver.

Regulating Charging Current.

The output of these generators can be increased or decreased by changing the position of the regulating brush. Each time the position of the brush is changed it is necessary to sand paper the brush so that it fits the commutator. Otherwise the charging rate will be very low due to the poor contact of the brush. This should not be attempted by any one until thoroughly understood, and this charging current should be carefully checked and in no case should the maximum current on this generator exceed 22 amperes. Also careful watch should be kept on any machine on which the charging rate has been increased to see that the commutator is not being overloaded.

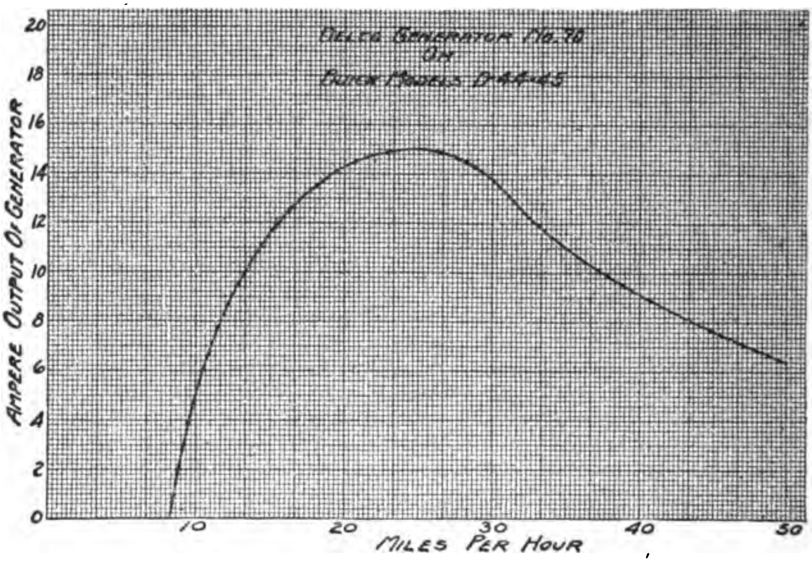

Fig. 15—Showing the amperage of the Delco generator at various speeds. Note the shunt field current decreases as the speed increases above 25 miles per hour.

To read this chart, note the miles per hour are shown at the bottom, and the ampere output at the left side of chart. Example: At a car speed of 20 miles per hour what is the ampere output? Find 20 at the bottom and follow vertical line until it meets the black wave line, then follow horizontal line to the left edge and we find 14 amperes,—the output at this speed. At higher speeds, say 35 miles per hour, the output drops to 11 amperes, and at 40 miles it drops to 9 amperes.

Considerable variation (from the curve shown) in the output of different generators, will be obtained as the generator is affected by temperature and battery conditions.

*To Time the Delco Ignition.

When timing the spark the cam A (fig. 7, page 378) is moved with respect to the shaft upon which it is mounted, which is done by loosening a screw (A) in the end of the shaft and again tightening it after the cam has been moved the desired amount. Turning the cam in a **clockwise** direction, or toward the right, **advances** the time of ignition, and **counter-clockwise**, or to the left, **retards** it. **To adjust timer,** see page 378.

To time Hudson-Delco; place spark lever at top of steering wheel quadrant. Place No. 1 cylinder piston on top of compression stroke. No. 1 cylinder is due to fire in advanced position, when mark (A) on fly wheel reaches the pointer attached to the crank case. This may be observed through the inspection hole on the fly wheel housing left side of engine. Mark (A) is ⅛" before top center (top center is marked D-C-1 & 6).

Loosen cam and set to break at this point. The adjusting screw A, fig. 8, page 377 and fig. 7, page 378, on the cam must always be set tight after changing adjustment. The spark occurs at the instant timer contacts are open.

In checking the timing, the cam should be held on tension in the opposite direction of rotation so that all back lash is taken up when rotor button comes under No. 1 contact on distributor head.

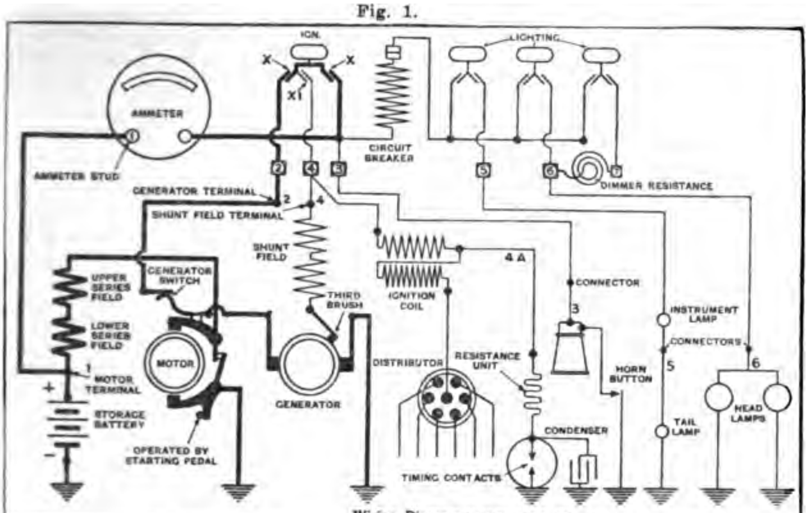
After checking the timing replace rotor (K), fig. 8, page 377. Rub a little vaseline on the rotor track of the distributor head before seeing that it is down tight in position.

†To time Buick "six" and "four;" see page 246.

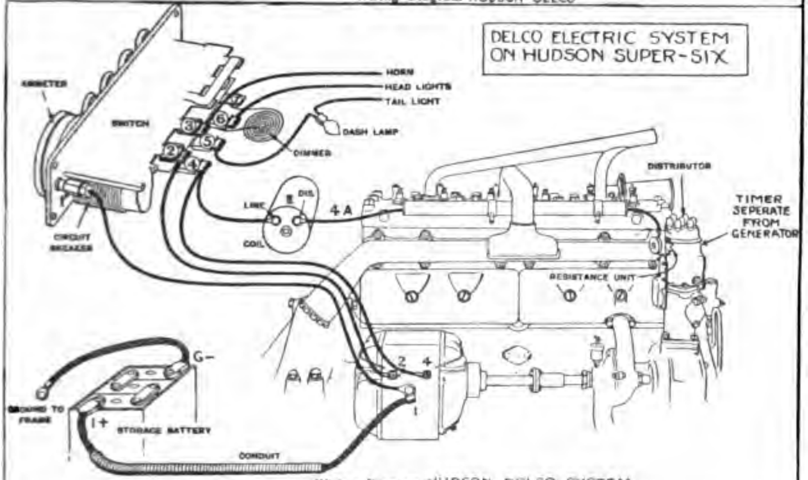
To time Cadillac-Delco; see pages 132 and 729.

*See page 543—"Standard Adjustments." †Also for Buick "D44 to 47."
**See pages 544 to 546 for cars using Delco system.

Fig. 1.



Wiring Diagram HUDSON-DELCO



Wiring Diagram HUDSON-DELCO SYSTEM

Hudson-Delco Generator.

A new feature of this generator which differs from the Hudson system in charts 187, 188, and 188A is the third brush method of regulation as shown in chart 188B. Referring to this chart, it will be seen that all the current passing through the shunt field winding must pass through this third brush. At the higher speeds of the armature the voltage at this third brush decreases, and less current will flow through the shunt windings thus weakening the magnetic field of the generator. This decreases the output of current at high speeds.

The output can be varied by adjusting the third brush; moving this brush to the left decreases the charging rate; moving it to the right increases the charging rate.

The adjustment of this brush should not be changed except when absolutely necessary, and must be carefully checked to make sure that the charging rate is not above the capacity of the generator or battery.

The brush must be sanded to fit the commutator each time it is adjusted. (See chart 188-K. and L.) Poor contact lowers the charging rate. If the charging rate is materially increased, the battery will be subjected to an overcharge and the voltage of the entire system will be raised. This will shorten the life of the lamps and battery and cause excessive burning of breaker contacts.

Motor Circuit.

When the starting gears are meshed as explained on page 385, further depression of the starting pedal causes the generator switch to break contact, thus opening the generator circuit. When the starting pedal is fully depressed the motor brushes make contact with the motor commutator, thus closing the motor circuit, and the cranking operation commences. The current now flows through the heavy cable and around the windings of the armature and motor field. During the cranking operation, current will flow through the combination switch at contacts X-1, fig. 1, and through the shunt field winding. Thus the motor operates as a compound wound starting motor.

Ignition Circuit.

When the ignition button is pulled out, contacts X fig. 1 are closed. This allows current from the storage battery to flow through these contacts, then through terminal 4 to the ignition coil; then through the primary winding of the ignition coil and the timing contacts to ground. The high tension part of the ignition system produces the spark at each spark plug when the engine is being cranked, causing the engine to start and run on its own power. Note when the engine is running and generator delivering current to the storage battery, the ignition current is taken direct from the generator, instead of from the storage battery. Otherwise the circuit is the same.

Distributor and Timer.

The distributor and timer is separate from the motor-generator, and is carried on the front of the engine above the timing gears. It is driven by spiral gears from the pump shaft.

To time the ignition, see page 390. The timer is of the closed circuit type, fig. 7, page 378.

CHART NO. 188C—Hudson "Super-Six"—Delco Electric System: A "Two-unit" System. "Single," or grounded return wire. Ignition is "automatic advance," using a **closed circuit type** interrupter. See pages 382, 384 and 385 for Hudson "Six-40" Delco system.

See page 437 for explanation of the resistance type "dimmer" as shown above connected to 6 and 7.

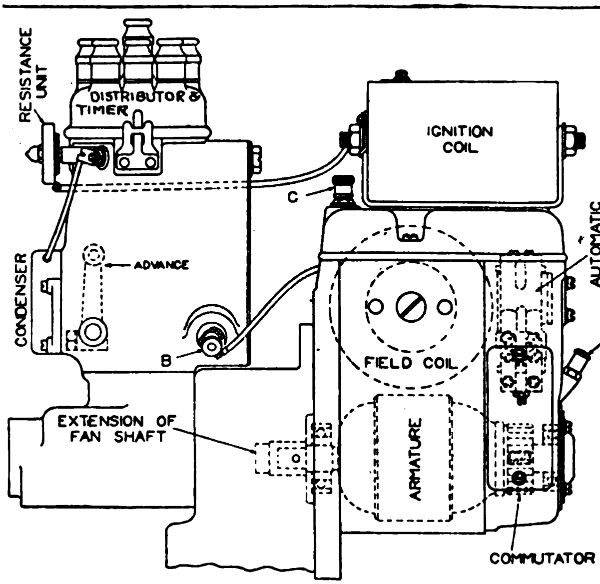


Fig. 3 Generator.

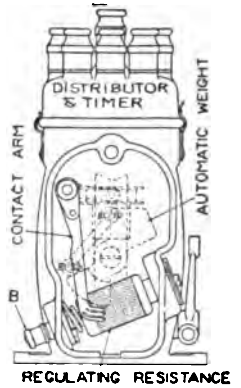
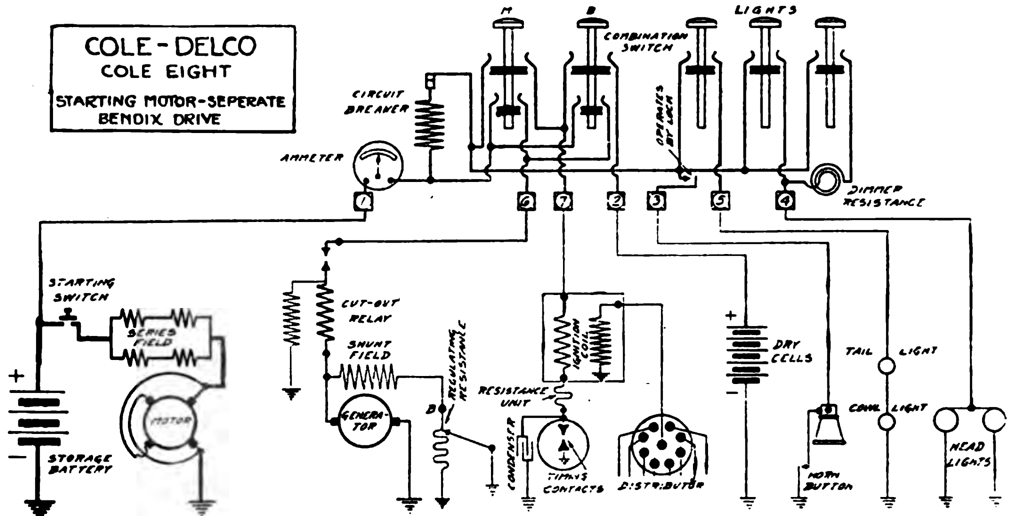


This Delco system differs from previous systems explained, in that the starting motor is separate and employs the Bendix drive system as explained in chart 160.

The generator therefore does not combine the principle of a motor and generator. Only one commutator is used.

The field coil contains the shunt winding, which is for the purpose of producing the magnetic field, the connections of which



COLE Wiring Diagram.

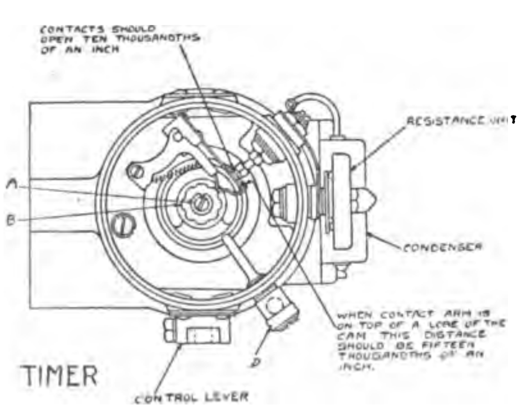


Fig. 37

are shown in the circuit diagram, and the location of the coil is also shown.

"Variable resistance regulation" is employed to control the output of generator as explained in chart 188, fig. 8.

The charging current increases as the speed of the generator increases, until the regulating arm in the distributor moves on to the wire on the regulating resistance (see above), which inserts resistance in the shunt field circuit and decreases the strength of the magnetic field in the generator, thereby controlling the output or charging current. This is called the "variable resistance" regulation as previously explained.

A "cut-out" is employed in this system to open and close the circuit between the battery and generator. This "cut-out" is not used on many of the other Delco systems.

The timer fig. 37, is of the open circuit type—see fig. 6, page 378.

CHART NO. 188D—Cole Eight—Delco Electric System. The starting Motor is separate with a Bendix Drive System. The Regulation of current output is the "Variable Resistance method as explained in chart 188. This is a grounded wire "two unit system." A magnetic "cut-out" is employed (1917 model).

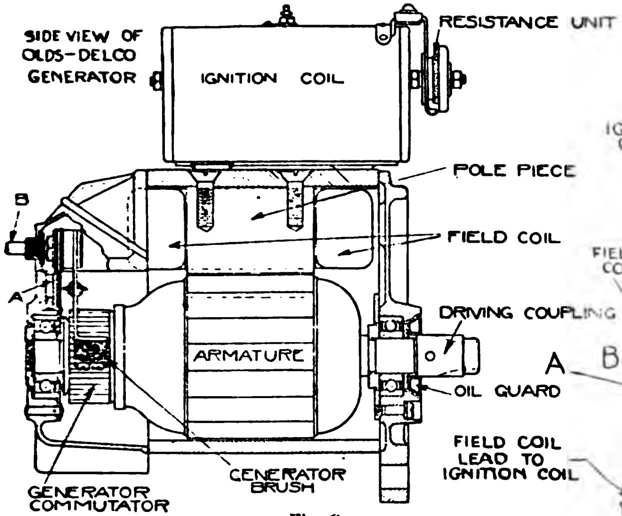

Fig. C.

Distributor & TIMER - DELCO - SEPERATE
Ignition Coil.

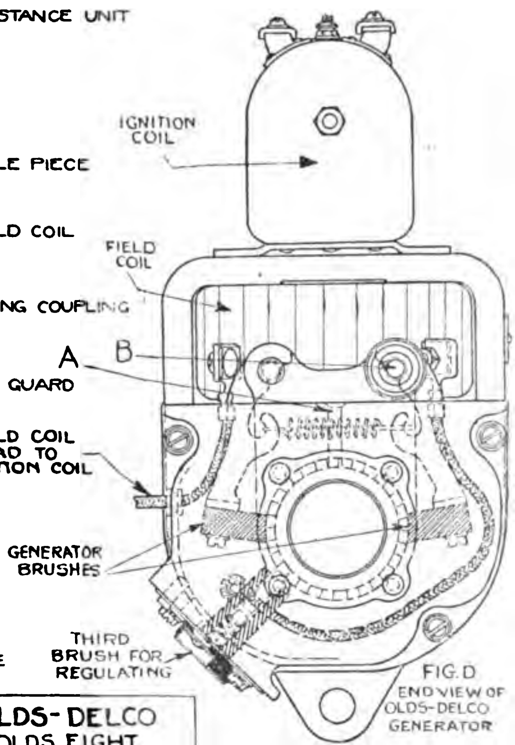

FIG. D
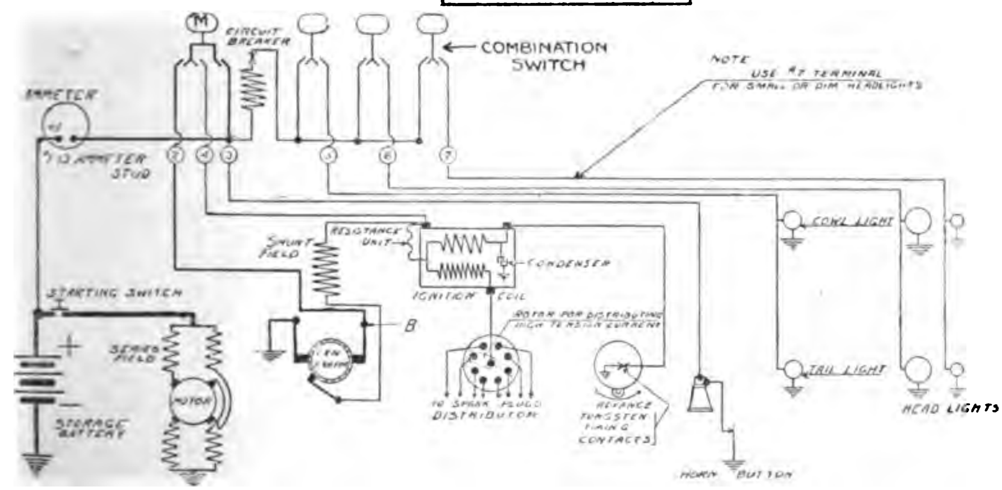
END VIEW OF
OLDS-DELCO
GENERATOR

OLDS-DELCO
OLDS EIGHT



The Delco generator employs the "third brush" system of regulation as shown in fig. D, above and as previously explained.

The wiring principle is the grounded return wire system. Note the wires are run in flexible conduit—see chart 188F.

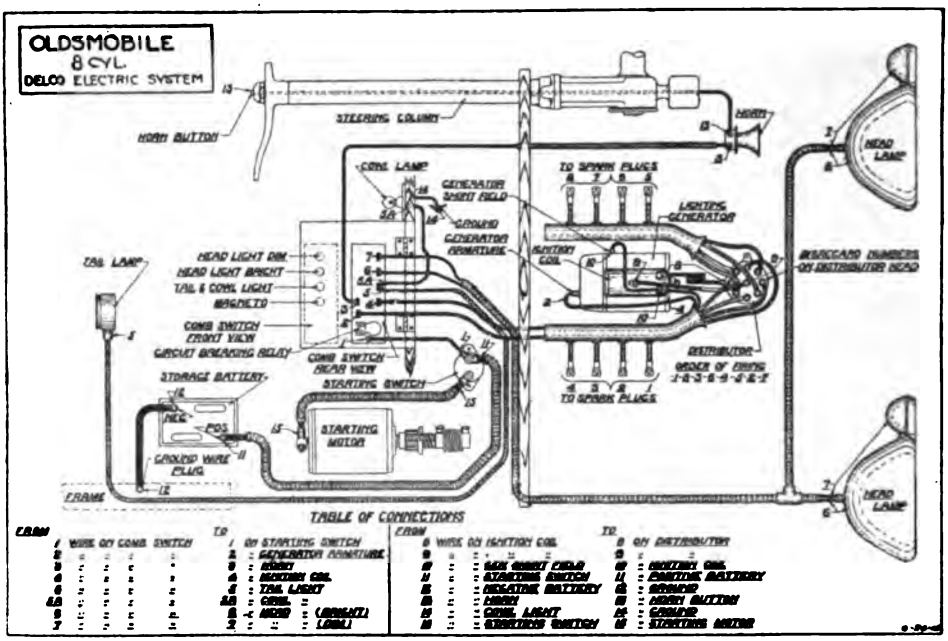
The ignition is similar to the other Delco systems previously explained with automatic advance. The distributor and timer are located in front of the engine and driven by gears from the same shaft which drives the generator.

The starting motor on the Olds is separate from the Delco generator.

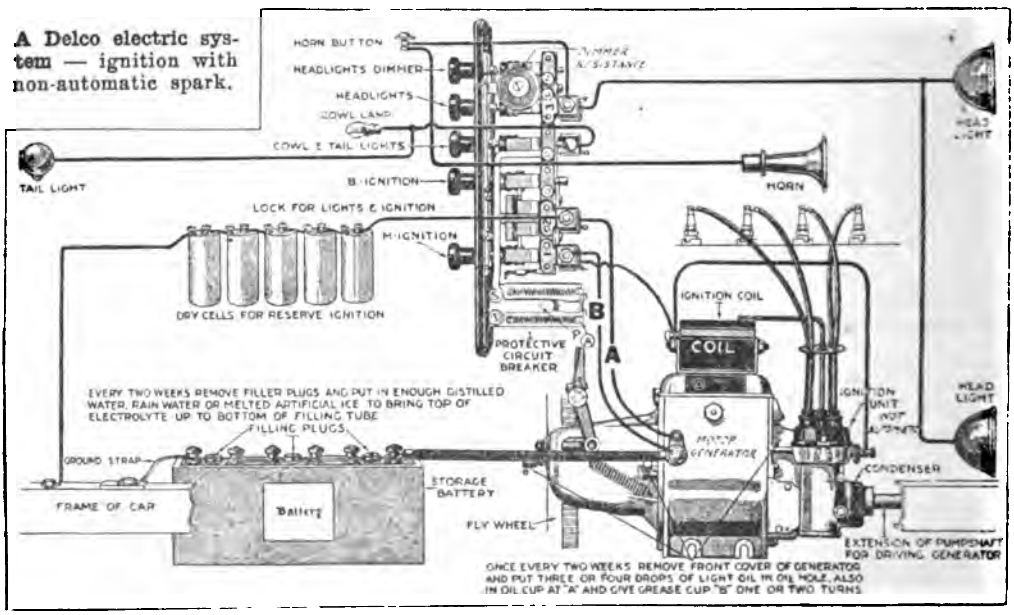
The starting motor is located back of the flywheel on the lower right side. This is a four-pole series wound motor, the circuit of which is very plainly shown in the circuit diagram (above). It will be noted that each field coil is connected in parallel with another field coil and each of these are in series with the armature winding. It is connected in such a manner that the armature is in the circuit between the two pairs of field windings.

The starting switch is located on the toe board and connected in the circuit between the storage battery and the starting motor. The drive between the starting motor and flywheel is by means of the Eclipse-Bendix gear which is entirely automatic in its performance. (See chart 188F).

CHART NO. 188E—Olds Eight—Delco Electric System: Starting Motor separate with Bendix Drive. Generator with "Third Brush" Regulation. Ignition separate. A "Three-unit" system. Automatic advance of spark. 1917-18.



Oldsmobile-Delco electric diagram as referred to on page 393.



A Delco electric system — ignition with non-automatic spark.

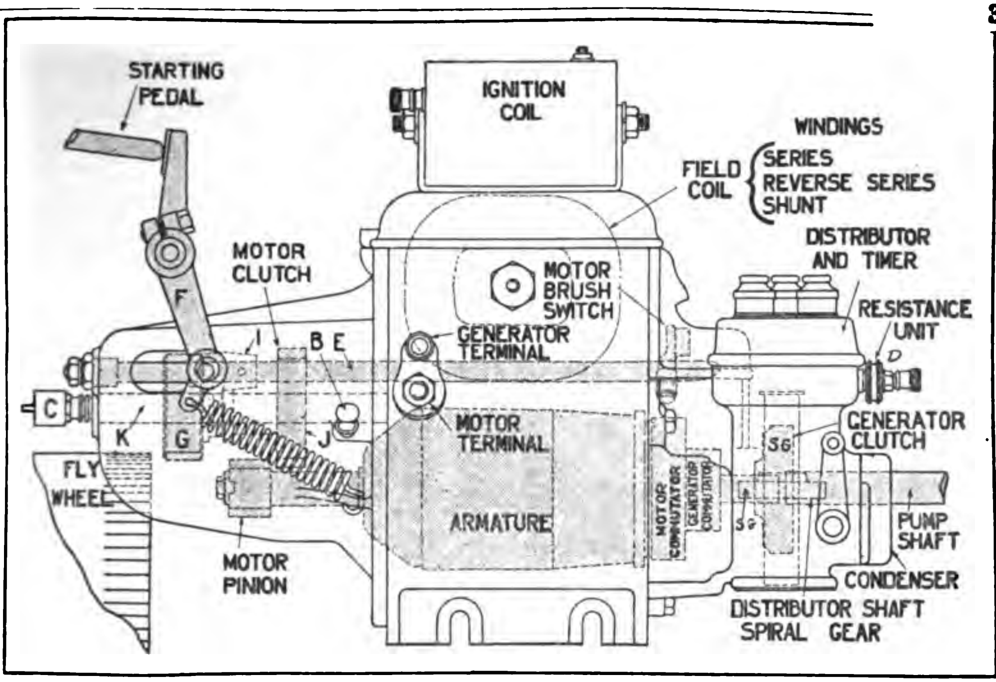
Fig. 2. Illustration shows a Delco system with non-automatic spark advance and an armature with both commutators on one end. This illustration shows a diagramatic view while fig. 1, chart 188G shows the circuit view.

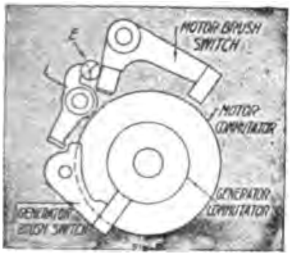
The regulation is called the "reverse-series"—see diagram in chart 188G. The principle otherwise is identically the same as other Delco systems.

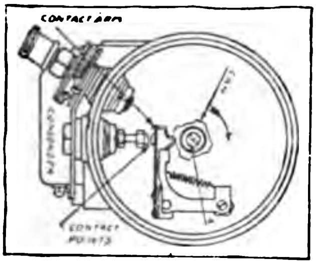
Ignition—Note the coil is mounted on the top of the motor-generator, it could be mounted on the dash under the hood.

The timer (see chart 188G) is a four point, therefore for a four cylinder engine, note **ignition resistance unit** and **condenser** is mounted on timer in this instance, instead of the coil, as per fig. 4, page 245.

CHART NO. 188F—Oldsmobile Eight—Delco Electric System. Also see chart 188E. **Another Delco System** is shown in fig. 2, which is a diagramatic view of system illustrated in chart 188G.







The timer for a four-cylinder engine has but four lobes, or projections.

STARTING OPERATION

Illustration shows the operation of the generator and the motor brush switches, both of which are operated by the Pull Rod "E." This also operates the starting gear. The complete starting operation is as follows:

1. **When either the "M" or "B" button on the Combination Switch is pulled out the circuit between the generator and the storage battery is closed.** The current will flow from the storage battery through the generator windings, which causes it to rotate slowly.

2. **As the starting pedal is pushed out, it operates the pull rod "E"** which causes the gear "J" of the motor clutch to mesh with the motor pinion, and this causes the motor clutch to rotate slowly. As the pedal is pushed further out the gear "G" meshes with the teeth on the face of the flywheel.

3. **As soon as the gears are meshed on the flywheel, the pull rod "E"** raises the lower generator brush off the commutator. (Also see below).

4. **When the pull rod "E" has been moved far enough by the starting pedal to bring the gears fully in mesh, it then allows the** motor brush to drop on the commutator and completes the cranking circuit.

After the Engine is started, the pull rod (E), throws gear (G) out of mesh with fly wheel, raises the motor brush (MB), places the generator brush (GB), on its commutator. (See below).

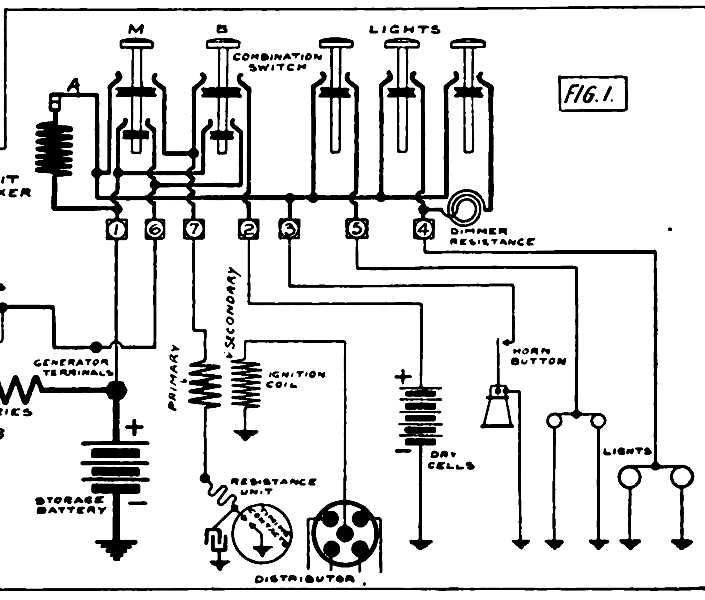


CHART NO. 188G—The Delco System where the Moter and Generator Commutators are placed on same end of Armature. Timer above open-circuit type. (Late systems, (B) switch eliminated.)

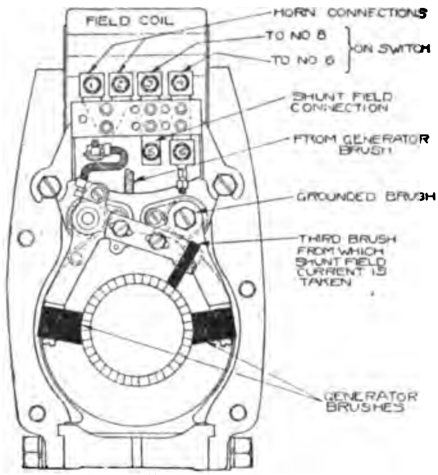

FIG 8 GENERATOR END VIEW CADILLAC-DELCO. Fig. 8.

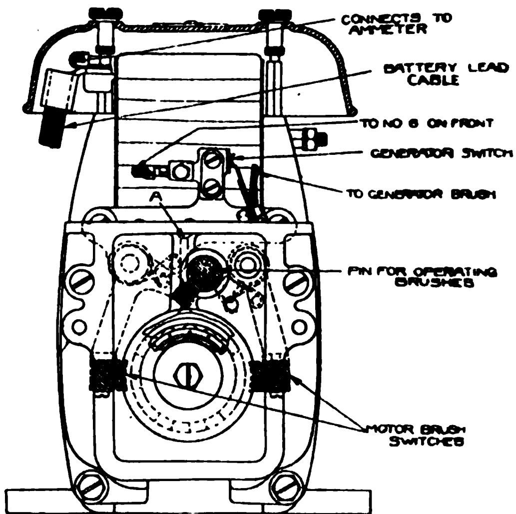

FIG 7 MOTOR END VIEW

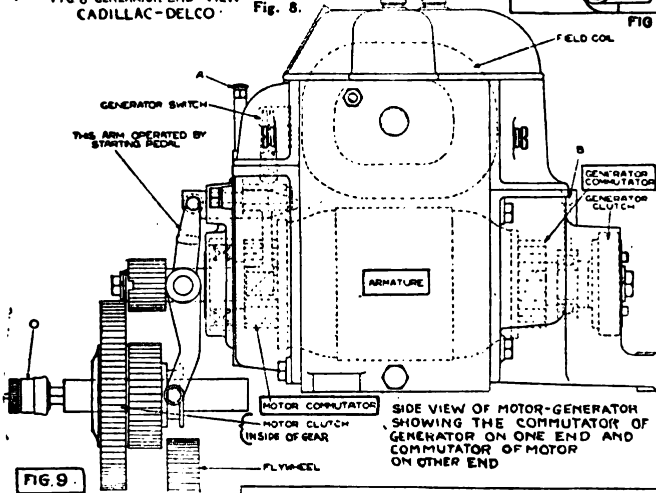

FIG. 9.

SIDE VIEW OF MOTOR-GENERATOR, SHOWING THE COMMUTATOR OF GENERATOR ON ONE END AND COMMUTATOR OF MOTOR ON OTHER END

The Cadillac Eight—Delco system differs but little from other Delco systems. The starting and generating of current is by means of one armature with commutator at each end. The "third brush" regulation system is employed.

The general principle of meshing gears is as per pages 376 and 388.

See pages 132 and 133 for Delco-Cadillac ignition wiring diagram.

The type 51 Cadillac used a "variable resistance" in the shunt winding of generator, whereas the type 53, 54, 55, 57 uses the "third brush" regulation as shown above.

See foot note bottom page 387 relative to windings on armature and field.

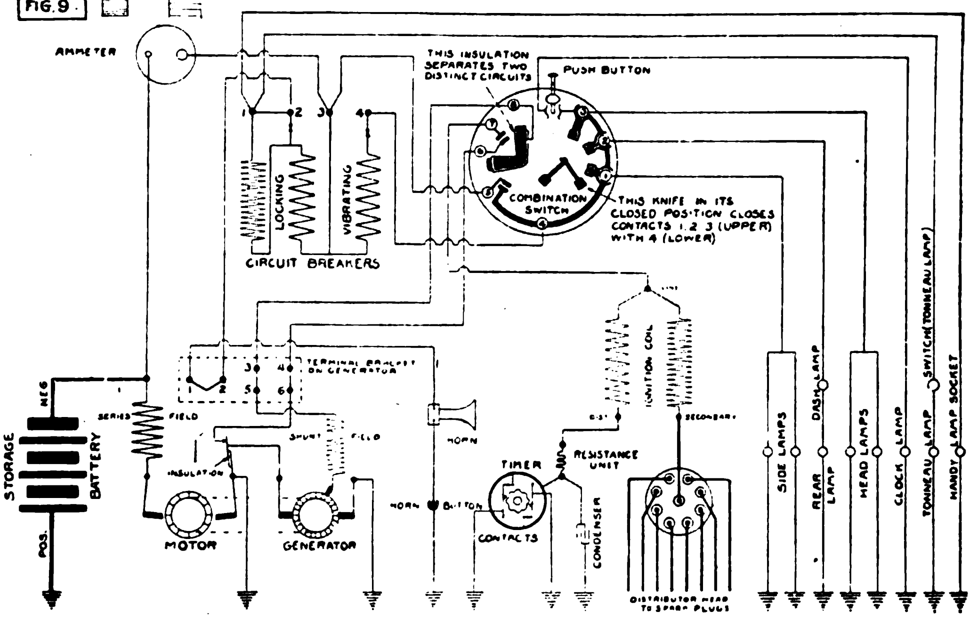

CHART NO. 188H—Cadillac—Delco Electric System. Also see pages 132 and 133. This system is a "Two-unit" single or grounded return, system of wiring.

INSTRUCTION No. 28-C.

CARE, TESTS AND ADJUSTMENTS OF DELCO ELECTRIC SYSTEMS: Lubrication. Size of Resistance Units to Use. Removing Generator Clutch. Testing for Defective Condenser and Ignition Coil. Testing Light Circuits, Short Circuits, Open Circuits, Armature, Field Windings, Etc. Volt-Ammeter for Testing. Principle and Construction of a Volt-Ammeter. Test Lights. Hints for Locating Delco Troubles. Adjusting Third Brush Regulation. Commutator and Brush Adjustments, Etc. Repairing Commutator, Etc.

Lubrication of the Delco System.

There are five principal places to lubricate the Delco System. 1—The grease cup for lubricating the motor clutch (D) fig. 1, page 388. 2—Oiler for lubricating the generator clutch and forward armature bearing (B) 3—The oil hole (C) for lubricating the bearings on the rear of the armature shaft. This is exposed when the rear end cover is removed and should receive oil once a week. 4—The oil hole in the dsitributor for lubricating the top bearing of the distributor shaft is at (A) and should receive oil once a week. 5—The inside of the distributor head. Lubricate with a small amount of vaseline, carefully applied two or three times during the first 2000 miles running of the car, after which it will require no further attention. It is desirable to secure a burnished track for the rotor brush on the distributor head. The grease should be sparingly applied and the head wiped clean from dust and dirt. (see page 377.)

Sizes of Delco Regulating Resistance Units to Use.

***Regulating resistance spools** shown at B, fig. 3, page 384, are individually suited to the generators in which they are installed and are marked. Those spools marked No. 817 have the greatest resistance and consequently give the smallest charge. Those marked No. 701 to 703 have less resistance and give a greater charging rate—No. 703 giving the greatest, and the others in proportion.

Since the contact arm (C) (operated by the centrifugal governor) is on the lower coil when running slowly, the resistance spools will not affect the output at these speeds. It is at speed of over 20 miles an hour when the arm has begun to travel over the coil, that the amount of resistance in the circuit affects the output.

In testing the output an ammeter should be inserted between terminal 6 and wire 6 on the generator. (See fig. 2, page 382). On no account should the output exceed 20 amperes, regardless of the speed of the car.

Between 15 and 20 miles an hour, the output should be 12 to 15 amperes, and will gradually decrease as the car speed increases.

Before testing the output of the generator the condition of the battery should be noted. A battery showing about 1250 gravity test is best adapted for checking the generator. (see pages 450 and 451.)

In removing and replacing the resistance units great care should be exercised not to bend the contact arm so that it bears too hard on the spool, or so that it does not touch sufficiently hard to make a good contact. The former makes the arm stick when in the higher position, reducing the charging rate, and the latter increases the resistance, and causes arcing on the resistance unit, eventually burning it out. The resistance units must be snapped into place between the spring retainers so that there is a good contact. When there is no contact the generator is not delivering any current.

By installing a spool of larger size wire the maximum charging rate is but slightly increased and a higher rate is secured above the maximum point. By installing the spool with the wide cap at the bottom the maximum charging rate is increased, with a corresponding increase at higher speed.

*On the generators, which are driven at or near engine speed, the spool 702 is most often used, but 701 and 703 are sometimes used. On generators Nos. 52 and 58, which are driven at 1½ times engine speed, spools Nos. 817 and 955 are used. This "variable resistance" regulation is now seldom used. The "third-brush" regulation being the modern method.

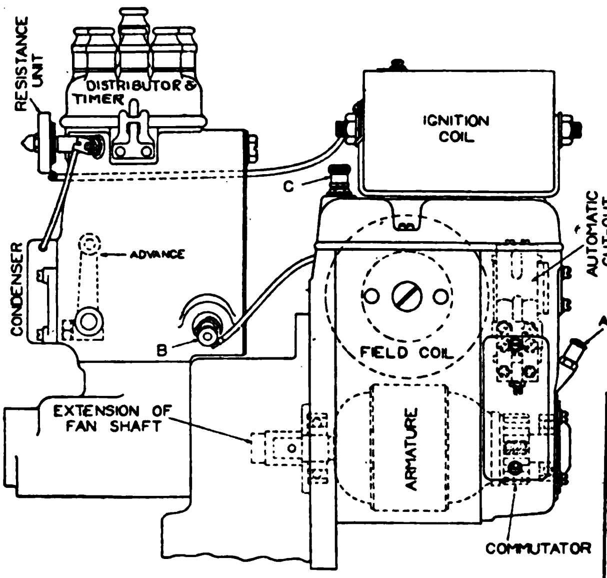

Fig. 3 Generator.

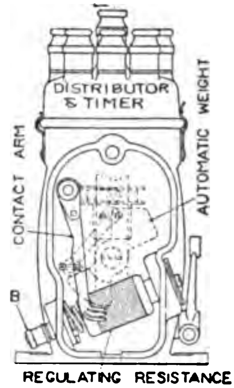
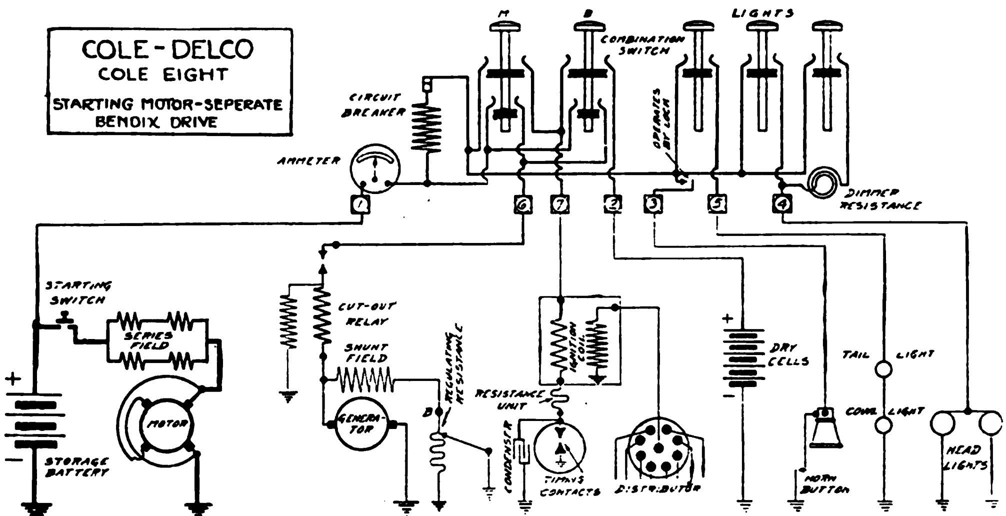


This Delco system differs from previous systems explained, in that the starting motor is separate and employs the Bendix drive system as explained in chart 160.

The generator therefore does not combine the principle of a motor and generator. Only one commutator is used.

The field coil contains the shunt winding, which is for the purpose of producing the magnetic field, the connections of which



COLE Wiring Diagram.

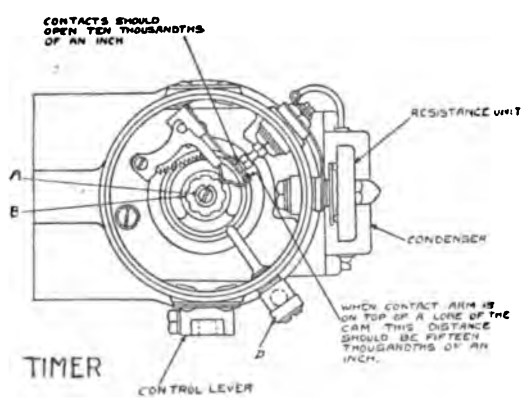


Fig. 37

are shown in the circuit diagram, and the location of the coil is also shown.

"Variable resistance regulation" is employed to control the output of generator as explained in chart 188, fig. 8.

The charging current increases as the speed of the generator increases, until the regulating arm in the distributor moves on to the wire on the regulating resistance (see above), which inserts resistance in the shunt field circuit and decreases the strength of the magnetic field in the generator, thereby controlling the output or charging current. This is called the "variable resistance" regulation as previously explained.

A "cut-out" is employed in this system to open and close the circuit between the battery and generator. This "cut-out" is not used on many of the other Delco systems.

The timer fig. 37, is of the open circuit type—see fig. 6, page 378.

CHART NO. 188D—Cole Eight—Delco Electric System. The starting Motor is separate with a Bendix Drive System. The Regulation of current output is the "Variable Resistance method as explained in chart 188. This is a grounded wire "two unit system." A magnetic "cut-out" is employed (1917 model).

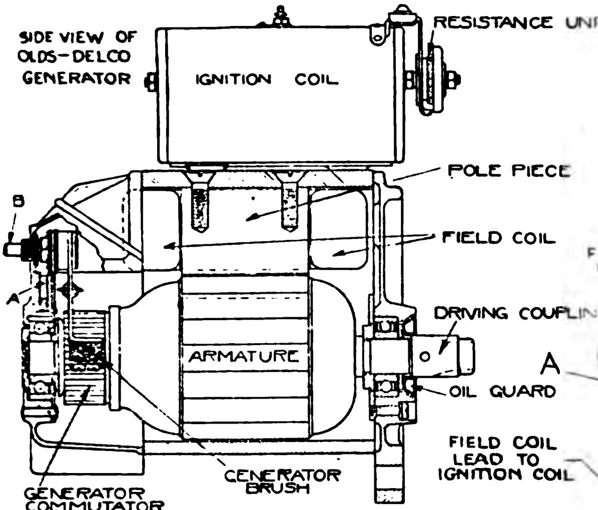

Fig. C.

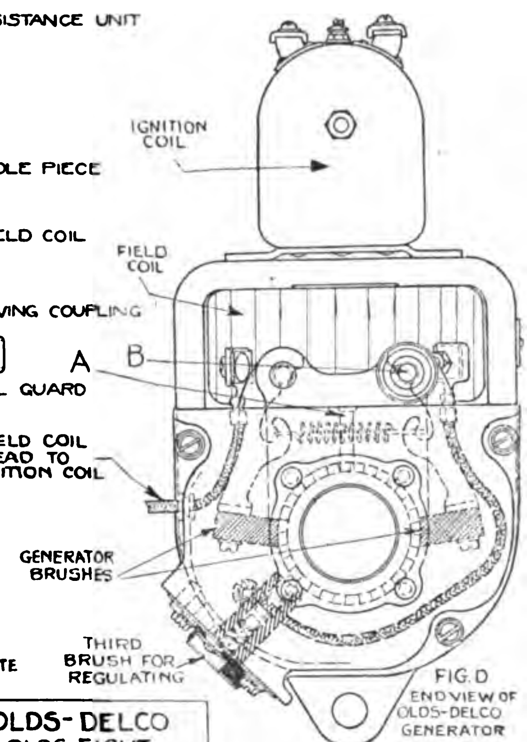
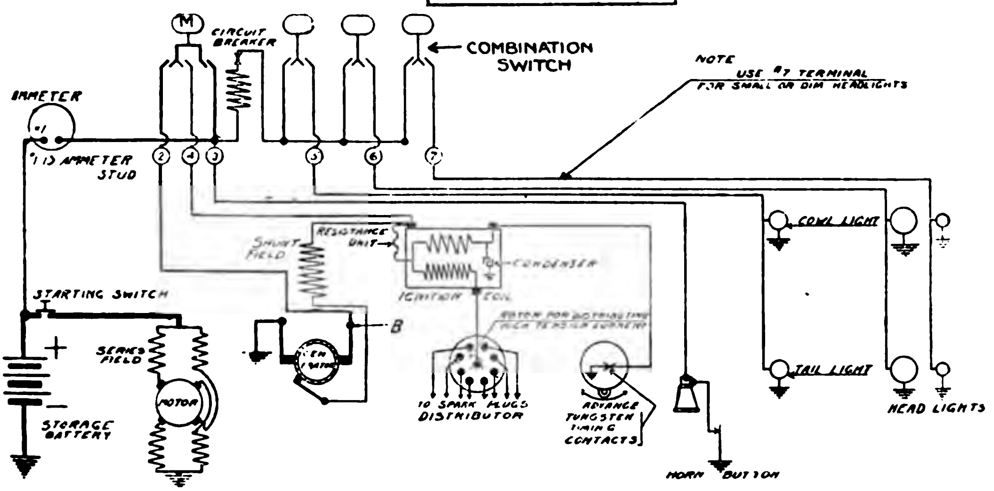
OLDSMOBILE EIGHT ELECTRIC SYSTEM

It is a three-unit, six-volt, grounded system
Starting Motor. BENDIX DRIVE
Starting Motor Switch.
Generator. DELCO
Combination Switch
Distributor & TIMER - DELCO - SEPERATE
Ignition Coil.



OLDS-DELCO
OLDS EIGHT



The Delco generator employs the "third brush" system of regulation as shown in fig. D, above and as previously explained.

The wiring principle is the grounded return wire system. Note the wires are run in flexible conduit—see chart 188F.

The ignition is similar to the other Delco systems previously explained with automatic advance. The distributor and timer are located in front of the engine and driven by gears from the same shaft which drives the generator.

The starting motor on the Olds is separate from the Delco generator.

The starting motor is located back of the flywheel on the lower right side. This is a four-pole series wound motor, the circuit of which is very plainly shown in the circuit diagram (above). It will be noted that each field coil is connected in parallel with another field coil and each of these are in series with the armature winding. It is connected in such a manner that the armature is in the circuit between the two pairs of field windings.

The starting switch is located on the toe board and connected in the circuit between the storage battery and the starting motor. The drive between the starting motor and flywheel is by means of the Eclipse-Bendix gear which is entirely automatic in its performance. (See chart 188F).

CHART NO. 188E—Olds Eight—Delco Electric System: Starting Motor separate with Bendix Drive. Generator with "Third Brush" Regulation. Ignition separate. A "Three-unit" system. Automatic advance of spark. 1917-18.

Principle of a Motor.

When current from the storage battery flows through the field winding it magnetizes the pole pieces and creates a magnetic field between them, in which the armature revolves. Without going to much into technical detail we will simply state that whenever a current of electricity flows through a wire there is a magnetic "field of force" created around it, see page 221, and if this wire be formed into a loop, or closed coil and is placed in the "field of force" flowing between the poles of the motor—it swings around in exactly the same manner as a compass needle or two magnets (as in fig. 12) and will rotate until the unlike poles come to rest as near as possible to each other. This single loop will swing around until it places itself parallel with the lines of force that are flowing from N. to S. pole and there it would come to rest or "dead center."

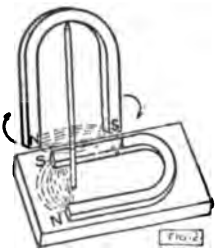


Fig. 12. Magnets will rotate, until "unlike" poles come to rest, near as possible to each other.

To overcome this dead center point it is necessary to have more than a single loop on the armature which you know is always the case. Each loop in turn tries to place itself in this parallel position and in so doing, helps pull the one already there away, due to the fact that they are all on the same revolving piece.

In a motor there is no current in any of the armature coils except those coils with ends fastened to the particular commutator segments that happen to be under the brushes. Each in turn receiving current as it comes under the brush.

During the motoring of the generator the pole pieces are magnetized by the current through the shunt field winding. The armature is magnetized by the current through the brushes and generator winding on the armature. It is necessary that current flows through both of these circuits before the armature will revolve. It is a familiar mistake to think that when current is passing only through the armature the armature should revolve. The shunt field current can be easily checked by disconnecting the shunt field lead from the generator at the ignition coil terminal.

Ammeter reading when "motoring" generator: The ammeter in this line should indicate approximately 1¼ ampere when the ignition button is pulled out. The ammeter on the combination switch can be depended upon to determine the amount of current flowing through the generator winding during this operation. Both the ignition current and the shunt field current flow through this meter in addition to the current through the generator armature. The timing contacts should be open. This will cut off the ignition current and leave only the armature and shunt field current. Since the shunt field current is only 1¼ amperes the reading of the ammeter will readily indicate whether or not current is flowing through the generator armature.

Tests for "Motoring" Generator.

Should it be found that the current through both the armature and the shunt field windings is normal and the armature still does not revolve the trouble may be caused by either (1) the armature being tight mechanically, due to either a sticking driving clutch, trouble in the bearings or foreign particles jammed between the armature and pole pieces. This can be readily tested by removing the front end cover of the generator and turning the armature from the commutator; (2) the shunt field winding or the generator armature winding may be defective in some manner, such as shorted, grounded or connected to the motor winding. (See testing armature on page 402.) Any one of these would show an abnormal reading of the ammeter in some position of the armature when it is revolved by hand.

If the ammeter vibrates at each revolution of the armature during the motoring of the generator, and when the engine is running at low speeds, this is very conclusive proof that the armature has either a ground, open coil, shorted coil, or is connected to the motor winding.

In the generator windings each coil consists of 4, 5 or 6 turns of wire, depending upon whether the generator is to be driven at engine speed or one and one-half times.

***Cranking the Engine.**

Cranking the engine is performed by the current from the storage battery which flows through the series field winding, the motor brushes and armature winding. This much being what is known as a "series" motor, but in addition to this the current flows through the combination switch and the shunt field winding on the generator, making what would be considered, strictly speaking, a compound motor for the cranking operation.

The shunt field current is not absolutely necessary for this operation, but is used because it increases the efficiency of the cranking motor. It can be seen by referring to the circuit, page 388, that the shunt field current would not be in use in the event of the cranking operation being performed when the ignition button is not pulled out.

**This cranking current is a heavy discharge on the storage battery, the average car requiring approximately ½ horse power to perform the cranking operation. 9/10 of all cranking failures is due either to the storage battery or poor connections in the cranking circuit. The first rush of current from the storage battery during the cranking operation varies from 180 to 450 amperes, depending upon the condition of the engine and the storage battery. This is only a momentary flow of current, however, but a poor connection prevents this heavy flow of current and prevents the starter from giving its full force.

This heavy discharge will naturally cause the voltage of the battery to be decreased, and the amount that it is decreased, depends to a great extent upon the condition of the charge of the battery. On a storage battery which is charged so that its specific gravity registers 1200 or more the voltage should not fall below 5 volts on the voltmeter reading when cranking.

**See also, pages 407, 427 and 327. See also page 386 on "cranking operation."

*Hints for Locating Delco Troubles—condensed.

1. If starter, lights and horn all fail, the trouble is in the storage battery or its connections, such as a loose or corroded connection or a broken battery jar.

2. If the lights, horn and ignition are all O. K., but the starter fails to crank, the trouble is in the motor generator, such as dirt or grease on the motor commutator, or the motor brush not dropping on the commutator.

3. If the starter fails to crank or cranks very slowly, and the lights go out or get very dim while cranking, it indicates a loose or corroded connection on the storage batery, or a nearly depleted storage battery.

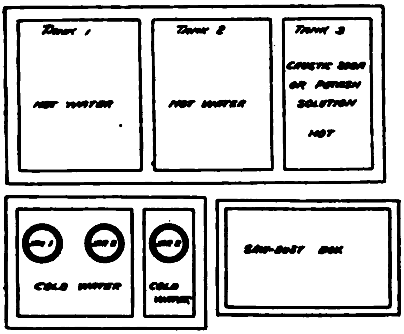
4. If the engine fires properly on the "M" button, but not on the "B" button, the trouble must be in the wiring between the dry cells or the wires leading from the dry cells to the combination switch, or depleted dry cells.

If the ignition works O. K. on the "B" button and not on the "M" button, the trouble must be in the leads running from the storage battery to the motor generator, or the lead running from the rear terminal on the generator to the combination switch, or in the storage battery itself, or its connection to the frame of the car.

5. If both systems of ignition fail, and the supply of current from both the storage battery and dry cells is O. K., the trouble must be in the coil, resistance unit, timer contacts or condenser. This is apparent from the fact that these work in the same capacity for each system of ignition. (Does not apply to all Delco systems.)

Instructions for Cleaning Repair Parts of Delco Apparatus.

The cleaning outfit should consist of three sheet steel tanks of suitable size (preferably about 35 gallons), which are mounted in such a manner that the contents may be kept heated to the desired temperature; three stone jars of approximately 15 gallons capacity; and a sawdust box.



PLAN OF ARRANGEMENT OF TANKS AND JARS FOR CLEANING

Two of the steel tanks should be equipped with overflow pipes so that they can be kept about two-thirds full at all times. These will be spoken of as tank No. 1 and tank No. 2. They are used for clear, hot water for rinsing the apparatus after it has been cleaned. A supply of water should be available, so that this water can be kept as clear as possible.

The third tank does not need either a drain or overflow pipe and should be used for the potash or caustic soda solution. This solution can be used for a long time without changing it by simply adding a small amount of potash or soda as the solution is found to be weakened. All three tanks are maintained at a temperature of from 180° to 212° (degrees) Fahrenheit, or approximately at boiling point.

The three jars mentioned above are to be used for the acid solutions and will be spoken of as jar No. 1, jar No. 2, and jar No. 3 respectively.

A wooden tank should be provided which is large enough to permit the three jars to be set in it and also to carry a supply of clear, cold water. This tank should also be divided so that jars No. 1 and No. 2 are in one division and jar No. 3 in the other. This is very important, as the work cannot be rinsed in the same cold water bath after being immersed in these various solutions. The sketch shown in figure will give an idea of the outfit.

Cleaning Solutions.

The solutions recommended are as follows: In tanks one and two, clear, hot water; in tank three, a solution of Potash or Caustic Soda, which is made by mixing one pound of Potash or Caustic Soda with one gallon of water.

The jar No. 1 is filled with a solution made up carefully of the following formula: four gallons of Nitric Acid; one gallon water; six gallons sulphuric acid. The water is placed in the jar first, the nitric acid is added slowly and the sulphuric acid is poured in last. This order should be very strictly observed, as it is dangerous to attempt to mix up a solution of these acids in any other manner.

*See also, pages 377, 398 and 406.

The solution in jar No. 2 is made up with the following formula: one gallon Hydro Chloric Acid to three gallons of water. Jar No. 3 is filled with the following solution: one-half pound of Cyanide to one gallon of water.

Tank No. 2 should be used for parts which have been in the Potash solution **and for no other purpose;** tank No. 1 for general rinsing.

Cleaning Various Metals.

Steel is boiled in the Potash solution until the dirt is removed. This should take only a few minutes. It is then rinsed in tank No. 2 and dried in sawdust.

Cast Iron is boiled in the Potash solution until dirt is removed, rinsed in tank No. 2, dipped in the acid solution in jar No. 2, rinsed in cold water, rinsed in tank No. 1 and dried in sawdust.

Brass is boiled in the Potash solution until the dirt is removed, rinsed in tank No. 2, dipped in the acid solution in jar No. 1, rinsed thoroughly in clear, cold water, dipped in the Cyanide solution, rinsed in clear, cold water, rinsed in tank No. 1, dried in sawdust. **Copper** can be cleaned in the same manner.

Polished aluminum should first be thoroughly washed in benzine or gasoline, rinsed in tank No. 1, dipped in the acid solution in jar No. 1, rinsed thoroughly in clear, cold water, rinsed in tank No. 1 and dried in sawdust.

Plain aluminum (polished), should be dipped in the Potash solution, rinsed in tank No. 2, dipped in jar No. 1, rinsed thoroughly in clear, cold water, rinsed in tank No. 1 and dried in sawdust.

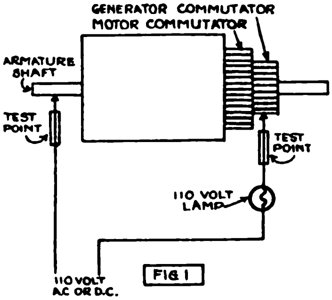
Plain aluminum, (not polished), should be dipped in the Potash solution, rinsed in tank No. 2, dipped for a few seconds in the acid solution, rinsed in tank No. 2, dipped for a few seconds in acid solution in jar No. 1 rinsed thoroughly in clear, cold water, rinsed in tank No. 1 and dried in sawdust.

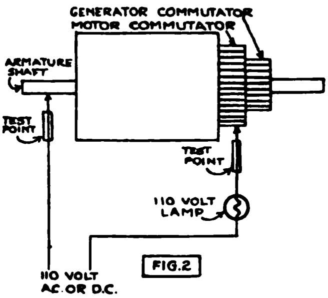
It will be noticed when the aluminum is put in **the Potash solution that the metal is attacked or eaten** away very rapidly. Care should, therefore, be taken not to leave the work in this solution any longer than is absolutely necessary. In cases where the work is covered with caked grease or has hard grease deposits on it, these pieces should first be washed in benzine or gasoline. Aluminum parts should never be washed in the Potash or Soda solution unless they can be put through the acid immediately after. The acid dip is used to neutralize the effects of the Potash solution. Parts should only be held in the acid solution for a few seconds.

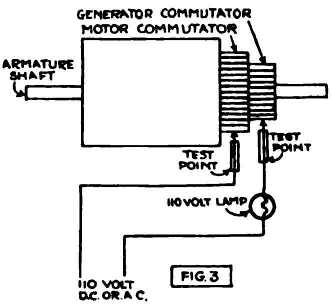
Paint on aluminum should be removed with a good varnish or paint remover, unless it is a very small quantity and the work is to go through the Potash solution.

With regard to enameled work, it is recommended that it be washed with soap and water, dried thoroughly and then polished with a cloth dampened with three in one or O'Cedar oil.

The methods described above are for solid metals only and should not be used on any plated materials. Practically all Delco clips are tinned and should be cleaned, therefore, in benzine or gasoline. All plated parts should be cleaned in benzine or gasoline.







*Testing Delco Motor-Generator Armature.

Test points, per pages 399 and 418 are used in connection with a lamp for part of the tests and a combination volt-ammeter is used for the other tests shown on this page.

It is not necessary to remove the motor-generator from car. Where there are grounds in armature winding, or short-circuits between them or short-circuits between generator and motor armature winding, simply raise brushes and insulate them from commutator with pieces of cardboard.

Armature Tests with the Test Light for Grounds.

Fig. 1. A grounded generator armature coil will result in slow cranking and materially reduce the charging rate. (Note armature and generator winding is on one armature in this particular system.)

To test to see if armature coil is grounded see fig. 1. If lamp lights, a ground is indicated.

Fig. 2. A grounded motor armature coil will cause excessive amount of current to be drawn from battery while cranking, or prevent cranking entirely (meaning of the word "cranking" is explained on page 400).

To test to see if grounded, see fig. 2. If lamp lights, a ground is indicated.

Fig. 3. Short circuits between motor and generator armature coils will decrease speed of cranking and also cause armature to continue to run after engine is shut down.

To test, see fig. 3. If lamp lights a short circuit between motor and generator armature coil exists.

Armature Tests with the Volt-Ammeter for Open-Circuited and Short-Circuited Armature Coils.

Testing for open and short circuited armature windings with a volt-ammeter. Before proceeding, turn to pages 414, 416 and study the construction of the Weston model 280 volt-ammeter, which is used in the following tests.

Fig. 4. Open or short circuited generator armature coils. The generator brushes should be left on contact with commutator, but disconnect storage battery from system. Then connect a dry cell as shown; one connection to the 30 ampere shunt and the other to the brushes, see page 414 for meaning of "shunt."

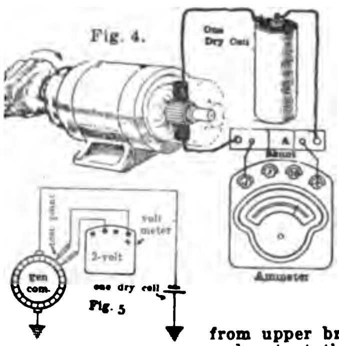
To test, turn armature slowly by hand. If commutator is in good shape and brushes are making good contact, the ampere reading should be the same in all armature coils—when brushes make contact with the different coils through the commutator segments, but if a very noticeable change in the ammeter reading takes place while turning, this will indicate an open or short-circuited armature coil.

Fig. 5. To then tell if generator armature coil is open-circuited or short circuited proceed as follows:

To test for open-circuited coil, connect brushes on commutator to a dry cell as per fig. 5, so that about 1 ampere will flow through the brushes. The field winding should be disconnected. Then connect test points to the 3 volt scale of meter and measure the voltage across two adjacent commutator segments. The readings should be the same, as the test is made on all commutator segments, but if there is a material **increase** in the reading on any two segments, then there is an open circuited coil.

Fig. 6. If there are no open circuited armature coils but the test per fig. 5 shows there is some armature trouble, then test for a short-circuited coil. This, however, should only be done after making the test per fig. 5, as we will now use the .1 volt scale of meter, and if there was an open-circuited coil, the voltmeter might be burned out if this test was made first.

To test for a short-circuited armature coil—see fig. 6. Connect test points on meter with the one-tenth volt (0.1) terminal and the + terminal—see also page 414. Turn armature slowly by hand and test each adjacent commutator segment as shown in fig. 6. If on testing any of these coils, the reading drops to zero, it will indicate that one or more of the armature coils are short-circuited.



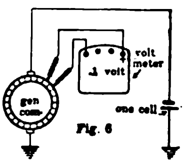


Fig. 67: These diagrams will explain what is meant by an open and short circuited armature coil. A, shows diagram of commutator with brushes which make contact with segments and carry the current during the test. It will be seen that the current **divides equally** from upper brush, passing down each side of the armature coils, or winding circuits, and out at the lower brush, and **if in good condition** the voltage between two commutator segments will be the same.

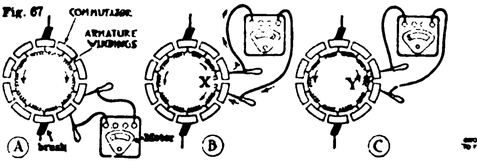
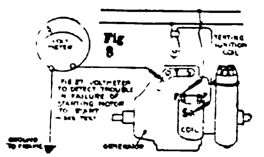
If an open current in one of the coils, as at X fig. 67, (B), there will be an interruption of current flow on that side, and if test-points are placed on the two segments shown there will be a big **increase** of needle since meter will carry **all** of the current flowing down that side. If points are placed on adjacent segments on that side, there will be a **zero** reading.

If a coil is short-circuited, per Y, fig. 67, (C), the meter, if placed on the segments shown will be zero, the short circuit having the effect of a shunt across meter.





Testing Ignition Coil.

Fig. 8. In this instance it is placed along side of the motor-generator. **To test**, place one "light test point" on secondary terminal (S), and other on primary (P)—see page 398 for explanation—see also pages 284 and 302 for other coil tests.

CHART NO. 188-I—Testing Delco Armatures. *Although these tests apply to the Delco System, they will also apply to many other systems. See also pages 414, 416, 410, 406, 411, 424, 418.

Testing The Delco Motor-Generator Field Coils.

Fig. 2: To test for grounds in the field coils of motor generator, place one point on frame of motor-generator, the other, on terminal of field coil.

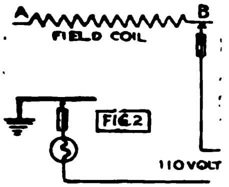


FIG. 2

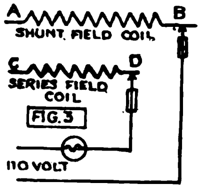

FIG. 3

Be sure all grounds which are regularly connected to these terminals are first removed.

If lamp lights a ground is indicated. If it fails to light coil circuit is o. k.

Fig. 3: To test for open circuits in the field coil, place test points as shown, on each terminal of the winding.

If lamp fails to light the circuit is open. The coil should be replaced or repaired.

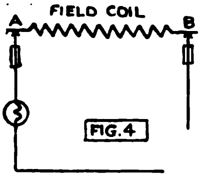

FIG. 4

Fig. 4: To test for short circuits between motor-generator windings; the test here is between the "shunt" and "series" field winding.

Place one of the test points on the terminal of one of the field windings and the other test point on terminal of other winding.

If lamp lights, a short-circuit is indicated between the windings.

Meaning of Grounds and Shorts.

A grounded coil is where the insulation is off the wire and it makes contact with metal.

A short-circuited coil generally applies to a field or armature with two windings on it and on which the insulation is off and in contact with each other.

Testing The Delco Wiring Circuit.

To test the wiring circuit for troubles, use the test points illustrated on page 399. Either direct current or alternating current can be used with 110 volt lamp placed in series.*

A typical single unit Delco wiring circuit is shown below. The tests however will apply to many of the other systems.

Parts Which Are Grounded.

It will be observed that certain portions of the circuit are grounded to the frame of the car. The battery terminal, the lamp return wires, one motor and one generator brush, one of the timer contacts, one terminal of the horn push button and one terminal of the condenser in the coil are grounded.

When Testing For Grounds.

First remove the grounded connections by disconnecting the **negative battery terminal from battery which is grounded to frame of car, and remove all lamp bulbs.

Then place a piece of cardboard between commutator and brushes of the motor and the generator (third brush also).

Disconnect the lead wire from the horn button and distributor and raise the base of the ignition coil so that it is insulated from the top cover of the motor-generator.

To Test For Grounds.

To test for grounds, see test No. 4; place one of the test points on the frame of the car and the other test point on the negative terminal of the battery (A).

If the lamp lights, then a ground is indicated and will likely be on the switch or in the motor windings (if all the switch buttons are pushed in).

Now with one of the points still grounded to frame of car, touch with the other point different terminals of the combination switch.

If lamp lights, then a ground is indicated and should be found and removed.

To Test For Short Circuits.

Testing for short-circuits between two wires which are supposed to be insulated from each other —see test No. 5; place one test point on one wire and the other point on the other wire.

If lamp lights, a short-circuit is indicated between the two wires.

If lamp does not light, then this portion of circuit is o. k.

To Test For a Broken Wire.

To test for a broken wire—see test No. 6; place test point at each end of wire as shown.

If lamp lights, the circuit is complete. **If lamp does not light,** then there is a break somewhere between the two points. By gradually moving the test points towards one another, the break can be definitely located.

If Lights Burn Out Often.

It is likely due to using a lower voltage lamp than generator circuit. **Test** the voltage at the lamp socket with the voltmeter when generator is running at normal speed and use lamp bulbs accordingly.

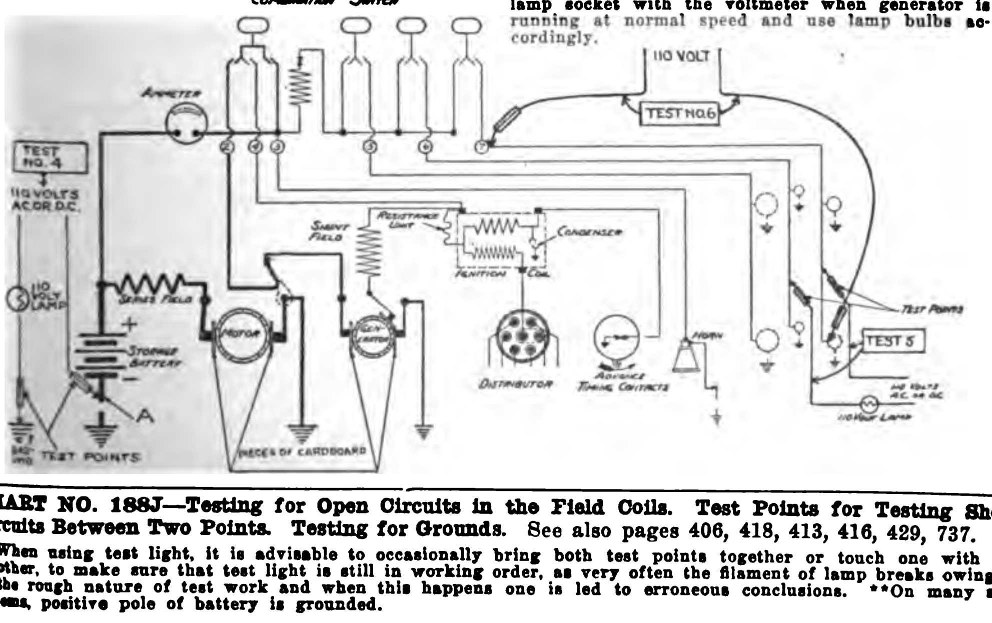

CHART NO. 188J—Testing for Open Circuits in the Field Coils. Test Points for Testing Short Circuits Between Two Points. Testing for Grounds. See also pages 406, 418, 413, 416, 429, 737.

*When using test light, it is advisable to occasionally bring both test points together or touch one with the other, to make sure that test light is still in working order, as very often the filament of lamp breaks owing to the rough nature of test work and when this happens one is led to erroneous conclusions. **On many systems, positive pole of battery is grounded.

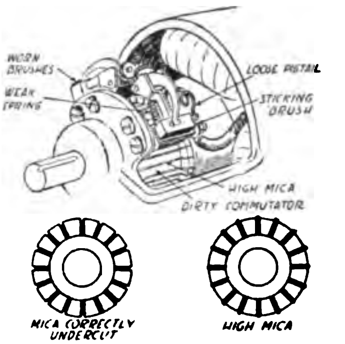

Fig. 3. Commutator and brush troubles. Copper is softer than mica and wears more rapidly, until the mica is so far above, that brushes cannot make good contact. When this occurs, the mica must be undercut as shown at the lower left.

Fig. 4. Dressing commutator.

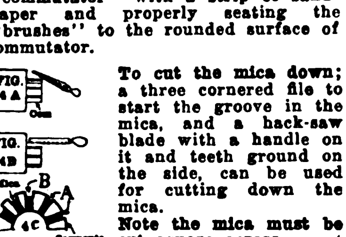

Fig. 5. Method of smoothing down a "commutator" with a strip of sandpaper and properly seating the "brushes" to the rounded surface of commutator.

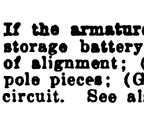

To cut the mica down; a three cornered file to start the groove in the mica, and a hack-saw blade with a handle on it and teeth ground on the side, can be used for cutting down the mica.

Note the mica must be cut square across, as at B, and not leave a thin edge, as at A.

**Commutator Troubles.

Commutator troubles are: arcing at brushes, weak brush holder springs, loose pigtails or connections of wires to the brushes, sticking brushes, overloading of generator and short-circuits between the motor and generator windings.

Arcing at brushes is usually due to mica protruding above the commutator segments—see fig. 3, lower right illustration, "high mica."

The cause of mica protruding is due to the copper segments wearing down below the level of the mica as stated under fig. 3. The brushes then cannot make good contact, therefore arcing occurs and commutator burns and blackens and becomes rough.

This trouble is more common on generators. On starting motors, where brushes do not make good contact, the commutator becomes rough and causes arcing.

††**Most of the troubles of this nature are due to the use of carbon brushes,** which are not hard enough to wear the mica down. The "generator" commutator on the Delco therefore requires more care in this respect. The Delco "motor" commutator however, where metal brushes are used, the trouble is not so great, as they are harder.

To remedy protruding mica; remove the armature and very carefully true or dress it up on a lathe per fig. 4. Then cut out the mica between the bars with a hack saw blade, the sides of its teeth having been ground off so that it will cut a groove slightly wider than the mica insulation, per fig. 4B. This will leave a rectangular groove free from mica; the depth should be about 1/32 inch.

The edges of the slots should then be slightly beveled, using a three-cornered file, in order to prevent any burrs remaining, which would cause excessive brush wear.

When properly finished commutator will have the appearance of illustration, fig. 4 "after." See also pages 409, 406.

Note. The mica can also be cut by placing a special tool in the lathe and moving it laterally as a planer—fig. 4 as suggested by Motor World.

The blackened and burned appearance of the commutator is not always caused by high mica. The same effect may be caused by having brushes of improper size or material, by an insufficient spring tension on the brushes, by an overload on the generator and by an open or short circuit in the generator windings, or where there are two windings on one armature with two commutators, by a short-circuit between the motor and generator windings. (from Weston Inst. book.)

†Commutator Noises and Cleaning Commutator.

If it makes a noise and trouble is not from the protruding mica, the commutator can be cleaned by speeding engine up to about 1000 r. p. m., then wipe off commutator with a piece of cloth dampened with gasoline to remove grease and dirt—or new brushes fitted.

If commutator is rough, smooth down with sandpaper cut a little wider than the brush and wrapped around the commutator so as to make contact with at least half of its circumference, as per fig. 5. Use 00 fine sandpaper—never use emery cloth. Don't lubricate, see page 406.

Noise can also sometimes be eliminated by slightly setting the brush to one side with a small wood stick—never use a screw driver or metal.

Fitting Brushes.

***The brush must always make good contact with the commutator;** they should have sufficient spring tension to press the brush to the commutator, yet move freely.

When fitting new "generator" brushes, they don't always fit the commutator perfectly, that is, they are not rounded to the commutator surface. This can be remedied by placing the rough side of a strip of grade 00 sandpaper **under the brush, when it is in its brush holder** (each brush separately), and work the strip back and forth holding the ends close together as per fig. 5, so it will conform with the curvature of commutator. The entire surface of the brush must be treated, otherwise it will be uneven. The "pig tails" or brush connections must also be kept tightened.

When fitting "motor" brushes to Delco armature, the same method is applicable, but something harder than sandpaper must be used. A strip of carborundum cloth can be used on the "motor-brushes," but sand cloth on the "motor-commutator." It is seldom necessary to cut mica down on the motor-commutator. See page 406 for cleaning brushes.

When Starting Motor Fails to Start.

If the armature fails to start when pulling out the ignition button, the trouble may be due to: (A) weak storage battery; (B) switch contacts defective; (C) the clutch may be sticking; (D) armature shaft out of alignment; (E) bearings of generator defective; (F) waste or foreign substance between armature and pole pieces; (G) generator brushes not making good contact; (H) loose, dirty connection, ground or short circuit. See also, page 577.

CHART NO. 188K—Commutator and Brush Troubles. When Motor Fails to Start.

*See foot note page 407 and next to lower right paragraph, page 400. **See also page 409. †See page 325 for kind of brushes used on starting motors and 408 generator brushes. See also, page 864C. ††See foot note page 405.

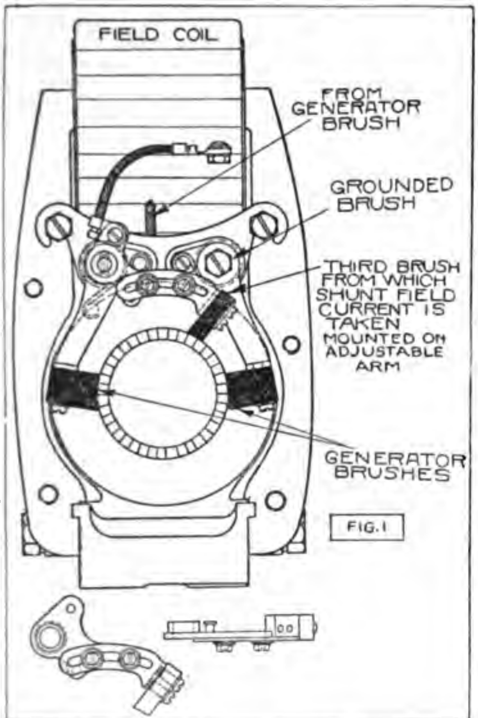

FIG. 1

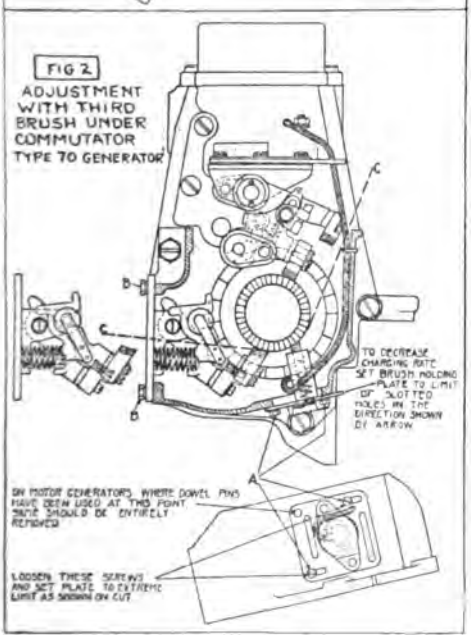

FIG 2. ADJUSTMENT WITH THIRD BRUSH UNDER COMMUTATOR TYPE 70 GENERATOR

Adjustment of Delco Third Brush.

There are two arrangements of the Delco third brush; over commutator and under commutator: The third brush is supported on an arm which is arranged to lengthen or shorten by means of screws and slots in this arm. In the single unit system, using generator No. 70, and on all the two-unit systems, the third brush is located on the lower side of the commutator, and is mounted on a plate which is arranged to move to obtain similar results.

The moving of this brush in the direction of rotation increases the charging rate and moving the brush in the opposite direction, of course, decreases the charging rate. These generators leave the factory adjusted to give ample charging rate for the average driver.

If the car is driven a great deal and the lights and starter used comparatively little, it is possible to overcharge the storage battery unless the charging rate is decreased.

The overcharging of the storage battery is indicated by the rapid evaporation of the water, and occasionally a too frequent burning out of the lamps. Therefore for this type of drivers it is advisable to decrease the charging rate by moving the third brush in the opposite direction from that in which the armature rotates. If this brush is moved, it is necessary to draw a piece of fine sand paper (with the sand side next to the brush) between the brush and the commutator a few times. If this is not done the brush will not make good contact and the charging rate will not be as high as when the brush is well seated.

With the type of driver who uses his car a great deal at night and drives a very little in the day time it is advisable to have a higher charging rate than these generators develop with the factory adjustment. With this type the third brush should be moved in the direction of rotation of the armature, and the brush sanded as described above. When the charging rate of the generator is increased, it is always essential that the charging rate be carefully checked up by use of the ammeter on the combination switch, and in no case should this exceed 20 amperes to any extent unless it is positively known that the driver never operats his car at fairly high speeds, excepting for short runs. Checking of the charging rate, should be obtained after the brush is well seated and the engine is gradually speeded up, observing the maximum charging rate indicated on the ammeter. This test should be made when all the lights are off.

To adjust the Delco third brush over commutator: By reference to the accompanying figure, it will be noted that the third brush is mounted on a brush arm, which is made up in two pieces. The part to which the brush is fastened has a slot through which pass two screws, attaching it to the other part. By loosening these screws it is possible to slide one part upon the other, and so increase or decrease the length of the arm.

When the arm is shortened, the charging rate is decreased, and the reverse is also true. Care should be taken to sand in the third brush carefully every time it is shifted, so it will have good contact with the commutator. (See instructions for "seating motor and generator brushes.") The screws on the brush arm should be tightened firmly after a change has been made, in order to prevent slipping.

The charging rate should rise to its maximum at a car speed of from fifteen to twenty miles per hour, and then drop off as the speed increases beyond this point.

In order to change the charging rate on the 70-motor-generator it becomes necessary to shift the third brush on the generator commutator. **To reduce the rate,** shift the third brush bracket plate in the direction indicated by the arrows on the accompanying cut.

To shift this brush bracket plate, loosen two screws "A" fig. 2, shown in the cut, and shift plate in the direction indicated by the arrow, to the full extent permitted by the slotted holes receiving the screws marked "A."

Note—The charging rate should be limited to 12 to 14 amperes with lights off. In case the charging rate cannot be sufficiently reduced, it may be necessary to lengthen the holes in the brush bracket plate with a file. After the brush is shifted it will be necessary to carefully sandpaper it so that it fits perfectly.

Carbon brushes are used on all Delco generators because they give better commutation and are porous, which allows lubricants to be forced in them, making them self-lubricating .

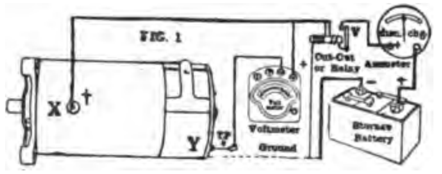
The copper composition brush is used on all Delco starting motors because the carbon brush has too high a resistance to carry the high cranking current required. The copper or composition brush has a high carrying capacity and smaller brushes can be used.

CHART NO. 188L—Adjustment of the Delco Third Brush for Charging Rate.

Closer the third-brush to the adjacent brush, the higher will be the voltage produced. Move brush counter direction of rotation to reduce the rate. See also, pages 389 and 864C.

Testing for Dirty or Rough Commutator with Voltmeter.

Fig. 1. Connect voltmeter terminals, 0 to 30 volts as shown. (The construction of this Weston voltmeter is shown on page 414).



The positive (+) terminal of voltmeter is connected to the positive (+) wire of the generator. The other terminal from voltmeter which has a test point (TP) at its end, makes contact with the frame of generator at Y (this being a grounded or return wire system).

Then speed engine up to a speed corresponding to a car speed of 10 to 15 miles per hour. **The voltmeter should show slightly over 6 volts** and the cut out (V) should be closed, showing "charge" on the dash ammeter or indicator.

If voltmeter does not show slightly more than 6 volts, this indicates a dirty or **rough commutator,** or else an **open circuit** in the shunt field. Press down lightly on the brushes while the generator is running, and if this causes the voltmeter to indicate and the cut-out to close, the trouble is due to **bad brush contact,** which can be remedied as just mentioned.

If voltmeter cannot be made to indicate and the cut-out point (V) to close, by cleaning the commutator and pressing on the brushes, the trouble is probably an open circuit in the shunt field winding, which will have to be repaired locally or sent to the factory.

If the voltmeter does show 6 volts or more, by pressing down on the brushes, or by cleaning the commutator and brushes, but the cut-out will not close, it means that the cut-out is not in proper adjustment, and a new one should be provided if it is defective internally. The trouble may be due to loose connections on the cut-out, or disarrangement of the contact-points on V, which can be examined and tested per page 410 and 409.

To Clean Commutator.

See page 404, fig. 5 and also page 409.

If commutator is too rough to smoothe down with sandpaper, then it should be dressed down on the lathe and probabilities are the mica is **protruding** which can be remedied as explained on pages 404 and 409.

To Clean The Brushes.

It is not necessary to remove them from the holders. Lift the brushes and wipe off the surface with a piece of cloth dampened with gasoline.

If the brush surface is apparently rough then use sandpaper to fit them to commutator, per fig. 5, page 404.

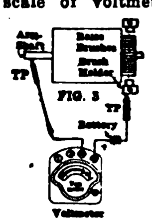
No lubricant is to be used, as the brushes are usually self-lubricating. Application of vaseline or grease is harmful, as all forms of grease possess insulating qualities to a greater or less extent.

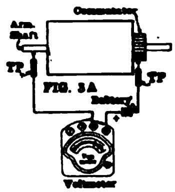
Test For Grounded Brush Holders.

Fig. 3: Use the 0 to 30 volt scale of voltmeter. Connect as shown and place one test point (TP) on armature shaft and the other on brush holder. If an indication is obtained, the brush holder is grounded.

Test For Grounded Armature and Field Coil.

Fig. 3A, grounded armature: Use the 0 to 30 volt scale of voltmeter. Connect as shown. One test point (TP) connects with each commutator segment, the other with shaft of armature. If an indication is shown, there is a ground between the coil connected with that commutator segment and the armature core. The cause of the ground is very likely due to damaged insulation on the wires. The armature should be examined carefully. A grounded armature coil will result in a reduced output.





A grounded field can be tested by transferring the connection from the commutator segment to one end of the field winding. If a deflection of needle is obtained the field is grounded. Be sure the ends of field coil are not touching the frame of generator or motor—see also pages 416 and 403.

To test for an open circuit in field winding, see page 416 and 403.

Tests at Battery Terminals for Grounds and Short-Circuits in Different Parts of the Electric System

(a) Disconnect wire at generator and starter.

(b) Disconnect one terminal of battery—fig. 5.

(c) Connect these wires (which are disconnected) to one terminal of ammeter, using the 0 to 300 shunt (see page 414).

(d) Connect a piece of wire to the other terminal of ammeter and hold this wire (A) in the hand, ready to touch the battery terminal (B).

(e) **Disconnect starter and generator, open all lighting switches and ignition switch.** Touch ammeter wire A, to battery terminal B. If ammeter registers any current, no matter how small—**a ground in wiring system of car is indicated,** somewhere between battery, generator or starter. If ammeter shows a **heavy** discharge—**a severe short circuit is indicated.**

(f) **Reconnect wire at generator** and touch wire A to battery terminal B. If ammeter indicates current—**very likely due to cut-out points being stuck.**

(g) **Disconnect generator again, and remove all lamps from sockets,** then turn on each lighting circuit separately and note indication of ammeter after touching A to B. If ammeter registers current when either switch is turned on—**there is a short-circuit or ground in that particular circuit.**

(h) **To test for short-circuit in starter.** Replace wires to starting motor, turn on the ignition switch and press starting motor switch. See explanation under "test A2," page 410. A short-circuited starting motor will be indicated by slow turning and possibly smoke coming from the winding. The battery must be fully charged. Use only the 300 ampere shunt on these tests—see page 414.

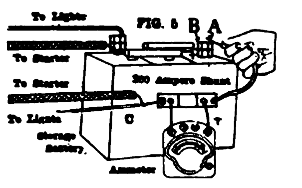


CHART NO. 189—Testing For Defective Commutator. Cleaning Commutator and Brushes. Tests at Battery Terminals for Short-Circuits. See also pages 416, 410, 411, 402, 403, 418.

*The meter used in these examples is the Weston, page 414.

INSTRUCTION No. 29.

*CARE, ADJUSTMENTS AND TESTS OF ELECTRIC STARTING, GENERATING AND LIGHTING SYSTEMS: Care of Starting Motor. Locating Starting Motor Troubles. Care of Generator; cleaning and adjusting commutators, brushes; armature troubles, etc. Testing Armature and Field Windings; short circuits and open circuits. Miscellaneous Troubles and Tests. Ammeter and Voltmeter; how to read and test with. Shunts, etc. Electrical Testing Outfits. A Digest of Lighting Troubles, etc.

Care of the Starting Motor.

The starting motor. Any trouble developing in starting motors, such as grounds, short circuits, brush and commutator troubles, will be taken up in detail under care of lighting and generator systems, and apply here.

The starting motor, is used very little in comparison to the generator, therefore it does not require the attention which the generator does, if it is a separate unit.

Oiling: Each of the oil cups should be given three or four drops of oil about once every two weeks. Use best machine oil.

The gear case of a geared motor (if gear case is an integral part), should be filled with a good quality of heavy oil; always first, drain old oil, and don't use more oil than called for.

Commutator: Keep commutator free from dirt cleaning when dirty, with a cloth (not waste). When commutator and brushes are in good condition it will show a glaze and commutator will be chocolate brown in color. If rough, smooth up with fine sandpaper as per chart 188K and 189, don't use emery paper and note in using sandpaper, strip must be width of commutator and must be held down as far around commutator as possible. Be sure and remove all grit and dirt, see chart 189.

****The brushes** should not be disturbed until you are sure trouble exist in them. If worn, get a new set. Keep the brushes in perfect contact with commutator. One of the greatest troubles with brushes is poor brush contact with commutator, on account of insufficient spring tension. Clean all dust from brush holder case with compressed air. See page 404, 406, 408.

†**Starting switch:** for flywheel application, the moving contacts should touch both stationary contacts during the first part of the motion. The adjustments of switch should be carefully investigated if the motor gives trouble. See pages 326 and 331.

Locating Starting Motor Troubles. —See also, page 577.

Only when you have made sure that the wiring is in perfect condition and that everything is connected up according to the wiring diagram should trouble be looked for in the electrical instruments themselves.

Surprisingly few troubles have been experienced with starting systems and of the troubles that have occurred, by far the greater part have not been due to the electric starting system, but to the carburetion or ignition, as failure of gasoline, carbonized spark plugs, etc. Therefore, first see if the ignition and carburetion are o. k.

If the starting motor fails to start when starting pedal is pressed down as far as it will go, test out the trouble as follows:

(a) Battery weak or discharged. Test battery with hydrometer or throw on lights (starting switch off) and note if dim—if so, battery is weak. If lights are bright then the probabilities are, the battery is o. k. also see chart 190, showing how the volt-meter is used to detect the cause or failure of starting motor.

(b) Look for an open circuit (broken wire) or loose connection in the wire from battery to starting switch, from switch to starting motor, from motor to ground, from ground to battery.

(c) See that the brushes and commutator are in good condition, and not sticky with oil and brush sets firmly on commutator. (see also page 331).

If motor with flywheel application:

(d) Press the pedal slowly so as to close the contacts, then motor should turn if battery, motor, and all connections are all right. See page 326.

(e) Examine the switch lever and switch adjustments and see that they have not worked loose in such a way that the switch does not close.

If sometimes the gears mesh and the motor runs satisfactory, and at other times it is impossible to mesh the gears, the motor refusing to turn when the contacts are closed, it indicates the possibility of an open circuit in switch or starting motor.

*This instruction applies to all systems in general. The Delco tests (Instruction 28-O), will also apply to some of the different systems. See also, pages 429, 737.

****Owing to the high volume of current carried through starting motor brushes,** if worn or not properly adjusted, the commutator may become pitted and cause excessive wear—result failure of starting motor to operate properly or excessive sparking and weak motor. Remedy; take armature out and true up commutator on lathe (see page 404. See pages 325, 408 and 405, about kind of brushes used on starting motor and generator). †See page 408.

If engine does not pick up immediately after two or three trials though motor turns the engine over, the trouble is in: Either the gasoline supply; the spark plugs; the carburetor; or the ignition system.

If starting motor continues to run after the switch lever is released, see that the return spring on the switch or switch lever, is strong enough to return the parts positively and fully to the "off" position.

Failure of engine to start when starting motor is working satisfactory. This may be due to failure of gasoline or spark; test out as follows:

(a)—**Ignition switch,** examine to see if "on."

(b)—**See that there is gasoline in the carburetor.** If there is not, the gasoline may be used up, it may not be turned on, or the gasoline feed pipe or valve may be stopped up. If the system involves gravity feed, the gasoline may not flow into the carburetor on steep hills.

(c)—**If there is gasoline in the carburetor, take out one of the spark plugs** and lay it on the engine with the sparking point in the air while the engine is turned over by hand or by the starting motor. Also examine the spark plug points—they may be too far apart. 1/64 to 1/32 of an inch apart is about right. If a spark passes, the trouble is not in the electric system, but probably due to cold gasoline or need of priming.

If there is no spark, then see "Digest of troubles" and Index, and follow the diagnosis.

Summary of Starting Troubles.—See also, page 577.

Starting motor cranks engine very slow.—Battery almost discharged. ‡Battery sulphated. Engine stiff. Brushes loose and poor contact.

Starting motor does not rotate at all.—Battery may be discharged. Starting switch not making good contact. Motor brush may not make contact with commutator. Battery terminals may not make good contact. Switch contact poor.

Starting motor rotates but does not crank engine.—Roller clutch does not work properly. Gears not properly meshed. If Bendix automatic; spring broke. See page 331.

Starting motor cranks engine a few revolutions and then stops.—Battery weak—almost discharged. Loose switch contact. Engine stiff.

Starting motor cranks engine and will not pick up under its own power.—These symptoms indicate that trouble is not in the starting system. If Bendix starter; gear on threaded shaft stuck or spring broke.

***A weak starting motor is sometimes caused by** using carbon brushes instead of metal composition brushes. The latter have 3 to 4 times the conductivity, and for this reason their replacement by cheap carbon will not allow sufficient current to pass.

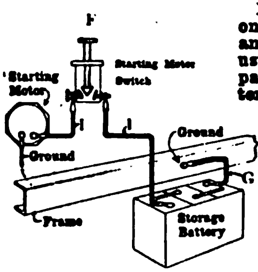
****If the battery is all right proceed to examine the connections,** beginning with the battery. The current may be shorted, due to electrolyte spilled over the top of it; or terminals may be sulphated, in which case enough resistance will be offered to the current to prevent proper operation.

Scrape off the sulphate, wash surrounding metal parts in carbonate of soda or some other alkali.

Clean battery terminals inside with round file, **clean wire terminal** with flat file—replace wire and draw connections tight.

Next examine the ground connection of battery to frame—this should be cleaned and tightened if not soldered. Looseness here is frequent cause of open circuit. Then examine connections from battery to starting motor switch, thence brushes to commutator.

Watch the Starting Motor Wire.



Fuses, which will melt on a dead short circuit and open the circuit, are usually provided on all parts of the electric system, except from the battery to starting motor. The current here is too great for a fuse. Therefore it is plain to see that if the insulated cable (I), should become frayed and touch the frame or any metal part of car, a **dead short circuit** would result—and if left shorted for several hours, the plates would likely become buckled inside of battery and touch each other and cause an internal short circuit which could not be repaired. A battery is on practically a dead short circuit each time engine is started, but only for a moment.

Care of the Generator.

Care of the generator is next in importance and should be given more frequent attention than the starting motor.

†Brushes.

Brush care—Once or twice a season the flat coiled springs holding the brushes against the commutator should be raised and the brushes examined, to see that they operate freely in their holders. Oil or dirt should be removed with a stiff bristle brush and gasoline.

Faults in brushes and brush holders can be classified into five divisons namely; grounded, poor spring tension, sticking in holder, poor fit to commutator surface and over-heating holders. When grounded, it is due to defective insulation or dust deposit.

When spring tension fails, the brushes are worn too short, the tension is not adjusted or has been thrown out, due to heat, or the springs themseleves may be broken. **When the brushes stick,** it may be due to binding or from dirt and grease. A little gasoline may tend to loosen same. When the brushes do not fit the brush holders it is a matter of manufacture. **Overheating of brush holders,** is caused by the sparking due to ill fitting brushes or no brush lead connection and lack of sufficient pressure on brush.

*See page 400, next to lower right paragraph. **See also, pages 422, 454, 457, 458, 416, 410, 429, 737.

†**Brushes for generators are usually made of carbon,** because it is often necessary to have a brush with a high "contact drop," (meaning slight loss of voltage between brush and commutator because of contact resistance). See also, paragraph 5, page 404, about relation of the carbon brush and mica.

The starting motor brush is usually made of wire gauze, or composition, see page 405.

‡**Often times a battery will show 1.275 on a hydrometer test**—yet fail in current supply immediately after use; due to plates being sulphated. Test each cell with voltmeter and if test shows any of the cells below the others (see page 410), then test that cell with a "Cadmium Test" (page 864D), as plates are likely sulphated.

Sparking at the brushes. If there is any sparking, or if the commutator becomes dull, you may be perfectly sure that either **the brush holder springs are too loose**, or **there is excessive vibration**, which may be due to a bent shaft, an unbalanced gear pinion, or defective mounting. Brushes should be kept in perfect contact with commutator, and it is advisable to use only the kind recommended by the manufacturer.

It may be found that where the generator is also used as a starting motor, sparking will in time develop at the commutator. This is due to the arcing of the heavy starting current at the trailing edges of the brushes, and the trouble may be eliminated by filing down their contact surfaces.

Carbon dust (providing carbon brushes are used) may be worn from brushes by commutator, and deposited in lower part of generator—**this ought to be blown out with air**, otherwise it might cause a ground.

****Commutator.**

Commutator troubles can be divided into two heads. First, those due to defective manufacture and those due to surface wear or deterioration in service.

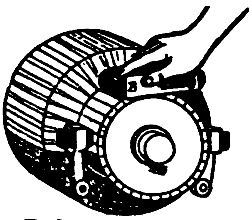


*Fig. 2.—The commutator is smoothed with a block of wood around which is wrapped a piece of sandpaper. (see also page 404.)

Sometimes this work may be done with the armature in place, but more often it must be removed.

Defective commutators may be grounded, have a short-circuit between their segments or have loose segments and are generally denoted by sparking at the brushes.

Those that have deteriorated in service show a rough or blackened surface due to the following causes: sparking from worn or short brushes, sparking on account of high mica, cheap brushes, oil collection on commutator surface, loose copper segments, poor contact between brushes and commutator, (generally due to sticking holders) or poor contact, due to weak brush spring pressure.

†Commutators should be kept smooth. If blackened or rough they can be dressed with fine sandpaper, while armature is rotating. (see fig. 5, page 404 and page 406.)

Never use emery cloth. After smoothing down examine and see if particles of metal bridge across the copper segments.

****High Mica.**

Mica between commutator segments should not protrude, (see fig. 3, page 404); this can be dressed down on the lathe, per fig. 4, page 404, or in some instances filed down by using a very fine cut file, but care must be taken that no small particles of copper are left bridging across segments. A knife edge file can be used to cut between segments to get effect shown in upper illustration "after," fig. 4, page 404. This work must be done by removing armature and preferably on a lathe.

Commutator greasy—wipe with dry cloth, not waste, remove grease (chart 189).

Submerged Motor-Generator.

The generator must be kept free from excessive moisture. Ordinary moisture will not affect it, but should not be allowed to become thoroughly wet, such as would be the case if the generator were to become submerged under water. This is likely to happen while fording a stream. If the generator is wet it should not be operated until it is thoroughly dried out, this can be done by removing from car and baked 24 hours in an oven, whose temperature shall not exceed 220° Fahrenheit. A higher temperature in the baking oven would damage the insulation.

‡Generator Does Not Generate Full Output.

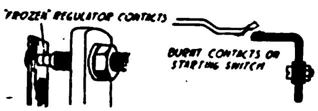
Symptoms; if meter shows 9 to 15 amperes (varies on different systems), at a speed of 18 or 20 m. p. h. then generator is probably giving its maximum output. If however, meter shows but 5 to 8 amperes at same speed then it is not giving its output.

Cause; (1)—if a third brush is provided (page 405), the adjustment may not be correct; (2)—ground in circuit; (3)—brushes grounded with brush holder and frame with carbon dust; (4)—brushes worn or not seating; (5) commutator dirty or out of round; (6)—high mica (see pages 404 and 409).

On many generators, as Autolite for instance as used on Chevrolet "490," page 364, there is no third brush or adjustment and failure of generator to generate full current is likely due to one of the above causes. See Overland "Autolite," page 358.

***Cut-Out or Relay.**

Failure of the cutout to operate may be due to several things. In the first place



a back kick will cause the points to close and stay closed and when ever this happens, no time should be lost in separating the points. This may be done by starting the engine again or by pulling them apart.

There are several mechanical reasons why the cutout may fail to operate. The points may be too near together or too far apart; they may be rough or pitted. If the former, they should be adjusted and if the latter, they should be smoothed with a fine file and then adjusted. The spring which holds the cutout open may be weak or broken or the armature on cut-out may stick, due to worn or tight parts or dirt. Be sure points are smooth.

The cut-out armature may be drawn to magnet core, yet points may not make contact. See page 334 for principle.

Electrical defects in the operation of the cut-out are confined to bad connections or grounds. These troubles are rare and should be quickly evident after an inspection. Failure of the cutout armature to open when the engine is stopped would indicate trou-

*See pages 421 and 417. **See pages 404, 406. †Sometimes brushes wear down and brush holder cuts commutator. In this case, armature must be removed and trued up on a lathe—see fig. 4, page 404. ‡Usually due to improper brush adjustment if "3rd brush" constant current system of regulation. If a constant voltage regulation system, see pages 345, 925.

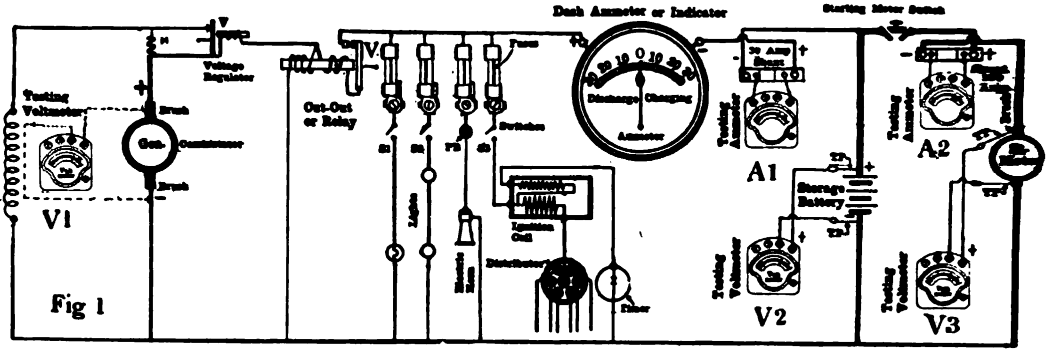


Fig 1

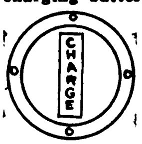
How the Volt and Ampere Meter are Used.

The idea of this combination electric system is to show where and how a volt-meter and ampere-meter can be used on the average electric system. It is understood that the battery is a 6 volt 3-cell battery and also that the only instrument which is a regular equipment is the "dash ammeter"—or which could be an "indicator." The other instruments V1, V2, V3, A1, A2, are testing instruments, as will be explained.

An Indicator.

Is now seldom used but will be found on some cars. It is placed on the dash. When generator is charging battery it shows "charge" as per illustration to the left. When battery is disconnected from generator at cut-out (V), it shows "discharge" if lights are on and engine running below speed where cut-out operates. If lights are off, ignition off and generator off, it will show "off."



The Dash Ammeter.

Is in general use and instead of showing the word "off," "charge" and "discharge," a scale is used per fig. 1 above, and fig. 8, page 415.

Note. On some of the dash ammeters the "charge" is on the left side, or reversed, for instance, see fig. 9, page 378.

Meaning of zero center: Note the "0" is in the center and when no current is flowing the needle will remain at 0 or zero. The needle can read up to 30 amperes on the "charge" side, to the right, or 30 ampers on the "discharge" side, to the left and is termed a "30-0-30" scale.

If generator is running sufficient speed to charge battery, then cut-out point V will close and connect generator with battery and charge battery, at which time needle will move to the right or "charge" side of 0—if connected correctly.

If engine slows down, and cut-out V opens, then battery is disconnected from generator, and as ignition is being consumed from battery the needle will move slightly on the left of 0, or "discharge" side of zero—as the battery would be discharging instead of taking a charge. If lights were on, then the needle would go further on the discharge side, as more current will be discharging from battery.

The above clearly shows that needle moves one direction when current is flowing from positive connection (+) of generator—to (+) of meter—to (+) of battery, but needle operates in opposite direction, when current is flowing **back from battery to meter**—as you will note connection is with negative side (—) of meter in this instance—hence **reason for zero (0) in the center on the dash ammeter.**

Voltmeter Tests.

The voltmeter is always placed across the line and shows the voltage or pressure of a circuit. The instrument used is the Weston, per page 414—which read carefully.

Test V1: To test voltage of generator: Use the 0 to 30 connections and scale. The **maximum** voltage will be indicated when generator is operating at 7 to 10 miles per hour car speed. The cut-out (V) should close and voltage going to generator should be slightly over voltage of battery, in order that it may force current into battery.

If voltage is lower, or no indication at all, then commutator may be dirty, brushes may not bear on generator commutator, or rough commutator, or grounded brushes, open circuit, or short-circuit or grounds in field or armature winding—see pages 406, 404, 409, 402, 403.

Test V2: To test voltage of battery when discharging, with lights only, on, use the 0 to 30 volt connections and scale. The voltage, if charged, for a 3 cell battery will be 6 to 6.3 volts or 2 to 2.1 per cell. If **discharged**, it will be 5.4 volts, or 1.7 volts per cell.

If tested when starter is on, a charged battery will drop to 5.4 or 1.7 volts per cell, but will regain its normal voltage after a short while. If it drops to 5 volts or less, or 1.6 volts per cell—it is discharged, or if fully charged and drops this low, then, plates are sulphated or an internal short-circuit. See also page 416 and index for "cadmium tests."

Test V3: To test voltage which reaches starting motor from battery, to see if considerable drop, test with engine idle but starter switch closed for an instant. If drop is considerable there may be poor connection at battery terminals or ground connection—if a grounded system.

Ammeter Tests.

Ampere tests are to ascertain the quantity of current flowing. A "shunt" must be used—see page 414. Connect the shunt in the circuit as shown at tests A1 and A2, being sure positive (+) wire of circuit is connected to (+) connection of meter, and the negative (—) wire of circuit to .1 binding post of meter—see page 414.

Test A1: To test accuracy of dash ammeter; use the 30 ampere shunt and connect as shown. Speed engine up and note if the reading is the same on the dash ammeter as on the testing instrument—see also page 398.

Test A1: To test cut-out: Use 0 to 30 shunt and scale. At a car speed of 7 to 10 miles per hour, cut-out (V) should close and at 15 or 20 miles car speed generator should be charging battery at 10 to 20 amperes—if lights are off—(varies on different systems). If it shows less than 10 amperes the "regulator" or "third-brush" should be regulated to bring the current up to at least 10 amperes, 15 amperes being the average.

Throttle engine slowly and note needle will drop back towards zero and note when it reaches zero if cut-out (V) opens and at what car speed. See page 417 for trouble indications told by ammeter.

Test A2: To test amperage required by starting motor: Use the 300 ampere shunt and connect as shown. Test with engine idle. It is assumed that battery shows 1,275 to 1,300 hydrometer test, and is supposed to be charged. **Average starting motor requires 130 to 150 amperes.** If it shows 220 to 225 or more amperes, engine is stiff, short-circuit in motor or brush holders—or may be the starter mechanism is out of order. See also pages 416, 406 and index for "cadmium tests."

CHART NO. 189A—How the Volt and Ammeter are connected to the Electric System of a car for Various Tests. How to Test the Accuracy of the Dash Ammeter or Indicator.

See also pages 414, 416, 402, 406. See pages 334, 342, 344 for principle of cut out and regulation.

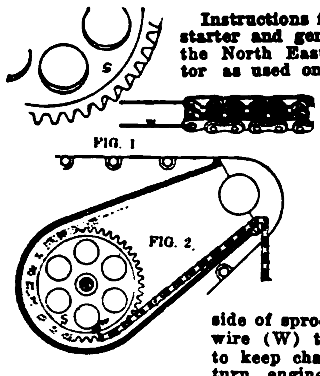
ble in the series coil, while failure to close might be caused by a defect in either series or shunt coil.

††**To determine whether the cutout is working properly** the car should be driven on high gear at speeds varying from 6 to 15 miles per hour and the speed at which the cutout operates should be noted. The correct speed can usually be found from the makers instruction book.

Circuits.

See that all circuits between dynamo and battery are intact and all binding posts and contacts tight and remember that a complete circuit is necessary in order that the electric current may do its work.

***Adjusting Silent Chain.**



Instructions for replacing the starter and generator chain on the North East starter-generator as used on the Dodge car is shown in figs. 1 and 2 as an example.

First:—Pass short piece of wire through end of chain and bend into form of staple.

Second:—Start chain on lower side of sprocket (S). Hook wire (W) through sprocket to keep chain in mesh and turn engine with starting crank unit until end of chain appears at top of sprocket. Remove wire from sprocket, hold end of chain and continue to turn engine until chain is in position for applying master link.

Chain driven starting motors and generators should have the chain kept lubricated and adjusted, but never adjust chain too tight.

The silent chain which drives the generator should have frequent and thorough lubrication. Ordinary lubricating oil will do for this purpose and as soon as the oil has penetrated to all the joints the outside of the chain should be wiped clean so that a minimum of dust will adhere.

The chain may be tightened by loosening the two screws which hold the generator on its bracket and moving the generator over the required distance by means of the adjusting screw on the side next the engine.

Locating Generator Troubles.—See also, page 577.

Under the heading of "care of the generator" the subject of commutators and brushes was treated. This is usually the first place to look for generator troubles. Other troubles are:

Armature Troubles.

Armature windings may be burned out or grounded. When burnt out the trouble may be due to a current overload, due to improper regulation, a soaked winding or a steady and prolonged return flow from the battery, due to failure of the circuit breaker contact points to open. A grounded armature winding is due to defective insulation.

****Locating Armature Troubles.**

Armature troubles are sometimes found in the attaching leads at the commutator segments. The solder attaching same, may be thrown off in revolving. This can be soldered back to the segment by an electrician.

Dim lamps, low voltage and undercharged battery might be the result of armature trouble. One of the armature coils might be short-circuited, burned out or a connection might be loose or broken.

Any defect in the armature will be indicated by an uneven torque. In the case of the generator this may be very easily tested by disconnecting the driving mechanism, holding the cutout points closed and allowing the generator to operate as a motor.

If everything is all right the armature will rotate evenly and in the same direction as when it operates as a generator. **Whether the torque is even or not may be determined** by holding the end of the armature shaft in the hand, and noting whether the pull is steady. An uneven pull means that one or more of the coils is not working; it is just like an engine with a missing cylinder.

If an armature coil is burned out or there is a broken connection the armature will invariably stop at a certain point; if this is the case, the commutator segments between the two ends of the coil will also be burned. Sometimes the broken connection occurs at the junction between commutator bar and the coil in which case the remedy is to resolder. All other armature defects should be left for the factory to remedy.

Another way to test for defective armature coils is to disconnect the field and then connect the ends of the lamp test wires to the brush holders. If the armature is perfect the lamp should stay lighted during a full rotation of the armature, but if there is a broken connection or defective coil it will go out when this is reached.

No current in the generator may be due to a broken connection, short circuit or broken driving mechanism. The last trouble should be looked for first, and simply means that the generator driving shaft should be tested to determine whether it is solidly connected to the engine or not. It is possible that one of the driving keys has sheared off or that the driving gear, chain or belt, as the case may be, has failed. (see page 402.)

*See pages 733, 369, 113, 729 for "silent chains." †See instruction 32A, for storage battery troubles.
**See pages 402, 406, 416 and 864C.
††Ward-Leonard Co. state that the only way the cut-out manufactured by them could give trouble, would be due to an open circuit in armature of generator, or open lead wire between battery and generator, or else the connections at battery be reversed. (see pages 342, 344 for Ward-Leonard.)

A broken connection at one of the brushes would prevent delivery of current by the generator. Likewise a **dead short circuit in the generator** would cause the same trouble.

Armature tests for ground, etc. are treated further on—see pages 402, 403, 406, 410.

A grounded generator can be caused by an accumulation of dust worn from the brushes or a defective insulation of the armature or field coils.

Weak field magnets will vary in cause, according to whether the magnets are permanent or wound. In the permanent magnets the cause is generally due to exhaustion through long use, no keeper used when removing them or magnets reversed when reassembled. In wound magnets, shunt field coil or coils may be grounded, due to a water soaked generator or short-circuited through burning out, by running the generator with the battery disconnected. They may also be oil-soaked.

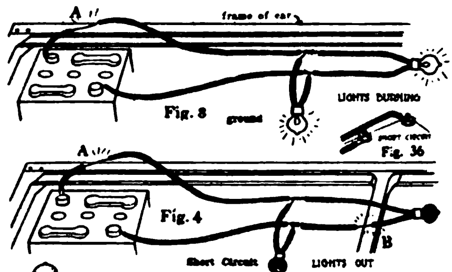
In the circuit-breaker or main contact, as it is often called, there may be a direct mechanical break, a burned out coil due to current overload or a ground due to defective insulation, a bad adjustment which does not allow the generator to cut in at all or if so at an improper speed or the contact points may be sticking. The latter is due to a mechanical break, disintegration of weights where worn out or dirty contact points, reversed wires at the generator terminal or a backfire of the engine.

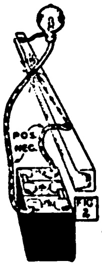
A short circuit in the circuit-breaker allows current to discharge battery through generator at less than charging speeds.

*Short-Circuits and Grounds.

A short-circuit means that two conductors of current are in metallic contact when they should not be.

For example, on a two-wire system as per fig. 4, if one wire was "grounded" to frame of car at A and B, a short-circuit would be the result—as the path of the current would be shorted.





On a single-wire system per fig. 2, we would have the same result; the frame of the car acting as the return wire.

On a two-wire system, fig. 3, if wire was "grounded" at A, the current could still flow to the lamp—therefore this would be termed a ground.

Therefore, the term short-circuit means that the wire is in metallic contact with its return circuit, which could be another wire, or the frame of the car or any metal part of car, if the latter is in metallic contact with frame.

A **"dead short-circuit"** is a term often used and applies to a short-circuit of such magnitude that the entire current carried is fully short-circuited by making firm contact. For instance, refer to fig. 4, in this instance a dead short circuit exists at A and B—therefore the battery would be shorted and result would be that wire would probably melt and lights would not burn at all. Therefore a fuse, if placed in circuit would protect the wiring and battery.

A slight short-circuit is where the wires are not making full contact but enough to make slight contact. For instance two wires close to engine, not properly insulated may make a slight contact due to heat, through insulation and dim the lights, or frayed ends of wires at switch terminals may bridge across and short the connection from jolting of car and occasionally cause the lights to dim or go out. Oil soaked wires may be close together and also cause a slight short circuit and result in dim lights and gradually weaken battery.

A ground means that the conductor or wire is in contact with metal part of car, as frame, engine, etc. It can be a bad ground where contact is firmly made or slight, where oil soaked or a damp wire, or poorly insulated wire is in contact with metal part of car, but not firmly as resistance of insulation prevents, but enough to cause **leakage** of current which will gradually discharge battery, and in some cases may become entirely discharged in a very short while.

This kind of a short circuit is first noticed when the starter seems weak and the lights seem to grow dim at low car speed, and brighten up as the dynamo cuts in.

Fuses.

Purpose is to protect the circuit against short-circuits which would heat the wire and discharge battery. Instead of the wire heating and melting, the fuse would melt.

Fuse wires are made in different diameters. It is made of lead alloy and will melt at a given temperature. If a lighting circuit required 10 amperes of current, then a 15 ampere fuse would be placed in the circuit. Therefore current up to 15 amperes could pass safely, but if more, which would naturally be the result if a short-circuit existed, the fuse would melt and open the circuit, (see page 428.)

See pages 441 and 207 for meaning of amperes, etc. (Illustration from Motor Age, by B. M. Ikert.)
*See also, pages 406, 418, 403, 416, 429, 737.

Indications of Grounds and Short Circuits.

(1) Battery will become exhausted, regardless of the charging it receives. (2) Battery will run down (discharge) over night. (3) Lamps when turned on will burn dimly. (4) Ammeter pointer may go to limit of "discharge" scale. (5) Starting motor may act sluggishly, or not at all. (6) Fuses 'blow" repeatedly.

A short circuit in any lamp circuit will usually cause a fuse to "blow" or melt. If this occurs, it is evident that the wire leading from the fuse is in contact with the "ground" or frame of car, or other metal, or that insulation has been injured and conductor is in contact with other metal, thereby grounding it to frame. The wire must be inspected along its entire length until trouble has been located and corrected.

Wire having injured insulation should be wrapped with friction tape to prevent contact with frame or other conductive material.

Some Causes of Grounds and Short Circuit.

First of all, the ground may be in the battery itself, and may be caused by buckled plates or an accumulation of sediment. The former trouble is usually the result of charging or discharging the battery at too high a rate, and the latter is due to neglect to clean the sediment out before the chamber provided for its collection becomes filled. This would be termed an "**internal" short-circuit.**

The next place to look for the "ground" is on the battery exterior. Spilled acid may cause a partial short circuit. The top of the battery should be wiped clean, treated with a solution of potash and then the metal parts should be covered with vaseline.

If current is flowing into the external circuit, this fact may be determined by disconnecting one of the battery wires and then touching it for an instant to the terminal it was just removed from. If any current is flowing a spark will be seen. If any considerable amount of electrical energy is being lost, this fact should also be indicated on the ammeter if one is fitted.

The most likely place to look for trouble is in the cutout, as it may be closed. The failure of the cutout to open may be due to several things, taken up under the heading "Cutout or Relay."

As a precaution the starting switch should be examined, as it is possible that it did not release fully the last time it was used and that some current is short-circuited through it.

Having gone through these preliminaries, the next step is to start from the battery and examine all the circuits, taking the main ones first. Disconnect the main feed wires where they enter the junction box or battery, and note whether the ammeter goes back to zero. If it does there is a ground between this point and the battery.

Put these wires back and then disconnect all other wires from the junction box. If current is still flowing the trouble is in the junction box, but if not it must be in one of the circuits running from this point. If this is so, then remove wires and test each separately.

***Testing for Grounds and Short Circuits.**

First be sure a ground or short circuit exists. This test can be made several ways. **The amperemeter will indicate same by showing "discharge," but if there is no amperemeter on the car, then open all switches, disconnect one terminal of battery (usually a lead lug), strike the connection lightly against battery terminal in quick succession. If a spark occurs, even though very slight, it indicates a "ground" or "short circuit" (see page 406, 403, 418).

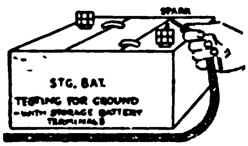


Fig. 6. Testing for grounds.

The next procedure is to find the ground or short circuit.

(1) Examine first, the battery wiring. Examine carefully all of the conductor wires connected at one end of the battery terminals and at the other end to the bus bars of the lighting switch. Make certain that the insulation is perfect, and that no sharp metal corners or edges cut through. Also that no frayed wires are bridging across at the bus bar. In the same manner examine carefully the wiring from the battery to the starting motor and starting switch. If battery has been discharged, have it recharged. See also page 241.

(2) Examine lamp base and socket, quite often the slight short circuits are located at this point. One of the strands of wire where attached to small screw in lamp socket may be touching—examine lamp base. If not at this point the trouble may be found in the wiring where connected to lamps having worn. Electric light bulbs, if loose where the glass part is cemented to the metal base, will also cause a short circuit, as the "lead-in wires" are very close together, and jolting of the car will cause these leads to touch one another, this means a new bulb and perhaps a new fuse. Defective lamps should be discarded, before they cause trouble, see also page 403.

*Also pages 402, 403, 406, 418, 416, 429, 737.

**This instrument is usually referred to as an Ammeter—see pages 410, 414.

A Combination Volt-Ammeter for Automobile Electric Tests.

Instead of having a separate voltmeter and ammeter, it is possible to combine both in one instrument using the same scale. The **Weston** model 280, garage testing voltammeter will be used as an example.

As a Voltmeter.

When using instrument for volts: See fig. 1, and note terminals are marked .1, 3, 30, +. The positive or (+) terminal of instrument is **always** connected with the positive (+) wire of circuit being tested. When making connections where polarity is not known, the needle will deflect to the left if connected wrong—reverse connections.

If voltage to be tested is known to be between 3 and 30 volts, then connect the other or negative (—) wire to terminal marked 30 and use the scale 0 to 30, the divisions of scale being 0.5 volt for each line (the scale fig. 4, has 60 divisions).

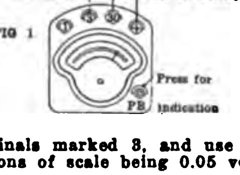

FIG 1

If voltage is known to be between 1 to 3 volts, connect negative wire with terminals marked 3, and use scale 0 to 3, the divisions of scale being 0.05 volt for each line.

If voltage is known to be less than 1 volt, connect negative wire with terminal marked .1, and use scale 0 to 3.

When making voltage or ampere tests, the button (PB) fig. 1, is pressed for indication.

The zero adjustment, fig. 2, is merely used to line up needle with zero or "O," when starting to use instrument.

A voltmeter is always connected across the line, as per figs. 1, V1 and V2, page 410. It is used to indicate the voltage pressure of an electric circuit.

*As an Ammeter.

When using the instrument for measuring amperes, it is connected in **series** with the circuit and is intended to indicate the quantity of current flowing.

It is important to note that a "shunt" must be used per fig. 2. The purpose of which is explained further on. A shunt is not used with the voltage tests.

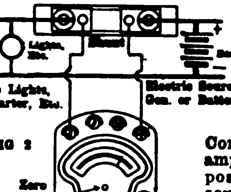

FIG 2

Connections for measuring amperes: Always connect positive (+) wire of source, with (+) terminal on instrument. Note fig. 2, the source of electric current is the positive terminal of storage battery. Current then flows to shunt connection, thence to (+) terminal of instrument, through instrument, out the .1 terminal on instrument, to other connection on shunt, thence to one side of light or starting motor, etc., through lamp or starter, back to negative (—) side of battery. See also page 410. Only the (+) terminal and .1 terminal are used when instrument is being used as an ammeter.

Shunts.

A shunt is merely a choker or a form of resistance metal R, fig. 2A, which is "shunted" between the two terminals (+ and .1) of meter per fig. 2. It must be used with all ampere tests.

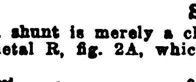

Fig. 2A.

The reason a shunt must be used is due to the fact that it is not practical to carry more than a fraction of an ampere through the moving coil K, fig. 4, of the meter. Where currents are small, the shunts are usually contained in the meter case, but for large current, external shunts are used so as to keep the heat developed in the shunts outside the meter and also for convenience, as the shunt can be located in the circuit wherever easiest and connected with meter by a small cable, thus saving running heavy wires to the instrument.

As stated only a fraction of an ampere can pass through the meter, therefore, in order that 1/10, 1/100, 1/1000 part of the total current shall pass through the meter, it is necessary that the **resistance** (R) of the shunt be such that 9/10, or 99/100, or 999/1000 part of the total current will pass **through** the shunt—which is all figured out by the **manufacturers** and it is only necessary to **know the** capacity of the shunt and connect as shown **in fig.** 2 and then take the actual readings on the **scale.**

A millivolt is 1/1000 part of a volt. The connection .1 on meter is often referred to as the **100** millivolt terminal, which is 1/10 of a volt. This however, refers to the millivolt drop in the **shunt,** which is figured out by the manufacturer and **is of** no interest with automobile work.

Capacity of Shunt to Use and Range of Scale.

Shunts to use with this instrument: There are **three** external shunts as follows:

300 ampere with which use the scale 0 to **300.** Each division or mark on scale represents 5 amperes.

30 ampere, with which use the scale 0 to 30. Each division or mark represents 0.5 amperes.

3 ampere, with which use the scale 0 to 3. Each division or mark represents 0.05 amperes.

When testing where you do not know what the amperage is likely to be, as testing for short circuits, it is advisable to assume that the highest possible amperage is to pass through meter, therefore use the 300 ampere shunt. If the deflection obtained is less than 30 amperes, then use the 30 ampere shunt and scale, to gain a more accurate reading. Should the indication now be less than 3 amperes, use the 3 ampere shunt.

The 3 ampere shunt and range is convenient for measuring single lights, and ignition.

The 30 ampere shunt and range is convenient to measure current delivered by generator to battery per A1, fig. 1, page 410; for measuring current required by the lights, horn, etc., and also for testing short-circuits and open circuits per page 402, 416.

The 300 ampere shunt and range is convenient for measuring the current required by starting motor, per A2, fig. 1, page 410 also for testing for shorts.

Internal Connections

Of the Weston model 280 garage testing voltammeter is shown in fig. 4. Note when button PB is pressed the current flows through the moving coil, then through resistors. Resistance C is the adjusting resistor for the 100 millivolt range; C and B are in series for the 3 volt range and C, B and A in series for the 30 volt range.

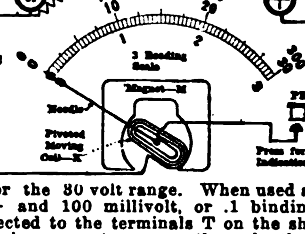

FIG. 4

When used as an ammeter, the + and 100 millivolt, or .1 binding posts, are connected to the terminals T on the shunt fig. 2A. The main current passes through the external shunt. When button PB is pressed only sufficient current passes through the instrument to cause it to properly indicate.

Ammeter Principle.

The original "gravity" principle of an ammeter, which is now seldom used, is shown in fig. 30. Note the "helix" draws the iron core into it, thus moving the needle. Greater the current, greater the draw. **The modern principle is the "moving coil, permanent magnet" type,** per fig. 4.

Fig. 30

CHART NO. 190—Description of the Volt-Ammeter. See also pages 416, 410, 402, 403, 406.

Note—A. L. Dyke, Electric Dept., Granite Bldg., St. Louis, Mo., is in position to supply electrical testing instruments. See advertisement in back of book. *For **direct** current reading only, see page 864H.

(3) Test each lamp circuit separate. With engine at a standstill, close the several switches to the lighting circuits one at a time and watch the ammeter needle closely as each switch is closed. If the needle swings to the "discharge" side of the instrument and holds there, a short circuit exists somewhere in the circuit whose switch is closed. Try all circuits in this manner, one at a time. If the ammeter indicates only the proper amount of current consumption for the several lighting circuits, as they are switched on, no further search for short circuits or grounds is necessary. However, if the ammeter needle swings against the side of the case as above, for one or more circuits, then you must proceed until the trouble is located—see pages 406, 418, 403.

If there is no ampere-meter on the dash to guide you, then it will be necessary to continue search until there is no spark at the battery terminal with switch open. If the trouble is found in poor insulation, then wrap the part with friction tape.

Testing wires for short circuits, also see pages 403, 406, 418, 410.

*Open Circuits; Meaning of, and Indication.

An open circuit is an incomplete circuit. Therefore, it does not offer a passage for current.

Ammeter does not indicate either "charge" or "discharge." Lamps do not light when turned on.

Starting motor does not crank engine when starting pedal is pressed to the full limit of its travel.

Open circuits, may frequently be located by examinations of all wires and terminals. Loose screws and nuts, poorly soldered and insecure wires, corroded connections and terminals are likely to be the cause of open circuit. Go over the wiring carefully before making tests.

Wire and terminals should make good contact. The parts making contact should be clean. Solder all wire connections and use common baking soda and water for cleaning battery terminals.

If ammeter does not indicate "charge" when engine is speeded up, or does not indicate "discharge" with lamps turned on, engine at rest, an open circuit exists between dynamo and battery.

If any one lamp fails to light, it indicates open circuit in that line. "blown" fuses, broken lamp filament, or broken lamp wire may be responsible.

If all lamps fail to light when engine and dynamo are speeded up, the open circuit is most likely located between battery and dynamo, or between dynamo and lighting switch.

The "blowing" or melting of a fuse opens the circuit and disconnects from system the short-circuited wire which caused fuse to blow.

In testing for open circuits the first thing to determine is, which one of the circuits is open; then see if connections are o. k. If so, then test the suspected wire and see if it is broken inside of its insulation by running another wire temporarily in its place and note if it remedies the trouble.

An open circuit that happens often, and one that is difficult to find, is a broken wire inside of the insulation of the lighting wiring. The easiest way to find the break, is to connect both ends of the suspected wire to a dry cell and a bell, in such manner that the bell would ring if the wire isn't broken. Then take piece of thin wire about 3 feet long and wrap each end of it around two ordinary pins with one pin in each hand, stick them through the insulation, when bell rings, the break is somewhere between the pins.

Testing current flow: Whether or not current is flowing in a given circuit may be determined by removing one of the wires forming the circuit, and then touching it to its terminal. If a spark occurs current is passing through the line—also see page 418, 403, 410, 406.

**The Ampere Meter (also Ammeter).

†Purpose: It is provided as a signal for the operator. In case current is not being generated, due to loose connections, broken wire or other causes, the operator is informed of this failure in time to have the trouble remedied before the battery is exhausted.

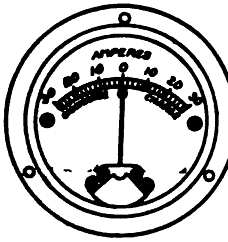

Fig. 8.

(1) It indicates when the dynamo charges battery, and at what rate. (2) It also indicates the rate of discharge from battery to lamps. It shows whether or not the system is working properly. (3) When battery is neither charging nor discharging, the pointer should indicate "O."

The ammeter is placed in series with the circuit, as shown on page 391, 410. It shows the amount or quantity of current, the lights, ignition, and horn use, and the amount of current the generator puts into the storage battery.

It does not show the amount of current used by the starting motor, and should not be used thus, unless special shunt resistance is used in connection as explained on page 410, and 414, 416.

The ammeter needle indicates that battery is being charged by generator when the needle is on the right side of (O.) The amount of charge in amperes is indicated on the dial by figures, fig. 8—see also page 410.

*See pages 416 and 418. †See page 414 for principle of operation.

**See page 398, 414 for construction of a volt-ammeter. Also note that on ammeter, fig. 8, the discharge is on the left side. On page 378 (Delco-Buick ammeter) the discharge is on the right side. This varies with different makes.

Electrical Troubles: Indications, Causes and Volt-Ammeter Tests for Same.

The electric system of a car consists principally of four units, per page 410 and as follows:

(a) generator, including the regulator and cut-out.
(b) battery.
(c) starting motor, including starter switch.
(d) wiring system.

(a) Generator Troubles.

Generator troubles are:

(1) failure to generate current at all.
(2) failure to generate sufficient current.

Indication of (1) is: failure of dash ammeter to show charge. Cause; fuse blown; open circuit; short-circuits and grounds in the field or armature circuit of generator. Tests; see pages 410, 406, 402, 403.

Indication of (2) is: low reading on dash ammeter. Cause; brushes not set for proper current; regulator defective; dirty commutator, brushes not bearing on commutator; commutator worn; brushes grounded. Tests: see pages 406, 404, 410, 402, 403.

(b) Battery Troubles.

Battery troubles are:

(1) failure of generator to charge battery.
(2) battery will not hold charge.
(3) battery voltage drops immediately after charging.

Indication of (1) is: ammeter does not show charge. Cause: may be due to generator, see "generator troubles;" may be due to cut-out not operating properly; may be due to open-circuit in the line. Tests: see pages 410, 406, 402, 403.

Indications of (2) are: slow cranking of starting motor, dim lights when battery supplies current; missing of ignition. Cause: may not be getting sufficient charge from generator; may be running mostly at night with lights on; excessive current consumption of starting motor; internal short-circuit of battery cells; grounded wiring system. Tests; see pages 410, 422, 403, 406.

Indication of (3) is: starting motor turns over very slowly and lights dim considerably. Cause: internal short circuit of one or more cells; grounded starting motor switch. Tests: see page 410 for battery test, then see index for "Cadmium test" of battery cells. See also, pages 422, 458, 461, 408, 456.

(c) Starting Motor Troubles.

Starting motor troubles are:

(1) failure to operate.
(2) operates slowly and not sufficient power to crank engine.

Causes of (1): Battery weak, test per figs. 2 and 1; open or short circuits or grounds may exist in wiring from battery to starter switch (see page 408); sticking starting switch (common); mechanical trouble with starter mechanism. Test by examining each carefully. If none of these causes, then the trouble is an internal one of motor and may be due to open circuit in motor armature or field. Test per pages 402, 403, 406. Or may be due to dirty commutator; grounded brushes. Test per pages 406, 404, 409.

Causes of (2) are: battery discharged—test battery; poor contact at battery terminal or ground wire from battery to frame; poor brush contact; dirty commutator. Test per pages 406, 410.

(d) Wiring System Troubles.

Wiring troubles are:

(1) all lights out, none burn.
(2) only one branch of lights burn.

Cause of (1): Fuses blown; battery discharged or disconnected; poor connection at battery terminal or ground wire; open-circuit; short-circuit. Test battery; examine connections—see page 406, 418, 403, 419.

Causes of (2): open-circuit; short-circuit or ground in this branch. Test per page 403, 406, 418. May be due to burned out lamp bulbs or poor contact at lamp sockets. See pages 419, 420, 424.

Miscellaneous Tests.

On page 414 a voltmeter is described which is used extensively by repairmen for electric tests as follows:

Horn test, page 418.
Cut-out and dash-ammeter, 410.
Fuses, 428, 418.
Generator and starting motor, 424.
Grounded armature coil, 402, 406, 410.
Short-circuited armature coil, 402, 406.
Grounded field coil, 403, 406.
Short-circuited field coil, 403, 406.
Commutator troubles, 404, 406.
Wiring system, grounded and shorted, 403, 406, 41
Starting motor shorted, 406, 410.
Battery tests, 410, 406, 450; also page 864: "cadmium tests."

Battery Tests.

A battery is usually tested with a hydrometer, b sometimes it tests 1275 to 1300 which is suppos to be charged, fails to hold charge. In this stance, use 30 connection on m per figs. 2 and page 410. Note it should show volts on page 41 If all cells do come up to test, test each cell of tery separately in order to on normal discha which cell is de tive, per fig. 2. page 410, sho what it should see also index "cadmium test." Each cell should show the sa

FIG. 2

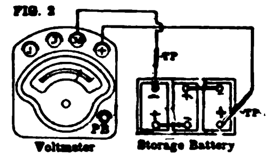

FIG. 1

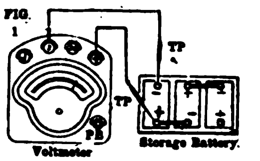
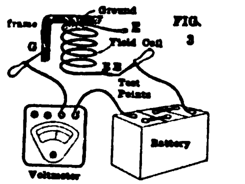


To test current consumed by starting motor, page 410.

Field Coil Tests.

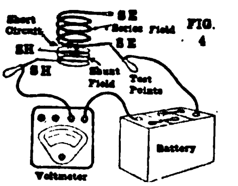
Note illustrations figs. 3 and 4 and observe the ference between a "ground" and a "short-circui

FIG. 3



When testing field fo ground, be sure both coil ends, E and EE disconnected from terminals. Use 30 connection as shown fig. 3. Place one t point on EE and ot on frame at G, if flection is shown, coil is grounded and new one must be s plied.

FIG. 4



To test if open circ place one test-point E and other on EE, the voltage is the sa as if the two test-poi were placed togeth then coil is o.k. needle of meter does move, coil is open.

On generators, there are usually two windings, series and a shunt, fig. 4. Disconnect both ends both coils (SE, SH), and be sure the ends are in contact with frame or metal parts. Use 30 v connections on meter. Place one test point on end of series (SE), other on shunt coil end (SH if short-circuited, there will be a deflection needle. If not shorted, there will be no deflecti of needle. See also pages 403, 402.

CHART NO. 191—Electrical Troubles and How To Test with Voltammeter—using meter expl on page 414. See also, pages 402, 406, 410, 429, 737, 577.

Above are electrical troubles. Generators and starting motors may have mechanical troubles, such as loose pieces, caused by screws on outside with counter sunk heads being loose; broken ball bearing; loose dri pinion; bent armature shaft (more common on starting motors); loose brush holders. See also, page 577.

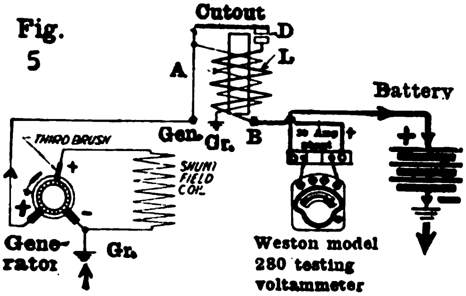
Ammeter Indications.

When generator is not charging battery, indicates the generator is producing exactly

(5)

1-**Connect cut-out between generator and battery,** as shown in fig. 5, as if on the car. Use the 30 ampere shunt with testing ammeter.

Fig. 5



2-**Use the pulleys for the 675 speed.** Permit belt to slip when first starting and gain speed gradually. The cut-out should cut in, or close at about 650 to 675 r. p. m. It will be heard to click when it closes and about 1 ampere will show on meter.

Permit belt to slip and thus slow the speed of generator down, or use the pulleys for the 450 r. p. m. and see if cut-out cuts out below 600 r. p. m.

The cut-out with most generators, cuts out when generator speed is low enough to permit battery to discharge slightly, back through series winding L of cut-out which demagnetizes the series coil, releasing the points. This discharge varies from 0 to 3 amperes.

3-**Use the pulleys for the 1425 speed.** At about 1400 to 1500 r. p. m. generator should deliver 10 amperes.

4-**Use the pulleys for the 1800 speed.** At about 1800 r. p. m. generator should deliver its maximum of 12 amperes. The generator is however, capable of giving a higher amperage, but 12 amperes is the maximum according to the manufacturers instructions. About 15 amperes is really necessary however to keep battery charged. If more, generator will heat.

5-**Use the pulleys for the 2400 speed.** At speeds over 1800 the amperage should not increase over 12 or 15 and should drop off at high speeds, or over 1800 r. p. m.

If the amperage is more at above speeds, the rate can be **decreased** by moving the third-brush in **opposite direction** to rotation of armature.

If the amperage is less, the rate can be **increased** by moving third-brush **with direction** of rotation.

The third-brush principle of regulation as used on the Delco and which is a similar principle on all third-brush regulated generators is explained on page 389. The adjustment is shown on page 405. See also page 925.

If after adjusting the third-brush this does not give the desired readings, then operate generator at 1400 to 1800 r. p. m. and note if there is a flashing at commutator and if there is a smell of burned insulation, if so, the **armature coil is likely short-circuited** and a separate test of the armature for a short-circuited coil should be made—see pages 402, 408, 416, 577. Be sure however, the flashing is not due to loose brushes, protruding mica, etc., as previously explained.

A short-circuited field coil will also cause sparking, but not so much heat, but shortened coil will heat more than the others.

Other tests of armature coils and field coils are shown on pages 577, 402, 403, 406, 416. The instruction book which accompanies the Weston meter will also give illustrations and explanation of tests on generators, starting motors, ignition condensers, electric horns, etc.

The Cut-Out.

The function of the cut-out is explained on pages 334, 342, 344, 864B, 925 and should be studied carefully.

There are two windings on the cut-out, a fine wire voltage winding A, fig. 6, see also fig. 5, and a coarse series winding L.

The winding A is always in the generator circuit but takes very little current.

The winding L is only in the circuit when battery is connected.

On the Delco some of the real old models had cut-outs, but later on the cut-out was dispensed with entirely, see page 383. On the late two-unit Delco systems the cut-out is used.

If the cut-out points stick and fail to open, the battery will discharge back through the generator.

It is well to mention here that it is permissible for the battery to discharge from 0 to 3 amperes back through the cut-out at low generator speed, and is usually the case, as the series coil is thus demagnetized which opens the points. If however, the points fail to open, then as high as 15 or 20 amperes will discharge through generator, thus run the battery down.

If the cut-out points fail to close, the generator will not charge battery.

Failure of cut-out points to open may be due to:

1-**Not sufficient air-gap space** between contact arm blade S, fig. 6, and iron core of cut-out coil, at G. This can be remedied by slightly increasing the spring tension (K) controlling the pull of blade as per fig. 8 and 9, page 342.

This air-gap is usually .010 to .015" clearance.

systems. **For testing storage battery with a volt-meter, see page 416, 864D.

Electrical Troubles: Indications, Causes and Volt-Ammeter Tests for Same.

The electric system of a car consists principally of four units, per page 410 and as follows: **Miscellaneous Tests.**

(8)

Total gear reduction of reverse: 3.74×4.437=16.594 rev. of engine crankshaft to 1 of rear wheels.

Above examples of ratios are used on the Cadillac Type 59 car. The Cadillac sometimes gives a 14 tooth drive pinion (r3) on their heavy closed cars and for touring cars used in hilly countries. The rear axle ratio would then be 71÷14=5.071 rev. of propeller shaft P, to 1 of rear wheels.

Miscellaneous Ratios.

Ford: Rear axle ratio n3, 40 teeth × r3, 11 teeth = 3.636. Transmission ratio, 1st speed 2.74; 2nd speed 1; reverse 4.

On some cars, for instance the Locomobile model 43, Mercer Series 5 and Pierce-Arrow Models 31 and 51, there are 4 speeds and on 4th the transmission ratio is 1 to 1. See also page 583. On Loco 43 and PA 51, first speed transmission ratio is 4 to 1. On Mercer 3.75 to 1.

On some cars with 4 speeds, the 4th speed is higher than 1 to 1, for instance the Wasp with 4 cylinders 4¾×5½, the 4th speed transmission ratio is .73 to 1. The rear axle ratio is 3.7, therefore the total gear reduction would be .73×3.7=2.701 rev. of engine to 1 of rear wheels. On 3rd speed the Wasp transmission ratio is 1 to 1. On 1st or low, 2.69 to 1. The total gear reduction on 1st speed being 2.69×3.7=9.953 rev. of engine crankshaft to 1 of rear wheels.

Truck Gear Ratios.

Federal 2 ton truck: Rear axle ratio 9.25. Transmission ratio, 1st speed 4.40; 2nd 3.08; 3rd 1.76; 4th 1; reverse 5.28.

Federal 5 ton truck: Rear axle ratio 13.66. Transmission ratio, 1st speed 4.99; 2nd 3.16; 3rd 1.79; 4th 1; reverse 5.78.

Replacing a Drive Pinion.

When replacing a drive pinion (r3) with one of a different diameter, it is always necessary to also replace the driven ring gear (n3), because the teeth will mesh too tight at either the big end of the tooth or the little end of the tooth, due to the fact that the teeth are cut at a different angle. See page 583, how to replace a differential gear.

Relation of Engine Crankshaft to Periphery of Road Wheels.

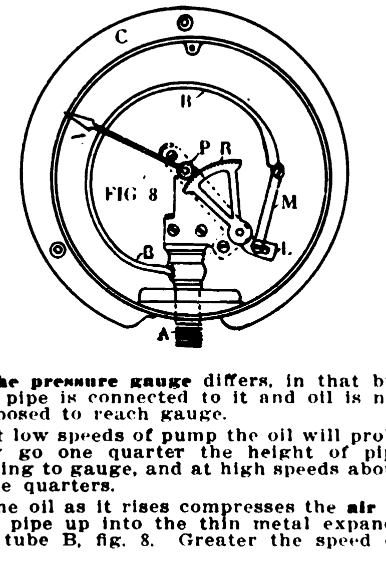
If the rear axle ratio on a certain car is 4.437 to 1, and say for instance, high gear is being used, then the rear wheels, no matter how large or how small the wheels or tires may be, will revolve 1 revolution to 4.437 of engine crankshaft.

It is then clear to see that the larger the rear wheels or tires, harder will be the pull on the engine, **smaller** the rear wheels or tires, **easier** will be the pull on the engine.

OIL GAUGES.

Two types are in general use: (1) sight feed; **(2)** pressure.

The sight feed gauge is generally used with a "splash circulating" oil system, where oil is only forced to the timing gears and to oil troughs. The gauge mounted on the dash has two pipes connected to it and the oil can be seen circulating.



The pressure gauge differs, in that but one pipe is connected to it and oil is not supposed to reach gauge.

At low speeds of pump the oil will probably go one quarter the height of pipe leading to gauge, and at high speeds about three quarters.

The oil as it rises compresses the **air** in this pipe up into the thin metal expanding tube B, fig. 8. Greater the speed of oil pump, greater the air pressure in B, which causes it to tend to straighten out, thus operating R, P and N.

Pressure gauges are of low pressure when operated with a "splash circulating" system, see fig. 3, pg. 198, and of **high** pressure when with a "force" system, fig. 4, page 198, or "full-force", page 199.

If needle fails to indicate: (1) See if oil in oil pan. "Oil level indicator", (see fig. 4, pg. 198), may be stuck; **(2)** If there is oil, then disconnect union leading to oil pump. Run engine. **If oil flows,** then look for air leaks, in piping, or in tube B, fig. 8. **If oil does not flow,** then look for clogged strainer, pump or pipes.

If needle reads lower than usual: (1) Look for air leaks; **(2)** Loose bearings permit oil to pass freely, reducing the pressure; **(3)** Thin oil or oil diluted with gasoline, due to excessive priming; **(4)** Pressure adjustment at pump, or at "ball and spring" relief valve (see bottom pages 198, 694), not properly adjusted, or weak or broken spring.

If needle reads higher than usual: (1) Heavy or cold, congealed oil, which produces back-pressure, due to slow circulation; **(2)** new and tight bearings after overhauling engine will also produce higher pressure, as the oil will not circulate as freely as when loose. See also, page 199.

Sometimes, when tube B, fig. 8, is expanded out of normal shape by too high a pressure, needle fails to return to zero. In some instances, this tube can be pressed back into shape with the fingers.

Read pages 199 and 200 about "adjusting" oil pressure when hot and "priming" pump.

HA

Ab
pie
pinion, bent armature shaft (more common on starting motors); loose brush holders. See also, page 577.

Ammeter Indications.

When generator is not charging battery, and if battery is being used for lights, ignition, or horn, the needle will be on the left side of (O) and amount of current being consumed, will be shown in figures on dial. (see fig. 8, page 415, 410.)

If on connecting a meter the needle should go to the left, or discharge side, when engine is running at fairly good speed and generator was generating current, then it indicates that the terminals have been connected wrong — reverse the connections. (needle may also be bent).

If needle is forced to the scale limit on discharge side, it indicates an overload or short circuit.

When engine is running and lamps burning and ammeter hand stands at zero, it indicates the generator is producing exactly the same amount of current that the lamps are consuming.

When car is running 12 miles or more per hour, with lights off, ammeter should indicate "charge."

Average Ammeter Readings.

The following scale will give an average reading of an ammeter with lights off and on:

Car Speed	Lights	Am. Readings.
At rest	Off	Zero
At rest	On	Discharge 5-7 amp.
Below 6 or 8 m.p.h.	On	Discharge 5-7 amp.
Below 6 or 8 m.p.h.	Off	Zero
Above 10-12 m.p.h.	Off	Charge 5 to 9 amp.
Above 10-12 m.p.h.	On	Charge ½ to 3 amp.

These readings are based on lamp equipment of two 16 c. p. 7-volt headlights, and one 2 c. p. rear lamp.

*Trouble Indications as Told by the Ammeter.

In this instance we refer to the ammeter as usually attached to the dash board of a car (pages 415, 410, 406.)

Ammeter troubles may be divided into two classes: those that manifest themselves when the engine is idle and those that only show when it is running. Both classes have two subdivisions, with lamps on and with lamps off.

Remember that the ammeter should show "charge" at speeds above 8 or 10 miles per hour; and that when engine is at rest and lights turned off, needle should stand at "zero" and not show "discharge." It shows "discharge" when lights are on and engine idle or speed less than 8 miles. In other words battery is then discharging—see page 415.

If ammeter shows "charge" instead of "discharge," and shows "discharge" instead of "charge," it indicates that the wires connected to the rear of ammeter should be reversed.

†**Ammeter shows "charge" at slow speeds and "discharge" at high speeds—or in other words opposite to what it should show;** this indicates that battery terminals are reversed, because at low speeds battery is supplying current for ignition and should show a slight "discharge," but as an ammeter hand operates opposite to what it should, when connected wrong, it would show a slight "charge."

When at nine miles speed or more, the generator should cut-in and charge battery and ammeter should show "charge," but as terminals are reversed it would show "discharge."

If ammeter indicates zero when the dynamo should be charging battery, it shows that the circuit is open, or dynamo is at fault.

Ammeter does not indicate "charge" when engine speeds up—but indicates "discharge" when lights are turned on, engine at rest.—Dynamo or regulator not working properly. Dynamo brushes do not slide freely in holders.

Ammeter does not indicate "charge" engine speeded up—and does not indicate "discharge" lights on, engine at rest.—Open or loose connection in the battery circuit. Battery terminals loose. Dynamo terminals loose. Ammeter may be at fault.

Ammeter indicates "discharge" lights turned off, engine at rest.—Ammeter pointer bent. Insulation on wires injured, permitting contact with frame, causing ground or short circuit. Cut-out points stuck.

If the trouble seems to be in the ammeter, it is well to place a **test** ammeter in circuit, to check the first instrument. If the instrument registers incorrectly it should be returned to its makers for repair.

Ammeter indicates "charge," engine at rest.—Ammeter pointer bent. If current is flowing, meter or battery terminals connected wrong.

****Ammeter "charge" indications below normal.**—Dynamo output varies with condition of battery. (see also page 409.)

Ammeter "discharge" indications above normal.—Lamp load excessive or old lamps. Wires grounded or shorted.

Ammeter pointer jerks intermittently to "discharge," limit of scale while engine is speeding up.—Short circuit in system.

Fuses blow out repeatedly.—Heavy ground or short circuit or the fuse may be too small for the current required.

If larger than standard bulbs or extra lamps are used "discharge" indications will be higher. The generator may not be capable of charging battery sufficiently to overcome the excess load, especially if there is insufficient day driving or excessive use of lamps at night, thereby permitting battery to discharge more rapidly.

†Varies on different systems. On some systems the cut-out will vibrate rapidly and meter needle swing back and forth—see also page 421.

*This applies as well to the indicator, which is in reality an ammeter. The instructions may vary for different systems. **For testing storage battery with a volt-meter, see page 416, 864D.

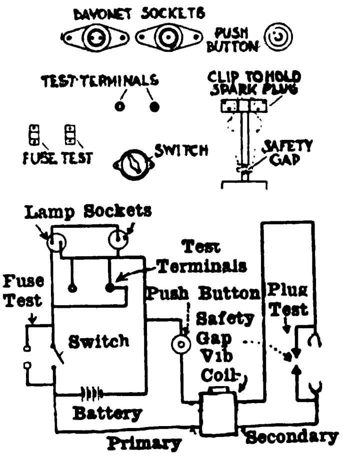


Fig. 3—A test board for bulbs, fuses, spark plugs and horns.

Electric Testing Board for Lamps, Spark Plugs, Horns, Etc.

Illustration fig. 3, shows a test board and wiring for same, for testing the following:

1—Lamp bulbs; either single or double contact bases, see page 432.
2—Fuses—see page 428.
3—Spark plugs.
4—Horns.

Quite often a lamp does not burn. It may be due to the lamp being burned, out, or an open-circuit in the wiring. To first determine if it is due to the lamp bulb, it can be quickly tested. If it is o. k. then the trouble is in the wiring. This also applies to the fuse.

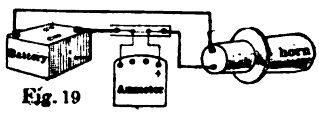

Fig. 19

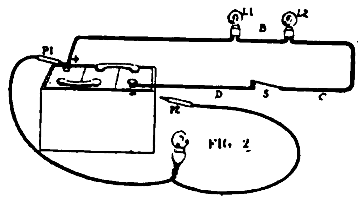
The horn can be tested by placing an ammeter with the 30 ampere shunt (see page 414) in the circuit, per fig. 19. Then adjust to take the least possible current. The average horn draws from 3 to 8 amperes, owing to its size—see page 514. The ammeter can also be used to test the horn for short-circuit or open circuit.



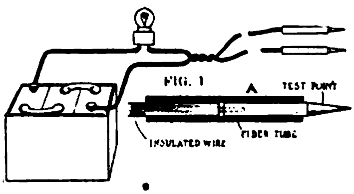


Fig. 1: A test lamp and battery, for locating troubles in the electric system.
Fig. 2: Test lamp for locating troubles in series lighting circuit.

Electrical Testing Outfits.

Testing outfits for the electrical repairman which can be added are:

5—Magneto tests per pages 301 to 304.
6—Magneto remagnetizer, pages 301, 303.
7—Cadmium test for storage battery, see index.
8—Hydrometer outfit, per page 452.
9—Storage battery portable testing outfit, page 474.
10—Portable lamp and plug testing outfit, page 710.
11—Battery bench, per page 474.
12—A steamer for batteries, per page 473.

Other outfits for the electrical testing and repair department could be added as follows:

13—A cleaning outfit for parts, page 401.
14—Test points and meters for generator and starting motor tests, per pages 402, 403, 414, 474, 424, 410.

How to Locate an Open Circuit with the Test Point and Lamp.

"Test-points" used in connection with a 6-volt "test-lamp" can easily be constructed by following the illustration in fig. 1. For emergency use any two lengths of wire with bared ends usually will serve.

Should test lamp fail to light under any of the following conditions, it is an indication that there is an open circuit between the last point where the test lamp would light, and the first point along the circuit where it failed to light. Suppose you had an open-circuit in your lighting wiring system—proceed as follows:

1—Be sure the **fuse** is not open, by testing it, per page 428.
2—**Test battery** by placing one test point, P1, fig. 2, to positive terminal of battery, the other test point, P2, to the negative terminal; if the test lamp lights, then you know the battery is o. k.
3—**Test the wire to switch,** by placing test point, P2, at D; if test lamp lights, then you know your wire to this point is o. k.
4—**Move** test point P2, to C, on the other side of switch, close switch; if test lamp lights, then you know **the switch** connections are o. k.
5—**Test the lamp L2,** by placing test point to the right-hand terminal of lamp L2; if test lamp burns the wire C is o. k.
6—**Move P2,** to the left-hand terminal of lamp L2. When this connection is made the test lamp and lamp L2 will be connected in series across terminals of battery. If lamp L2 is o. k. the filament of test lamp will brighten up, but not to the same extent it did when connected to the right-hand terminal of L2.
7—Move P2 to right-hand of terminal of lamp L1; if test lamp glows the same as when the test point P2 was connected to left-hand terminal of lamp L2, then wire B is o. k.
8—**To test lamp L1 and wire leading from (+) terminal of battery to lamp L1, may be tested** by placing test point P2 on the negative (—) terminal of the battery, and the test point P1 on the left-hand terminal of the lamp L1; if test lamp lights, this lead is o. k.
Then move test point P1, to right-hand side of L1, which places the test lamp and lamp L1 in series; if lamp L1 is o. k. the test lamp will light, but not at full voltage, due to resistance of lamp L1 in series with it.

Testing For Short Circuits with Test Point and Lamp.

Short circuits between two wires may be tested for, with the test lamp and battery shown in fig. 1, by placing one test point in contact with one of the wires, and the other test point in contact with the other wire. If the test lamp lights it is an indication that the two wires being tested are connected or short-circuited—see also page 403.

CHART NO. 192—Electrical Repairman's Testing Outfits. Test Points and Test Lights—see also pages 403, 402, 406, 410, 424, 414, 737, 429.

Ammeter shows excessive "discharge" at low speeds or engine idle; this is caused by the cut-out contacts being held closed or "stuck," and means a dead short circuit of the battery through the generator. This must be corrected at once by disconnecting the points, see pages 409, 411, 410.

The ammeter will always indicate if a short circuit exists in any part of the wiring, except from the battery to the switch bus bar, and in the starting motor circuit.

Ammeter Troubles.

Tapping the ammeter should jar the hand loose if it is only stuck. If it still refuses to register examine the connections, and if these are all right look at the cutout. Finally disconnect one of the main wires from the generator terminal to see whether any current is flowing from the generator, and follow the wires from thence to the ammeter, examining them at each terminal to see whether current is flowing by touching the disconnected wire to its terminal.

A rough check on the accuracy of the ammeter may be obtained by noting the ampere ratings of the various lights on the car and then switching them on one at a time. The reading of the ammeter should correspond to the total amperage required for the lights—see also page 410.

With the engine running and the lamps on, the ammeter may register either "discharge" or "charge," depending on the speed of the engine, the capacity of the generator with respect to the lamps, and the condition of the battery, that is, whether it is charged or not.

Unsteady reading of the ammeter may be due to a defect in the instrument, or due to loose contact or intermittent ground. See flickering lamps, pages 420 and 421.

Tests with a Volt-Ammeter.

In this instance we will refer to the volt-ammeter, as described in charts 190 and 191, and used for general shop testing work.

The tests for various troubles, such as, short circuits on the line, generator, testing coils of generator and battery cells, etc., is shown on pages 410, 402, 403, 406, 414, 453, 412.

*A Digest of Lighting Troubles.—See also, page 577.

Starting and lighting troubles are due to one or more of the following causes:

Bad contacts.
Broken connections.
Grounds.
Weak battery.

Symptoms of these various difficulties may conveniently be grouped under the following heads:

(1) Lamps.
(2) Generator.
(3) Battery.
(4) Motor.

No. 1, we will treat below. Nos. 2, 3, and 4 are covered on their respective pages as enumerated:

See page 407 for starting troubles.
See page 411 for generator troubles.
See page 422 for battery troubles.
See index for carburetor and ignition troubles.

(1) Lamps.

Lamps do not light up.—(a) Examine fuse block for blown fuses.

If the fuse is blown, do not replace it immediately, but look over the wiring for an accidental ground or short circuit. If the fuse in the headlight circuit blows, turn off the headlight switch until the trouble is located and removed. In looking for grounds, abrasion of the insulation on the wire, or a metallic contact between the wires, or between current-carrying part of the wiring devices and the metal of the car, should be looked for.

When the trouble has been located and corrected, then replace the blown fuse with another of the same capacity, being sure it is the proper size.

(b) If **fuse is found not blown**, look for open circuits, loose contacts, battery disconnected or accidentally run down, or burned out lamps.

Examine the "cutout" switch of the generator, to see that it is properly disconnecting the generator circuit from ground. This switch should be in the open position, when the engine is not running, and should be in the closed position when the generator is running at any speed over 300 to 450 r. p. m., this cut-in speed, varying slightly with the size of the generator.

(c) In case **battery is run down**, recharge it immediately, and if possible, give it a gassing charge—see page 447.

No lights or dim lights, with the engine running: there is a group of troubles which can be classified under the general head of open circuits. There are eleven of these which are prominent:

1—the generator terminal or brush connections may be loose or poor contact.

2—the wire connections to switch may be defective.

3—defective wire connections to connector terminals.

4—lamp socket terminal loose.

5—burned-out bulbs.

6—halves of connectors do not make contact.

7—bulb bases out of contact with lamp sockets.

8—loose connection on lighting switch.

9—broken wires, especially at taps.

10—joints or places subject to abrasion.

11—defective connections at the lamp.

*See Instruction 43 for additional "Digest of Lighting Troubles." **Remember, when testing for electrical troubles that a complete circuit is necessary** in order to have the electric current do its work. See pages 429, 787 and read foot note page 576.

Lamps in one circuit do not burn.—This may be caused by;

(a) The lamp is burnt out. Try another lamp in the same socket.

(b) If fuse is found blown, try the same fuse in another circuit. If the fuse is blown do not replace it immediately but look over the wiring for ground or short circuit.

If the trouble cannot be located immediately turn off the switch on the damaged circuit until the trouble has been located.

If the trouble is in a particular lamp socket, disconnect the attachment plug from this socket until the trouble can be removed and see that the removed attachment plug does not dangle in such a way, as to make short circuit on the metal of car.

(c) An open circuit, or broken connection in the wiring. Examine the places where the connections are made on that particular circuit.

(d) In case trouble is due to short circuit on some particular lamp socket, disconnect the attachment plug leading to this socket until the difficulty can be remedied.

Fuses blow repeatedly.—lamps defective —short circuits—first try new bulbs. Fuse may not be large enough capacity.

Lamps go out for an instant only.—if the lamps in one circuit act this way, there is probably a loose connection on the circuit so affected.

If all the lamps go out for an instant there is probably loose connection at one end of the wire from the generator terminal to the fuse box.

All lights burn dim,—usual trouble is loose or slightly grounded connections, or poor or corroded connection at the battery. More likely the battery simply has not had sufficient charging.

If the wiring is all right, run as much as possible with lights off so the dynamo will charge the battery at a higher rate.

If the battery continues to run down, examine cut-out. If cut-out is o. k., then test battery with switch off, for a "ground" or slight "short circuit" in the sockets, or switch. See chart 189, and fig. 6. page 413, and pages 418, 403.

If there is no ground, then test battery electrolyte, also each cell separate as per pages 416, 450.

Lamps may also be old and blackened, try new bulbs.

Lamps too bright.—Regulator evidently set for a higher voltage. Use lamps of higher voltage.

Lamps burn out often.—Due either to a poor grade lamps used, or not proper voltage or inferior grade—see page 403.

Lamps flicker and ammeter unsteady.—Loose connection in light wires. Loose connection between battery and dynamo. Loose contact at lamp bulb. Exposed wire touching frame intermittently, causing short circuit.

Lamps burn very dimly when starting pedal is used.—Battery very weak, almost discharged. Battery injured, probably one or more cells, due to lack of water. Battery terminals or ground wire not tight.

Lamps bright, engine speeded up, dim when engine slows down or idle; battery discharged or loose connection.

If possible, have the battery charged at once from an outside source.

If this cannot be done, endeavor to run with fewer lamps than normal, turned on for a few days, or until the battery voltage picks up again.

If the lights grow dim when the car is speeded up, wires **reversed** at dynamo.

Lamps will not light, but starter cranks engine.—Lamps burned out or filament broken. System short-circuited or open circuit, at fuse or switch.

Lamps seem to burn brightly, but fail to illuminate road sufficiently,—lamps out of focus. Rays of light directed too far upward (see "focusing" page 433.)

None of the lamps will burn—and no spark is obtained for ignition, this may be due to:

(a) Terminals of the battery are disconnected or corroded, so that they do not make good contact.

(b) Ground wire, from the battery to the chassis is disconnected or broken.

If the ignition is all right, the trouble may be due to:

(a1) Lead from the battery to the generator, disconnected or broken.

(b1) Lead from generator terminal to the fuse box is disconnected or broken.

(c1) The lamps are burned out. This is likely to happen when either of the troubles are a, b, or a1.

(d1) Battery is run down. (see battery instructions, also page 422, 416, 410.)

If one lamp burns dim, change the bulb. If the same lamp is still dim, test the wiring to the lamp. Examine lamp socket.

A great many of these troubles are found in poor connections in the lamp socket—or slight ground in this circuit.

Lamps flicker:—This trouble is usually attributed to loose connections.

It can also be caused by bad contact or an intermittent ground. For instance a contact might be just loose enough so that vibration would cause the circuit to be made and broken repeatedly.

A grounded wire might also cause this trouble by alternately making and breaking the ground connection. Every time the ground is made the light goes out because the current flows through the ground instead of through the lamp.

Obviously the trouble may be roughly located by noting whether all the lamps flicker or only one. If all do, then the trouble must be in the generator, or on the main lines running from it, and if only one does, then the trouble is in this individual circuit.

See page 577 for Digest of Starting Motor and Generator Troubles.

‡Reversal of Battery Terminals To Generator.

The generator connections to the battery should be positive pole of generator to positive pole of battery and negative pole of generator to negative pole of battery.

If battery is connected reversed, as would connect positive pole of generator with negative pole of battery, then it would appear that this series connection would double the voltage, but such is not the case.

On the Remy system the battery voltage would be sufficient to influence and control the generator polarity and generator would soon reverse itself—the ammeter however would read in reverse direction to what it did previously.

On other systems the field would not reverse readily and the needle of ammeter would swing back and forth, due to the cut-out switch vibrating. The generator in this case would build up as it normally would until it reached sufficient voltage to close the cut-out switch. The moment this was closed the strength of the field would decrease, consequently output of generator would drop until such a point the cut-out switch would automatically release, then the same action would continue causing the cut-out switch to vibrate.

In many instances, by merely holding cut-out switch down a few minutes it will cause a reversal of the polarity of the fields. However, the best plan is to connect the battery as it should be.

On the Delco late systems the polarity of generator would be reversed and no serious harm would result.

On the early Delco type which used the cut-out, the voltage of generator would drop, consequently strength of fields, similar to paragraph four.

The battery would not necessarily discharge itself if connected reversed—providing the generator immediately changed its polarity as cut-out would open circuit as usual when engine was idle. The battery would not receive a charge however until polarity of generator was reversed.

If polarity of generator did not change immediately then battery would discharge, because cut-out points would open and close repeatedly, causing a sparking until points become pitted and stuck together.

Don'ts and Do's—Read Carefully.

Always disconnect the wire from generator terminal, before disconnecting the battery, and reconnect the battery before reconnecting terminal. Otherwise the lamps may all be burned out if the engine should be started.

Don't use a piece of wire instead of a fuse.

Don't short circuit your battery with a pair of pliers or screw driver, to see if it's charged.

Don't advance spark, but retard when you start with starting motor—throttle partially open.

Don't use emery paper on your commutator; use fine sand paper.

Don't forget to see that your ignition switch, spark lever and gas lever, are all in their proper positions, before depressing the foot switch to start the engine.

Don't fail to push down the button of the foot switch to its limit.

Don't continue to crank your engine, if ignition does not take place after a few revolutions. There is something wrong with your ignition system, or the carburetor. Look for the trouble. Just turning over the engine will not help matters, but it will exhaust your battery, if continued for any length of time.

Don't allow connections on generator, battery or motor to become loose.

Don't blame the generator for every trouble you may have. As a matter of fact, 90 per cent of all troubles originate in switches or wiring connections, at the lamps, which are necessarily small and more or less liable to imperfect contact or short circuit.

Don't forget that it requires twenty times as long to restore current to the battery, as it takes to start the car. In winter, it is sometimes advisable to use starting crank to save the battery current.

Don't put oil or grease on the commutator of the generator or motor.

Don't tighten up on the silent chain drive unless the slack becomes excessive from stretching. The chain must be run with a reasonable amount of slack to prevent noise and wear.

Don't fail to lubricate the silent chain drive at frequent intervals. Noise will be eliminated and wear reduced. Keep the chain and sprockets clean, and free from dirt.

Don't run your car, if for any reason the battery is disconnected from the circuit, unless you have disconnected the chain driving the generator, or the generator itself has been removed.

Don't forget to examine your battery at intervals of about two weeks, and make certain that the electrolyte covers the top of the plates in each cell. See instruction 32.

Don't allow your battery to become loose in its box or container. Strap or wedge it tightly in position, and make certain, that the terminals cannot come into contact with anything which may cause a short circuit.

†The Starting and Lighting Storage Battery—See also, page 577.

Chief in importance, ranks the care of the battery, owing to the fact that it is extremely sensitive to the slightest ill treatment. (see storage battery instructions relative to the construction, care, charging, etc.)

Storage batteries used for starting and lighting must have heavier terminals and parts than one used merely for lighting or ignition. This is due to the fact that a greater volume or amperes of current is drawn for starting motor and the terminals must be of sufficient size to carry this heavy quantity without heating. (see chart 201.)

A storage battery used for lighting, will operate the lights until the specific gravity (SG), is down to 1.150, whereas **a starting** battery, should not be allowed to fall below 1.225 specific gravity.

If Battery is disconnected be sure and **reconnect it with same wires or terminals**—otherwise reversal of current will result.

The wires should be tagged if disconnected. See "index" disconnecting battery.

Color of terminals, of a battery. The positive terminal of a battery is always of a dark color, and the negative, more a grey color. Positive terminals are usually designated, by a (P) or (+) sign and the negative by an (N) or (—) sign.

To test a wire lead from generator for its polarity, if not marked, see chart 204-A.

If sparking occurs when switch is off, and when connections to battery are being made, even the smallest spark, it is evident that a ground or short-circuit exists in either the starting motor wiring or in the wire from the battery to the lighting switch. Go carefully over the wiring again, as this must be located and corrected.

See fig. 6, page 413, note the method for testing the circuit for a ground by suddenly making contact with battery terminal with switch off, see also page 406.

***Storage battery connections and ground;** the positive terminal of a storage battery is usually grounded to frame. This connection to frame should be filed clean and tightly drawn together with a bolt, or else soldered.

Often times poor connections at battery terminals and this ground wire, will result in dim lights and weak current supply. Always clean battery terminals with file when connecting battery. (see also pages 457 and 428). †See pages 457 and 451. ‡See also page 925.

*Starting and Lighting Battery Does Not Stay Charged—Causes.

The battery does not stay charged—This may be due to any of the following:

(a) ***The car is not run enough without lights or at high enough speed** for the generator to charge the battery and replace the current that is taken from it when the lamps are burning with the engine idle or running at very low speed.

(b) **A ground in the car wiring.** With the engine idle and all switches "off," disconnect the battery wire and touch it lightly on the battery terminal a few times, per fig. 6, page 413. If there is a spark produced there is a ground in the wiring between the battery, the generator, and the switch, or the magnetic switch in the regulator is not open, see also page 406.

(c) **Regulator or cutout switch not operating** properly. Examine the switch and see that it is properly connecting and disconnecting the generator circuit (see page 410). The cut-out switch should be in the open position when the engine is not running, or should stay in the closed position when the engine is running above "cut-in speed." If the switch does not close there may be oil on brushes or commutator of generator, or one of the brushes may be worn too short.

(d) **A constantly discharged battery can also be due** to an overload on the starting or lighting system, which may be caused by the leakage of current from short-circuits or grounds as described, by increasing the lamp load through the adding of higher candlepower or lower efficiency lamps, **by adding additional apparatus to the lighting system** or to operate from battery, by the improper operation of the starting motor or by burning the lamps much longer than normal.

(e) **A discharged battery can also be due** to an internal short-circuit, as explained on pages 413, 410 and 416.

(f) **Generator may not be generating** current properly.

(g) **Battery may be leaking** its solution slightly but continually.

(h) **Out-out points may be stuck** and when engine is operated below an engine-speed corresponding to about 8 or 10 miles per hour or less the battery discharges through the armature of the generator (see pages 409, 411).

(i) **A weak battery may also be caused by low gravity electrolyte,** in which case distilled water should be added to bring the level ½ in. above the tops of the plates, and then the battery should be charged. Loose or poor connections will cause weak current. (see foot note, page 421.)

(j) **A weak battery may be caused by lack of charging due to the cutout points not closing** as they should.

†Remedies for Above Troubles and Hints to Save Battery Current.

(a) Have battery recharged, from an outside source. Use starting crank often as possible. Use starting motor as little as possible. In winter the starting motor is used more than in summer on account of difficult starting. Use dimmer lights instead of head lights thus saving on the current consumption. Provide a good "choker" or primer which will start engine quick.

(b) The test is mentioned above. Other tests are shown in charts 190 and 191.

(c) On some cut-outs (also called relays,) they are sealed. If adjustable, examine the points. See pages 359, 410.

(d) Quite often extra large lamps or additional electrical devices, or short-circuit in the electric horn will cause undue waste of current. Replace lamps with lower candle power and use least number possible. Spot lights are handy, but consume current, use the headlights.

(e) If the battery becomes discharged immediately after having been charged, and there are no "grounds," examine each cell, and test voltage with starter on—see pages 410, 416, and cadmium tests, page 864D.

(f) Test generator as explained on page 411. Also pages 416, 410.

(g) Examine each cell carefully.

(h) This would cause a weak battery if allowed to continue for any length of time. Therefore, allowing the engine to idle, or running slowly on high gear, should not be done to any extent.

(i) Continued undercharging will result in sulphation, and the remedy is to give the battery a prolonged charge.

A weak battery is also indicated by a lowered specific gravity. When the battery is charged the gravity is 1.250, and when badly run down it drops to 1.150. Therefore, both charged and discharged conditions may be determined by measuring the specific gravity, with a hydrometer, which instrument will be fully treated under storage batteries. Don't let battery discharge in winter—it will freeze.

(j) Operate car at speed at which the cutout should close and note whether it does or not. (see pages 409, 410.)

***Note**—See pages 458, 577 additional battery and starting and lighting system troubles.

***There is more trouble from discharged batteries in winter than in summer,** due to the fact that engines are usually more difficult to start and battery is used more. **Consequently the generator does not have an opportunity to put back the current taken out—especially if car is run more at night with lights on.**

The engine crank is more difficult to turn over on cold days after standing a long while, due to oil being heavy and congealed and unvaporized gasoline.

†Keeping battery charged: Keep engine tuned up so that it starts on the second or third turn. This minimizes the amount of current used in starting, and, remember, this is very large. **Be economical with lights.** Use headlights only when absolutely necessary. **Determine the car speed at which cut-out relay makes connection with the battery** and operate the car as much as possible above this speed.

If you drive much in a congested city district and stop your engine many times, you will find that your battery can be kept more nearly charged by changing gears in traffic whenever necessary instead of trying to do it all on high gear, the reason being that by changing gears you boost your engine speed so that battery is charged, while if you try to pull slowly on high you get down to a speed at which charging stops due to the opening of the cut-out.

†Disconnecting Storage Battery and Generator.**

On many systems the storage battery, if disconnected, the lights would be burnt out because the battery acts as a voltage regulator and keeps the voltage constant. Therefore if removed, the generator voltage would increase with speed of engine and burned out lamps would be the result.

See page 925, explaining the meaning of "voltage" and "current" regulated generators.

As an example of disconnecting the generator and battery, from a car, questions will be answered on a few of the leading cars.

Q1—What make of generator is used?

Q2—Is the regulation "voltage" or "current" regulated?

Q3—What precaution is necessary in disconnecting battery?

Q4—What precaution is necessary in disconnecting generator?

Q5—Would it be possible to run engine if generator is out of service?

Q6—Would it be possible to run engine if battery is out of service?

Q7—If both generator and battery is out of service could dry cells be used?

Hudson.

A1—Delco single unit.

A2—Current regulated; third brush.

A3—If the battery is disconnected the motor cannot be operated.

A4—Disconnect the cables attached to the battery terminal of the generator and connect them firmly together. The joints should be wrapped with tape or insulated in some way to prevent any possible chance of contact with the frame. The battery circuit for the lamps will in this way be maintained. The cables connected to the shunt field terminal and to the armature terminal should also be disconnected and the ends insulated.

A5—Yes. By taking the precautions noted above the battery would furnish the ignition.

A6—No, the engine could not be started.

A7—Yes, if the generator and storage battery are both out of service, dry cells could be used in place of storage battery.

Cadillac.

A1—Delco.

A2—Current regulated; third brush.

A3—Care should be taken to prevent short-circuit.

A4—Generator should not be removed or an adjustment made on circuit-breaker, nor any of the wires to same removed without first disconnecting battery.

A5—Yes, so long as storage battery is charged, as current for ignition would be taken directly from storage battery.
If it is desired to do this, leave the cable connecting the motor generator and storage battery attached at the storage battery end. Connect the motor generator end of the cable securely to the red wire which leads to the ammeter. Connect the black wire from the horn switch to the yellow wire which goes from the No. 2 terminal on the generator to the circuit breaker. Tape the ends of the wires connected to No. 2 and No. 3 terminals on generator separately so that they will not short circuit or ground.

A6—Never run engine with storage battery off the car or disconnected.

A7—Yes. Use 5 dry cells in series and connect as follows: First, disconnect the wire from the ignition and lighting switch to the upper terminal on the end of the ignition coil on the dash, and connect one wire from the dry cells to this terminal. The other wire from the dry cells should be grounded to some convenient point on the engine or frame where a good contact can be secured. With dry cells thus connected it is possible to start the engine by hand cranking and to run it as long as the cells will furnish current for the ignition.

Packard.

A1—Bijur.

A2—Voltage regulated.

A3—Engine should not be speeded up, as generator current would not have sufficient outlet and injure generator.

A4—Be sure and tape terminals to prevent short circuits.

A5—Yes, from storage battery, but battery would not be recharged.

A6—Yes. A7—Yes.

Studebaker and Saxon.

A1—Wagner.

A2—Current regulated.

A3—Generator terminal should be grounded to frame so as to prevent generator becoming damaged.

A4—Ground generator terminal.

A5—Yes, battery will supply ignition current.

A6—No. A7—Yes.

Dodge.

A1—North East. See pages 732, 369.

A2—Current regulated.

*A3—If the starter-generator is run without being connected to the storage battery, ground the terminal of the starter-generator which ordinarily is connected to the battery. Failure to do this will cause the starter-generator to overheat and may in some cases cause a great deal of damage.

A4—Ground both generator terminals. It cannot be used for either lights or ignition if battery is removed.

A5—Yes, battery will supply lights and ignition.

A6—Dry cells not recommended.

Maxwell.

A1—Simms Huff.

A2—Current regulated.

A3—Remove field wire from generator.

A4—Use shorter fan belt to drive fan if removed.

A5—Yes, from battery.

A6—No, as there is no outlet for current produced by generator and it would damage itself.

A7—Yes, by using 4 dry cells in series, connecting one terminal to top of ignition coil and grounding other terminal. It will then be necessary to crank engine and disconnect generator per A3.

Overland.

A1—Auto-Lite.

A2—Current regulated, see page 859.

A3—Tape terminals to prevent short circuit—see also page 859.

A4—See ans. to A7.

A5—Yes.

A6—Yes—by using current for ignition, dry cells, but not from generator.

A7—Dry cells can be used. The ignition wire, or the wire that is attached to the positive terminal of the storage battery should be attached to the positive side of six dry cells, series connected, and the negative side grounded to some part of the body or car frame.
After installing the dry cells, and before starting the motor, a piece of bare copper wire should be used to ground the generator. This wire should be attached to the positive terminal on the generator to some part of the car frame. This will prevent the increased voltage from the generator due to no resistance from the storage battery, since it has been removed from the car, from burning out the lamps and seriously injuring the generator.

Reo.

A1—Remy.

A2—Thermostatic, see page 371.

A3—Ground two lower terminals on generator, as generator cannot be used for ignition or lights if battery is removed.

A4—Tape all terminals to prevent short circuits.

A5—Yes, until battery runs down.

A6—Not from current from generator. Dry cells could be used.

A7—Yes. If dry cells are substituted for storage battery, the two lower terminals on the generator must be connected.

*On the Dodge where magneto was formerly used, remove fuse from generator.

†See also pages 925 and 421. **Be sure and tag all wires so will be connected back right. Battery wires must connect correctly, else dash meter will read backwards.

A Testing Bench for Starting and Lighting Systems.

The test stand is divided into two parts; that for testing the generator and that for testing the starting motor.

The layout is shown in illustration. The generator equipment is at the left of the bench and the starting motor equipment at right.

The generator is clamped to a hinged table, and driven by a one-half h. p. varible speed motor, the variation of speeds, from 600 to 1,800 r. p. m. being controlled by a rheostat.

The starting motor is supplied with current by a 6 or 12-volt battery, as the case may be. The load is applied to the starting motor through a prony brake, regulated by a pedal and measuring the torque on a 25 lb. spring scale.

As the current flow to starting motor will be high, the ammeter will require a "shunt" permitting the measure of current flow up to 300 amperes, as described on pages 416 and 414. All wiring in connection with the starting motor, with exception of ammeter and voltmeter leads to be No. 1 flexible cable.

Testing Generator.

1—**Run generator as a motor from storage battery.** By knowing the amount of current required to run a generator known to be in good condition, and the number of revolutions per minute at which it should run, a comparison may be made with the similar operation of the generator being tested.

(a) **If an excessive amount of current** is required and the **speed** is somewhat **low**; a short circuit armature is indicated, or bearings may be too tight.

(b) **If speed is high**; a defective field is indicated.

2—**Drive generator** connected through the lamps to storage battery until from 8 to 10 amperes of current is generated.

(a) **Take the speed** of generator.

(b) **Compare this speed** with that of a generator known to be o. k.

(c) **If it is found necessary to drive generator much faster than normal,** providing brushes and commutators are in good condition; defective fields or armature are indicated. This condition should be checked with that of the first test.

3—Not only do the above tests show exactly what is happening with the generator as compared with a generator known to be in good condition, but also current cutouts and control can be regulated within the required limits. Any equipment manufacturer can supply the data required in making these tests, or it may be obtained from a generator known to be in good condition. See also, page 864C.

Testing Starting Motor.

1—**Run starting motor** without any load.

(a) **A high amperage reading and slow speed will indicate** that bearings are either tight or the armature or field circuits are shorted. This test may be made with one, two or three cells of a storage battery supplying the current.

(b) **If current is not excessive, but speed low;** the connections and conditions of brushes and commutator should be examined. Likewise the brushes should be adjusted.

2—**The next test is made under load,** to show whether the starting motor will deliver its full power at required speed and with the required amount of current.

(a) **For example,** a certain instrument having a current of 135 amperes passing through it at approximately 6 volts should turn 2000 r.p.m. and exert a torque of 1½ ft. lb. This amount, if the pulley were 2 ft. in diameter, would register 1½ lb. on the spring scale. However, it is not advisable to use so large a pulley, and by using a 6-in. pulley the spring scale reading is multiplied by four, giving the reading required.

(b) **In making the test** the motor is started and sufficient pressure applied to the pedal to bring the spring scale to the required reading. The ampere voltage and speed readings are taken and compared with the similar readings of a starting motor known to be in good condition. A low reading indicates defective armature or field.

CHART NO. 192-A—Electrical Testing Outfit for Starting Motors, and Generators. See also pages 577, 864C, 418, 410, 406, 404, 416, 402, 403, 737, 429.

(Motor World.)

INSTRUCTION No. 30.

WIRING OF A CAR FOR STARTING, GENERATING AND LIGHTING SYSTEMS: Single, Two and Three Wire Systems. Wiring Starting Motor, Generator and Lighting Circuits. Size Wire to Use. Comparison of Current Carried in Starting and Generating Circuit. Wiring Accessories.

The single wire system is also called the "grounded return" system because one wire which returns to complete the circuit is grounded to the frame of the car as shown at A, chart 193.

The single wire or grounded return system is used on seventy-five per cent of the cars. In this system only one main wire is insulated, the other being connected to the frame of car which acts as the return wire.

In this system the negative (—) terminal of the battery is connected to the electrical units and lamps through switches, and the positive (+) terminal is connected to the metal frame of the car. As the positive (+) terminal of each unit and one terminal of each lamp is also connected to the frame either through mounting or by cable, the circuit is completed when the switch is closed. See A, chart 193.

The two wire system: Where wires are not grounded but are run independent of the frame or ground connections, it is termed a two wire system. A simple explanation is shown at B, chart 193. In this system both wires are insulated and kept away from the frame.

The three wire system is shown at, (C). This system is sometimes employed where 12 volt or higher voltage batteries are used and where it is desirable to use 6 volt lamps. See also chart 205-C.

Kinds of Wire Generally Used.

Primary wire is used for **low tension** or **voltage, as ignition,** from battery to coil, and coil to timer (see page 240) and for **lighting**. It is usually flexible, consisting of several strands of wire. When used for lighting it can be "duplex" or even four wires together, and is usually encased in metal armor for protection.

1— 

PRIMARY WIRE—Single

2— 

PRIMARY WIRE—Duplex

3— 

PRIMARY WIRE in metal armor

4— 

PRIMARY WIRE metal armor

5— 

SECONDARY CABLE—note heavy insulation

6— 
STARTING MOTOR WIRE note heavy wire

7— 
LAMP CORD—twisted No. 18

Secondary cable is used for high tension ignition current. The wire is small but insulation heavy (see page 240).

Starting motor wire is very heavy, being several times the size of the secondary cable, but insulation is not so heavy. This is due to the fact that it does not carry a high voltage, only 6 to 24 volts, whereas secondary cable carries a voltage high enough to jump a gap.

The starting motor wire carries a large **quantity** or **amperage** of current, for instance, the wire runnig from the storage battery to the starting motor, when first starting, must carry from 80 to sometimes 400 amperes; or quantity of current, owing to the size of motor. This is used only for a few seconds. But, large wires must necessarily be used to carry this great quantity, even for a few seconds. **Compare the size of the starting motor wire (6, illustration to the left) with that of the primary wire (1), which can be used for generator or** lighting. Note the difference in size of wire.

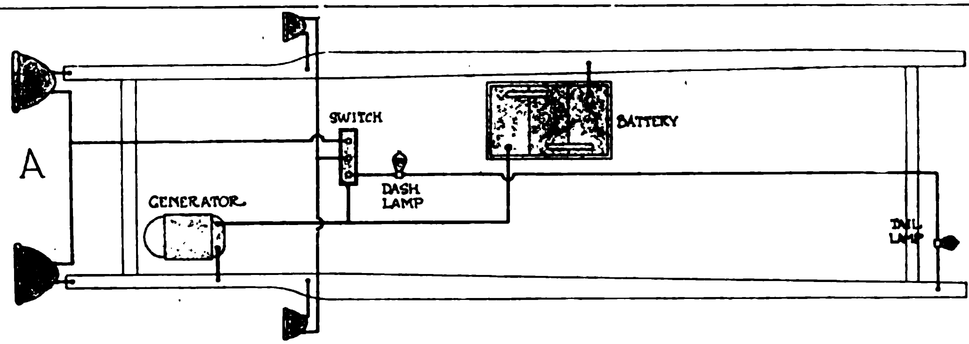
The wires running from the generater to the storage battery are much smaller, as the quantity of current which passes through this wire is only 5 to 25 amperes.

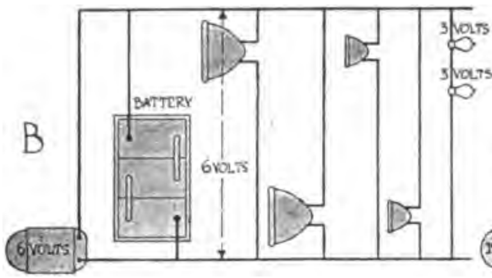
As a comparison; imagine water pipes. If you desired to pass 150 gallons of water through a pipe in one hour, it would require a larger pipe, than one where you passed only 25 gallons per hour.

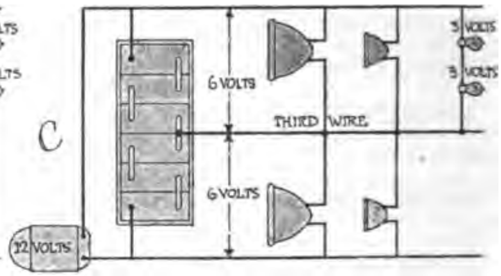
Size Wire to Use.†

Generator to battery........	no. 10
Battery to starter	no. 1 or 2
Headlights	no. 12 or 14
Tail light	no. 14
***Ignition** (primary)	no. 14
Ignition (secondary)	no. 14 or 16
Horn	no. 18

†Sizes very slightly according to length of car and number and size of lights and size of engine and starting motor, etc. But this is an average. *See page 240.







Wiring Systems.

There are three general systems employed for wiring a car; the single wire or grounded return, and the two and three wire system.

A—Shows the "single wire" system; one wire insulated from the frame and frame serves as a wire. One wire, usually the positive terminal of battery and generator is connected to the metal frame. Note where **the storage battery connects to frame.** This connection is made by a lead lug from the battery and tightly bolted to a cleaned surface with copper washers on each side—the connection must be water proof.

B—Shows the "two wire" plan, where both wires are insulated and kept away from frame.

C—The "three wire" system; consists of three wires, one known as the "neutral." Note in this illustration the storage battery is a 6 cell or 12 volt battery and the third wire divides three cells to a circuit, making 6 volts for each side of the third wire.

It is important that the lights or load be equalized, for if three of the six cells are worked more than the other three, and both sets are charged from the same source and at the same rate, one set would get more charge than the other. When the load is properly **balanced** there will be no flow of current through the neutral, which is the reason for so calling it.

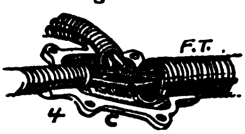


Fig. 4. Showing wires run through metal, flexible tubing or conduit.

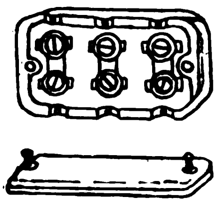

Fig. 6—Coupling box.

***Wiring Accessories.**

The coupling box (fig. 6) provides a convenient and easily separable means for connecting together the wiring on the chassis and on the car body.

The junction box (fig. 7) is used to connect a wire running in a different direction and is much better than making the usual connections. Taping the joints or soldering is not necessary. It also affords a convenient point from which to test.

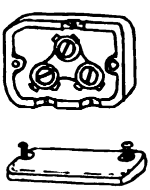

Fig. 7—Junction box.

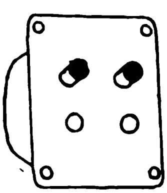

Fig. 9—Two circuit lighting switch.

The lighting switch; (fig. 9), called a "gang" switch—is a "two gang" type. The lower or light colored push is for lights, and the upper (dark) push is "off." It is usually placed flush on the dash.

Wire used for electric lights ought to be protected from oil and dampness and from the frame. The best wire has insulation of an outer covering of heavy braid, specially impregnated, an intermediate layer of treated cloth, and an inner covering of soft rubber. The copper wire itself is made of fine strands and is called flexible, stranded wire.

Conduits (fig. 4); provide a complete enclosed runway for wires from which they can be drawn if necessary and new wires installed. It affords protection from mechanical injury such as bruises, etc. The conduit is made of galvanized steel and is flexible (fig. 4).

Flexible steel armored cable is now very popular. It can be purchased containing one or more wires. The wires cannot be withdrawn.

CHART NO. 193—The Single or Grounded Return. Two Wire and Three Wire Principle. Wiring Accessories. *See also page 428.

**Starting Motor Amperage.

The starting motor consumes a quantity of current as stated on pages 425 and 327—but only for a few seconds—The exact amount of current consumed and the time required to put back the amount used, with generator, varies in different makes—see pages 410, 416.

To those not familiar with electricity, the question would arise, **how can the starting motor receive 120 amperes of current, if the generator which recharges the battery, does not give but 7 to 15 amperes to the battery when charging it.**

Taking for example, a storage battery of 120 ampere hour capacity. It would deliver at the rate of 120 amperes for one hour, or at the rate of one ampere, for 120 hours, or any proportional amount accordingly (varies according to discharge—see page 441 and 327).

**Now, assuming that when current is first applied by switch the quantity is 120 amperes; then after motor has started, the current consumption drops to 65 amperes. This would give us an average of say, 55 amperes used. The time for the operation, say was 10 seconds.

Assuming the average draw on the battery was 80 amperes for 10 seconds, the ampere-hours consumed is as follows: 10 seconds equal 1/6 minutes, or 1/360 hours, and 1/360 of 80 amperes equal 80/360 ampere-hours or .22 ampere-hour, per start.

Car running at 15 miles per hour generator would charge battery, say—at the rate of 7.5 amperes per hour. It then requires as long to recharge the battery per start as .22 is contained times in 7.5 which is 30 times. In other words the generator is capable of putting back into the battery, 30 times as much current in one hour as was used for starting and put back the exact amount used in 1/30 of an hour, or 2 minutes.

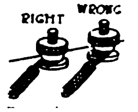
Another point; how can a storage battery of 120 ampere hour capacity deliver 475 amperes, per page 327? A good battery is capable of delivering an overload for a fraction of a second—but only good batteries can stand this—this is one reason why batteries fail.

†Wire Connections.

The connections, in electric wiring should be soldered. The unsoldered connection may work as good as a soldered connection at the time of being made, but the resistance always increases.

Soldering paste; do not use acid when soldering electrical apparatus or wiring, as the acid is an electrical conductor and it also destroys the insulation. It is much better to use a non-corrosive soldering paste.

Tape; do not use friction tape on high tension wiring or on other wiring where the grease or oil can get to it. It is much better to use linen tape and shellac. Friction tape will not insulate ignition current, neither will it hold when oily.



When placing a wire terminal under a terminal nut, twist the wire in direction nut turns.

When connecting a wire under a screw or nut—use a washer, (copper or brass).

Wiring Troubles.

Are numerous if not properly done. All connections must be soldered. Oil and grease destroy insulation. Moving parts must not touch wires. Protect wires from chafing. Avoid frayed ends. Tape all connections. Connections and terminals must be kept tight. Vibration often jars them loose. See foot note page 457 and page 241.

Ampere Capacity of Wire.

The size wire to use, depends upon the amount of current that must flow through it, and the length of the wire. The longer the wire the greater the resistance offered to the flow of current. Therefore there will be too much drop in voltage at the wire terminus, if it is not of sufficient size.

A conductor must be large enough to carry the required amount of current to a certain point with less than 4% drop.

Most all automobiles are using a single wire system and the length of wire is seldom over ten or twelve feet long.

The sizes given on page 425 for generator, starter, lighting and ignition is the average size used on most cars.

The carrying capacity of wires (*B & S gauge)—as given by the National Board of Underwriters for rubber covered wire is as follows:

No. 18	B & S gauge......	3 amperes.
No. 16	B & S gauge......	6 amperes.
No. 14	B & S gauge......	15 amperes.
No. 12	B & S gauge......	20 amperes.
No. 10	B & S gauge......	25 amperes.
No. 8	B & S gauge......	35 amperes.
No. 6	B & S gauge......	50 amperes.
No. 4	B & S gauge......	70 amperes.
No. 3	B & S gauge......	80 amperes.
No. 2	B & S gauge......	90 amperes.
No. 1	B & S gauge......	100 amperes.
No. 1 & 0	B & S gauge......	125 amperes.
No. 2 & 0	B & S gauge......	150 amperes.

Higher the number, smaller the wires. No. 0 is many times larger than No. 18. No. 18 is .04 or 3/64" di.; No. 0 is .32 or 5/16" di.

Accessories and Switches.

Some of the accessories for wiring a car are given on pages 426 and 428.

Ignition switches are usually placed on the cowl (dash) of car and operated with a key.

Starting motor switches are usually operated by the foot. See page 408 for diagram. The ignition switch must be "on" when engine is started.

Lighting switches are usually placed on the cowl (dash) of car and are of the push button type, per fig. 2, page 385 and fig. 9, page 426.

A touring switch is sometimes provided on a car for the purpose of allowing the operator to discontinue the charge from generator to storage battery when car is on a long tour running mostly during the day.

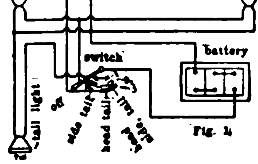


Fig. 1

To give the reader an idea of the various kinds of connections which may be made by one switch, see fig. 1. The contacts have been numbered 1, 2, 3, and 4. If 1 and 4 connect, side and tail lights are on. If 1, 2 and 3 connect, then side, tail and headlights are on.

†See foot note, page 421 and see also, page 423.

**These figures given only as an example—a nearer correct ampere discharge would be as given on pages 327, 410, 416.

*B & S gauge, means Brown and Sharpe gauge and is a recognized standard.

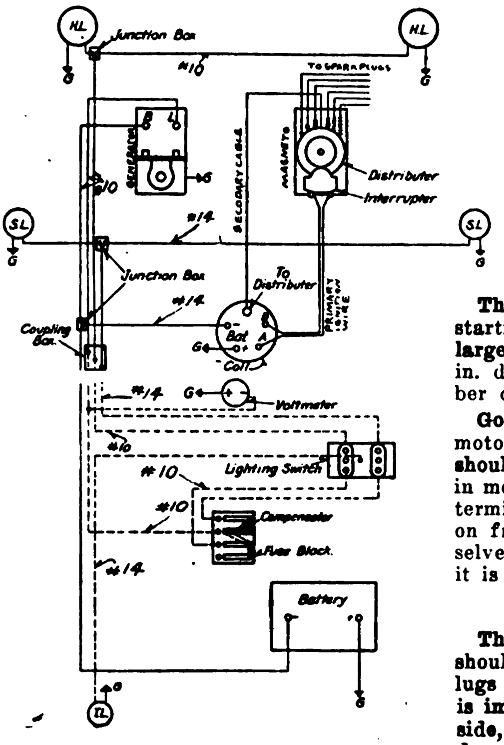

Fig. 2. Size of wires to use, indicated by number. G means grounded, TL means tail light, SL sidelight, HL headlight.

Wiring shown full run along chassis. Dotted lines are wires to be attached to body.

Wiring a Car.

The size of wires to use for ignition, lighting, and generator is shown in the illustration.

The kind of wire to use for each, is explained on pages 425 and 240. **The wire to the lights, and other wires running along side of the frame,** or near metal parts, should be the flexible "armored" type, see page 426.

The purpose of the coupling box, fuse block and junction box is explained on pages 426, 348 and this page.

Wiring the Starting Motor.

This wire must be large, especially with a 6-volt starting motor. Use No. 00 if a long distance and large car, or No. 1 or 2. The No. 00 measures .36 in. di. over the copper strands. Use flexible rubber covered wire.

Good connections are very essential for starting motor to switch and battery. The ends of wire should be cleaned and "tinned," by dipping them in molten solder and then good clean, strong copper terminals soldered thereto for attaching to ground on frame and to the switch. The terminals themselves should be cleaned also the part to which it is attached, and then draw up snugly.

Battery Connections.

The ends of wires connecting with the battery should be treated in the same manner, but lead lugs to fit the battery terminals should be used. It is important that both the terminal of battery, inside, and lug, be scraped and cleaned good and drawn tight. The acid tends to corrode the terminals, hence reason for cleaning.

FIG. 21

If it is necessary to have a coupling for this large wire, one method is shown in fig. 21. A regular brass pipe coupling (K) could be used. The two halves of the coupling E, have the ends of the wires C, sweated into them. The coupling should be well taped if near metal—see also page 408.

Note: When using stranded wire on any part of a car, sometimes one strand will play loose from the others and cause a short circuit. Always twist and solder ends of stranded wires.

Fuses.

Fuses are very important, particularly when the grounded or single wire system is used. The purpose of a fuse is to melt and open the circuit in case of a short circuit and prevent discharge of battery—see pages 412, 413 for meaning of "short-circuit."

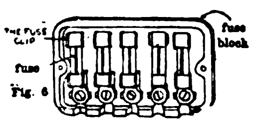

Fig. 6

FIG. 3 Fig. 4

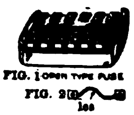

FIG. 1 open type fuse FIG. 2

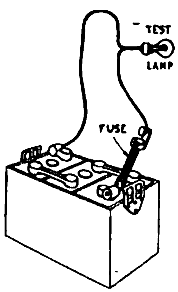
A fuse block (fig. 6), is usually placed on the inside of dash of a car, to which the different wires are connected. The fuse is then in series with circuit. If a fuse melts then it is an easy matter to insert another fuse of which extras should be carried.

There are three types of fuses, the cartridge type fig. 3; the visible type fig. 4; and the open type fig. 2. The visible type will instantly show when burned out, whereas in the cartridge type a hole will be blown in the side of shell. The cartridge and visible types can be slipped into place in the "fuse clip," fig. 6, by hand, the open type requires a screw driver and is placed in block fig. 1. Fuse shown in fig. 4, is the type in general use.



Testing a fuse.

Testing: with types of fuses which are not exposed, if suspected of being blown, they can be tested with the test light as shown below.

The capacity of the fuse in each circuit, should be as follows: Side lights, 3 to 5 amperes; headlights, 15 amperes; extra circuits when provided, 15 amperes. The extra circuit may be used for dome or pillar lights, horn and so forth, as desired.

In other words, the size of the fuse is determined by the amount of current that is to pass through it. If the fuse is to be placed in the head light and tail light circuit; and this circuit used 5½ amperes, a 10 ampere fuse is ample protection.

Compensator: The small cylindrical-wound resistance (B), incorporated with the fuse block in fig. 4, page 348, is the "ballast resistor." It protects the side lights from over-voltage when the headlights are not lighted, see also page 347.

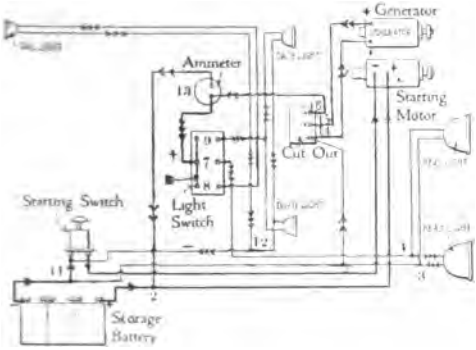
The circuit breaker, is a device used similar to a circuit breaker on a street car, but of lighter construction. It is sometimes used in the place of fuses—see page 377.

A fuse is not used with the starting motor, see page 408.

CHART NO. 194—Wiring the Starting Motor. Size Wire to Use for Motor, Generator and Lights Connections. Also see page 240 for Ignition Wiring. **Fuses.**

Pointers on Testing the Wiring of a Starting and Lighting System.

Illustration shows a two-wire system of the average starting motor generator and lighting system.



The purpose is to point out, as explained on page 737, just where to start when making tests if any part of the system fails to properly operate. (See also, page 577).

First it is necessary to learn the names of the parts and their **relation** to each other. **For instance, the parts of this system** can be divided into four parts as follows:

1—**Starting motor, starting switch and battery constitute the starting system.** Follow the **single arrow points from the battery**, for the circuit.

2—**Generator, cut-out, ammeter and battery constitute the generator system.** Follow the double **arrow points** for the circuit—**Start at generator.**

3—**Lighting system consists of the lighting switch from which point all tests are started.** The current to bus-bar (B) on switch, is taken from one side of the ammeter. If the engine is running slow or not running at all, current comes from the battery. When engine is speeded up, current comes from generator and in both instances must pass through the ammeter (for lights and ignition, but not for starting motor). When connection is made at 7, by switch button closing this circuit, the headlights are on; if closed at 8, the tail-light is on; if closed at 9, the side-lights are on. By following each circuit with the three arrow points, starting at the switch, each circuit can be traced. The other parts of the lighting system are the lamp bulbs and lamp sockets in the lamps.

4—**The ignition system would consist of a timer, distributor, coil and ignition switch.** This switch could be connected from the same bus-bar on one side (+), then through primary winding of coil to timer terminal, thence from timer to 12 (—). (not shown in above illustration).

5—**The electric horn** is connected from the same source as the lights, but the push switch is usually placed on steering post.

Therefore when making tests, first determine which of the four parts the trouble is in and then test that part from beginning to end.

For instance, if starter motor fails to start, begin with test at battery, as explained on page 737.

If generator fails to show "charge" on ammeter, start at generator, then cut-out, then the fuse (fuse system not shown, see fuse block on a grounded or single wire system, pages 428, 360), then wiring. **If fuse** is blown, there must be a short-circuit—find the **cause** by testing the wiring.

If lights fail to burn, first examine the lamp-bulb to see if burned out, if not, then the lamp-socket, then start at the switch and test the wiring. If fuse is blown find the cause.

Remember that this same principle also applies to a single wire system. One terminal could be grounded to frame of car, on battery, generator, starter and lights.

Remember that when a fuse-block is used (see pages 428, 360), the fuses are merely cut into each circuit, which will melt and open the circuit if a wire or part becomes short-circuited.

Remember that a fuse is never used in the starting motor circuit (see page 408). Also remember that the—ammeter is never connected into the starter circuit.

Remember that the cut-out is often placed integral with the generator, for instance on lower illustration page 360, the cut-out is not shown but is in the generator housing and is connected internally with generator as shown in fig. 6, page 925.

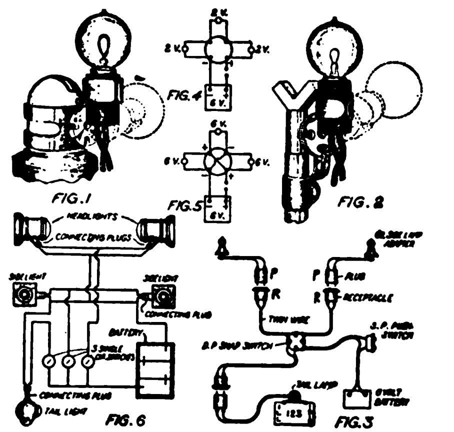
Remember that the regulation of the output of a third-brush generator does not have a separate mechanism to regulate the current—see pages 843 and 925.

Remember that a generator which has a voltage regulation system does **have a mechanism called a voltage regulator which controls the output—see** page 925.

Remember that a Wiring Diagram book will tell you just what kind of a regulation system a generator has and will also show the external and internal circuits of all parts and wiring.

Electric Lights for Old Cars.

If the old car is equipped with oil or gas lights, adapters, fig's. 1, 2 can be secured with sockets and electric bulbs ready to attach as shown.



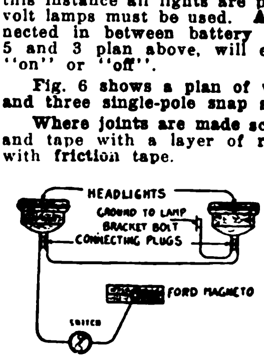
If the oil or gas lamps are entirely discarded and new electric lamps put in place, these may be connected by **plugs** (P) and **receptacles** (R) to the permanent wire of the circuit as per fig. 3. The plug-receptacles are convienent for disconnecting.

Fig. 4 shows a plan of wiring, using a double-pole snap switch (in connection with fig. 3) and turning it to the "off" position. Two-volt lamps may be used for the side and tail lights and the three lights placed in series with the 6 volt battery.

Fig. 5 shows a plan of wiring using the same switch, but turning switch to "on" position. In this instance all lights are placed in parallel and 6-volt lamps must be used. **A single-pole switch** connected in between battery and switch, in figs. 4, 5 and 3 plan above, will enable lights to be cut "on" or "off".

Fig. 6 shows a plan of wiring where five lights and three single-pole snap switches are used.

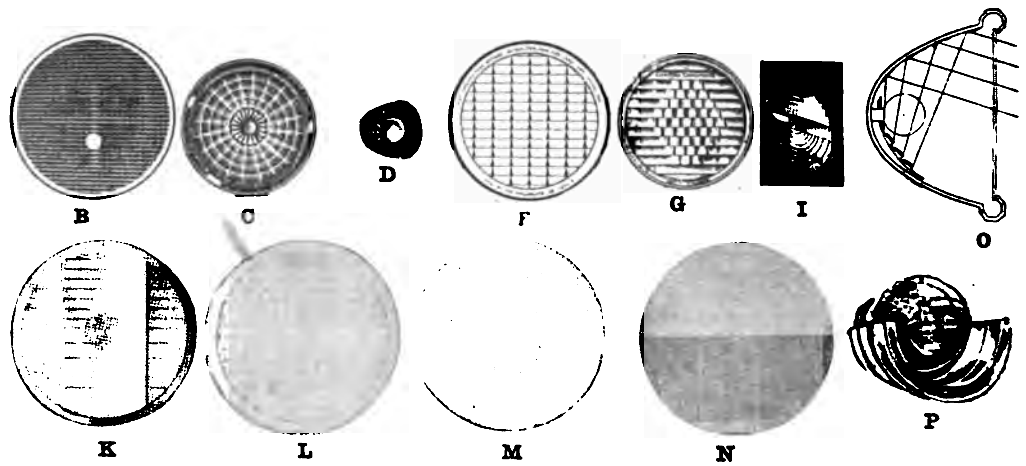
Where joints are made scrape wires clean, solder and tape with a layer of rubber tape, then cover with friction tape.



Method of connecting wires for lights, to the Ford magneto.

2—9-volt, 2-ampere lamps are usually placed in series. See pages 434, 864C.

CHART NO. 195—Pointers on Testing Electric Wiring Systems. Wiring old Cars for Electric Lights



Classification of Anti Glare Devices.

A, B, C and D, are "diffusing" type lenses. As these devices scatter the light in every direction, the adjustment of the headlamp has little effect on the road illumination. Both the light and the glare will be a little stronger if focus is for a straight beam.

A, Warner: Both sides of glass covered with small lenses. Adjusting focus for straight beams for best lighting—see fig. 65, page 483.

B, Prismolite: Front of glass covered with small pyramids except small spot near center. Adjust focus straight beam.

C, Morelight: Front of glass covered with short cylinders, arranged in circles. Adjust focus for straight beam.

D, Stewart: Cup fitting around bulb. Outside covered with small lenses. Inside with ribs. Adjust for straight beam.

F, G, H, I, are "deflecting" type of lenses, which are intended to be used with a straight beam. In making adjustments, adjust per plain glass adjustment, page 435, except lamp must be moved to the point in reflector which gives the smallest point of light on the screen or wall, instead of making the spot 3 ft. in di.

F, Sun Ray: Horizontal prisms throw light on center of road. Small triangular prisms throw a light along sides of road. Adjust for straight beam.

G, Conaphore: Horizonal prisms throw light on center of road, cylinders in center throw a soft light along sides of road. Adjust for straight beam.

H, Macbeth: Horizontal prisms throw light on center of road and cylinders on inside, spread the light to side of the road. Hood at top cuts off light from that part of lens. Adjust for straight beam—see fig. 66, page 483.

I, Holophane: Circular prisms at bottom throw light on road and give quite a spread. Horizontal prisms and vertical cylinders at top throw diffused light along side of road. Adjust for straight beam.

K, L, M, N, O, P: Are "deflecting" type lens designed to be used with a spread or crossed beam, depending on whether a part of the lens which bends the glare rays down is located at the top or bottom of the lens. The focus is adjusted to give a beam having some spread. Most of these devices depend more on the width given to the beam by the reflector than they do on cylinders, or other devices to add to the spread. On this account, these devices are apt to give a little greater proportion of diffused light along the sides of the road and a little less distance than devices which are used with a straight beam. The cut-off of light at the height limit is likely to be not quite so sharp as with those just mentioned, on account of parts of the beam being bent more than others. On this account it may be necessary to give the beam a considerable downward slant to bring the bright light below the glare level. This, of course, will shorten up the distance to which the road will be shown.

K, Osgood: Horizontal prisms on back of lens throw light down on road. Cylindrical section on center of front of lens is intended to add to the spread of the light. Adjust focus for spreading beam.

L, Legalite: Horizontal prisms at top and bottom bend light down on road prisms in center. Outer face is a reverse cylinder to give spread to light. Adjust focus for a very slightly spreading beam.

M, Noglare: The ribs or upper part of lens spread the light to each side. The plain surface below is slightly frosted and gives a diffused light down the road. Adjust focus for crossed beam.

N, Saferlight: Horizontal prisms on upper half throw light down on road. Vertical prisms on lower half spread diffused light toward side. Adjust focus for spreading beam.

O, Letts deflector: A deflecting device. The corrugated reflector is placed below the lamp and changes the angle of the light striking the reflector so that all the rays are sent down on the road. Adjust focus for crossed rays.

P, Fractor: A deflecting device. The prisms on the glass cup which is placed below the lamp change the angle of the light striking the reflector so that all of it is sent down on the road. Adjust for crossed beam.

With any of the deflecting devices it is best to make the adjustment for either spread, crossed or straight beam, while the plain glass is still in place in your headlamp.

CHART NO. 196—Classification of Anti-Glare Lens.

See page 435 for address of manufacturers. Fuses, see page 428.

Standard diameter sizes of lens are: 8, 8⅛, 8¼, 8⅜, 8½, 8⅝, 8¾, 9, 9¼, 9½, 9¾ and 10 inches.

LIGHTING A CAR: Electric Lighting, Gas Lighting, Oil.

There are three methods for lighting a car: Acetylene gas, electricity and kerosene oil.

The gas light can be produced from carbide in a "generator" or it can be stored in a "gas tank" and carried on the car.

Electric lights are supplied with electricity from a storage battery. When the storage battery runs down, it can be recharged from an outside source, or from a dynamo, run from the engine.

*The old style "carbon filament" in the electric globe, consumed so much current it was difficult to obtain a storage battery in a reasonable size and weight which would supply current for any length of time. The filament in the "Tungsten Mazda" globe reduces the current consumption and is not liable to break with the usual motor car vibration.

Lights on the car may be divided into those which are required by law (headlamps and rear lamps) and those which add to the convenience and comfort of the driver and his passengers.

Although some of the older pleasure cars and some trucks and other slow moving vehicles are still equipped with gas or kerosene lamps, electricity is the standard method of car lighting at the present time.

It is well worth knowing that any oil lamp can be quickly and inexpensively convered to electric by obtaining "adapters" from any of the accessory dealers. See chart 195.

Automobile Electric Lighting Systems.

There are three methods of furnishing current for car lighting;

(1) Independent storage battery system.
(2) Generator and battery system.
(3) Independent generator system.

(1) Where an independent storage battery system is used the capacity of the battery must be great enough to run the headlamps and rear lamps for a reasonable time before the battery has to be recharged.

From the lamp table page 434, we find that a current consumption of 7.85 ampere is required for headlamps and rear and dash lamps, the equipment of the average car.

A 100 ampere hour ‡lighting battery would run these lights for about twelve hours steady burning.† Under average conditions this would mean that the battery would have to be recharged about once a week. A 120 or 150 amp. hour battery will not cost much more than a 100 ampere hour and will give better service.

(2) Generator and Battery System.

The advantage of this system is that it automatically keeps the battery charged and permits more current to be used for lighting without danger of running down the battery while on the road. An example is shown on page 343 and 342.

(3) Independent Generator System.

The Ford as an example: The generator in this system delivers alternating current which is used for both lighting and ignition. Battery cannot be charged with alternating current, and on this account the lights can only be run when the generator is running and the strength of the light varies with the speed of the engine unless some type of regulator is installed.

This system is used only on Ford cars, page 265.

Another type of magneto which, if run fast enough will light electric lamps is the inductor type magneto, per fig. 8, page 256, or fig. 4, page 264. The "shuttle" type armature magneto will not light lamps.

Candle Power, Voltage and Amperage of Electric Lamps.

The candle power of a lamp is expressed as c. p. Alhough we speak of a lamp as being 24 c. p., we really refer to the spherical c. p. This means that 24 c. p. is sent out in every direction. **A reflector does not increase the brilliancy** of the light from the filament, it simply takes the total amount of light which is thrown in all directions, and **concentrates** it in one direction. For instance, with a "spreading beam" the brilliancy is not as intense as if a "straight beam."—see page 438.

The voltage is usually that of the battery, but quite often to save the lamp from burning out, a lamp of one or two volts higher is used. For instance, if 6 volt lamp is used on a lighting circuit using a 6 volt battery the light would be bright as long as battery was fully charged. If a generator is used to charge the battery and supply current for the lights when car is running over 10 or 15 m. p. h., then the probabilities are the generator would develop a slightly higher voltage than the battery—result would be that the higher voltage would increase the brilliancy of the lamps and cause them to burn out quicker than if voltage was exact or less than that of lamp. Therefore, quite often higher voltage lamps are used, say 1 or 2 volts higher.

The amperage or quantity of current consumed is governed by the candle power of the lamp—the c. p. averages from 2 to 32. The higher the candle power the more voluminous is the light—if voltage or pressure is in accordance with that of the lamp—therefore the higher the c. p. the more current or amperes consumed per hour.

Watts: if you multiply the volts by the amperes the result is expressed in "watts." For instance: 6 volts by 2 amperes, gives 12 watts (there are 746 watts to a horse power).

Where Lamps are Placed.

Head lamps of which there are two, are usually connected in parallel and the candle power varies from 17 o 32 c. p. each.

****Side lamps,** one on each side, usually connected in parallel, average 5 or 6 c. p.

Spot lamp—only one is used, usually a nitrogen lamp of 20 or 32 c. p.

Rear lamp also called tail lamp, always with a red lens in rear and white light to side, to illuminate the license number, is usually 2 c. p.

The tail light and instrument lamp are usually connected in series, as shown at A, page 426. If the rear lamp should burn out, the instrument lamp would not burn and vice versa.

This is an advantage, because the law requires that rear light burn during the night. Being unable to tell from the seat if rear light should fail, this method is used. **The voltage** is just one half of that of the regular lighting circuit when connected in series.

***The carbon filament lamp** is the old style lamp using a filament chemically treated and in a vacuum. **Electric lighting troubles,** see page 419. †See page 441. ‡**A lighting battery** (120 to 150 amp. hour capacity) can be used for both lights and ignition, but an **ignition battery** is usually but 60 ampere hour capacity. A **starting motor battery** can be used for lights, ignition and starting, but due to the great quantity of current reuired for starting motor the connections are heavier.

****Side lamps are seldom used,** but small 5 or 6 c. p. bulbs are used in the headlamps for city driving and are often termed "dimmer lamps."

Step lamp—two of which are sometimes placed just below the doors, are usually 5 c. p.

Dash or instrument lamp, placed over the instruments, as the speedometer, ammeter,—2 c. p.

Inspection or trouble lamp—is a lamp and extension cord, carried under the seat and in case of need is connected in dash lamp socket—5 c. p.

Tonneau lamp—back of front seat—5 c. p.

Dome lamp—placed in ceiling of car—5 c. p.

Pillar lamps—usually two, placed on rear pillars, one on each side in rear of car—5 c. p.

It is advisable to use the best grade lamp, as low a candle power, and as few lights as possible if the battery does not get sufficient charging from the generator.

Automobile Electric Lamp Bulbs.

‡**Two types of lamps are used for car lighting**; the vacuum type, usually known as Mazda B, and the **nitrogen gas filled lamp** known as the Mazda C.

The source of light is the fine wire at the center of the lamp bulb, known as the **filament.** The current heats this wire white hot. If bulb was designed for 6 volts and circuit was 12 volts, then this wire would become so white it would burn up. If designed for 12 volts and circuit was 6 volts, the filament would be yellow and dim.

The voltage lamp to use depends upon the voltage of system. If you do not know this, count the cells of storage battery, each cell gives 2 volts—or see table, page 434.

Mazda B lamps page 434, usually have this wire or "filament" made up in the form of a spiral about 5/16 of an inch long, and ⅛ of an inch in diameter. This gives a uniform distribution of light all around the spiral.

Mazda C lamps page 434, usually have the filament made up in the form of an inverted V. In most type C lamps the V is about ⅛ of an inch high and about the same distance across the base. Some makers of type C lamps make the V about 5/16 in. long and ⅛ in. across the base. This form gives a much better distribution of light than the short V.

The Mazda "C" lamp is brighter and gives more c. p. for same amperage consumption, but is more sensitive to voltage variations—see foot note.

Note—As the lamps become older, the current consumption increases. If the glass of the lamp bulb is blackened or the filament bends down if less than its rated (c. p.) is being used, it will be best to replace the lamp bulbs.

Standard Lamp Sizes.

The Mazda B lamp, page 434, is designed for all lights, as rear, side, head. It is made in 6 to 8 volt, 12 to 16 volt and 9 volt for the Ford.

The Mazda C lamp, page 434, is designed for headlights and spot lights and is made in 6 to 8 volt, 12 to 16 volt and 9 volt for the Ford.

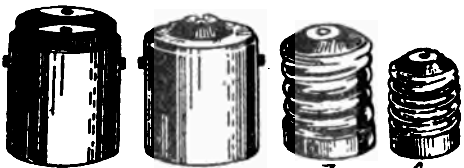
Candle power of above lamps are given in table page 434.

Where 24 c. p. or less is used in headlamps, the type B will usually give the best satisfaction, even though they take 20 per cent more current, due to the sensitiveness of the C lamp, as per foot note. The spiral filament of the B lamp also gives a better distribution of light than the C with a **short** filament.

Where more than 24 c. p. is desired, the type C must be used, but those with a long V are preferable.

Types of Lamp Bases.

The lamp base is that part which fits into the socket. There are four types as explained under the illustration. The illustrations are full size.



1 2 3 4

Fig. 1—Double contact bayonet base.
Fig. 2—Single contact bayonet base.
Fig. 3—Candelabra screw base.
Fig. 4—Miniature base.

Figs. 1 and 2 are the two types used for automobile work, are also known as the "Ediswan" DC and SC base; (DC meaning double contact and SC, single contact, also designated as D and S, also E. D. and E. S.)

Fig. 1—is used where cars are equipped with the "two wire" system.

Fig. 2—For "single wire" or grounded return.

Figs. 3 and 4—Seldom used for automobile work—used extensively for decorating purposes.

Lamps must be selected to correspond to the socket used.

Adapters consisting of small fibre discs with metal inserts can be secured at small cost and will enable both kinds of bases to be used in either kind of socket.

For voltage and base used on the different cars see page 434.

Headlamp Adjustments.

The light you get on the road will depend on the candle power you get from the lamp in the reflector; on the focus or adjustment of the lamp in relation to the reflector; and on the direction in which the headlamp itself points.

Different Focusing Adjustments.

Getting the lamp bulb in the proper relation to the reflector to give the best light on the road is called focusing. All headlamps are provided with some means of moving the lamp bulb back and forth along the center line of the reflector which line is called the axis. The four types of **adjustments, figs.** 6, 7, 8 and 9, shown, should cover practically all of the headlamps used.

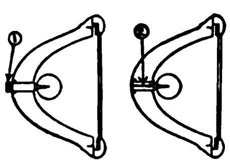


Fig. 6. **Fig. 7.**

Fig. 6: Has an adjusting screw or knob near the center, on the rear of the headlight shell. The lamp bulb is moved forward by turning the screw or knob (1) to the left and backward by turning it to the right.

Fig. 7: The lamp is held in place by a ratchet device (2). The lamp is moved forward or back by grasping the bulb and either turning the bulb to the right or by pressing it to one side or the other to disengage the ratchet, and then pulling or pushing the lamp in its socket to the next notch in the ratchet. If the lamp doesn't move easily, remove reflector and see how ratchet works.

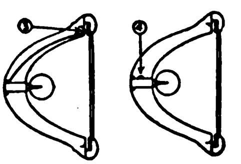

Fig. 8. Fig. 9.

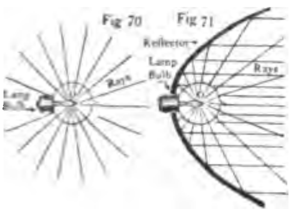
Fig. 8: The adjustment is made by turning the large screw (3) in the rim of headlight front just at the edge of the reflector. By turning this screw to the right it will move the lamp forward in the reflector. Turning it to the left moves it backward in the reflector.

Fig. 9: The lamp is held in place by a set screw (4) in back of the reflector. When the set screw is loosened, the lamp may be moved backward or forward. The set screw must be tightened securely to hold the lamp in place.

‡**The vacuum lamp** uses a "Tungsten" filament instead of a "carbon" filament. The air is withdrawn from bulb hence a vacuum. The **gas filled lamp** also uses a **Tungsten** filament but **the bulb is treated with nitrogen gas** which increases the brilliancy by increasing heating intensity of **the filament. For this reason the** "gas filled" lamp is very sensitive to increase of voltage and is best **adapted for** "constant voltage" regulated generators—see page 925.

Relation of Focus to Light on the Road.

A parabolic type of reflector, made of metal with a highly polished silver surface, is used in most headlamps. **If a lamp was used without a reflector** the light which leaves the lamp filament would be thrown in every direction per fig. 70. **When a reflector is used,** the light from the lamp filament is concentrated all in one direction, per fig. 71. See also, "candle power," page 431.



A ray of light is the light which falls on any one point of surface of reflector and is sent off from that point.

A beam is the toal mass of light rays leaving the opening in reflector.

One of the fundamental laws of light is, that the angle at which light leaves a surface is the same as the angle at which it strikes the surface. By referring to figs. 22, 23, 24, note angle which is made by the rays of light leaving the surface of the reflector at H, M, and N, is the same as the angle made by the ray of light striking the reflector at the same point. The angles at which the rays strike the reflector are called "angles of incidence" and those leaving the reflector are called "angles of reflection."

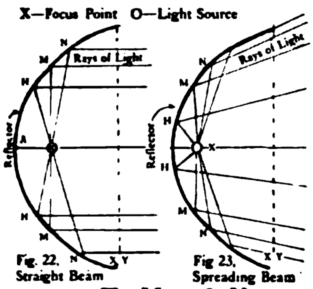


Fig. 22 shows distribution of light leaving opening of reflector when lamp filament O is at focal point X of reflector. The rays which start from point X, and strike reflector at H, M and N, must be reflected parallel to each other to make reflecting angles equal the striking angles. This gives a cylindrical or **straight beam.** The beam is theoretically the same size (XY fig. 22) throughout its entire length. A straight beam gives a very narrow streak of light down the center of the road like a spot light; but no light to the side of the road.

Fig. 23 shows the form of beam leaving the reflector when the filament O, is back of the focal point X. The rays spread or diverge from one another and form a **spreading beam,** with its narrowest point at opening of reflector, XY. Note that the light rays which leave the headlamp at a **rising angle** are those which come from the **upper half of the reflector.**

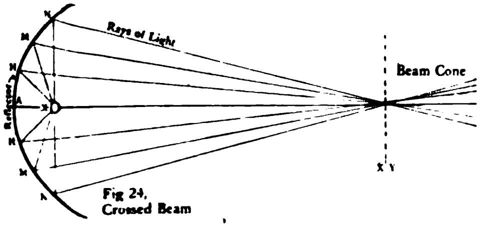

Fig. 24 shows the effect of bringing the filament O, ahead of the focal point X. This forms what we call a **crossed beam.** Note that the light rays which leave the headlamp at **rising angle** are those which come from the **lower half of reflector.**

Anti Glare Devices.

In most states, laws are being enforced to prevent glare. The light which produces glare is that part which leaves the headlamp at a **rising angle** and so never hits the road, but does hit the eyes of approaching drivers or pedestrians. These rays may come from either the top or bottom of reflector, depending upon the position of the lamp in the reflector.

Methods For Reducing Glare.

(1) **By using a very low candle power lamp; dimming the headlamps;** using whiting, semi-transparent paint or colored glass. Low candle power lamps reduce the brilliancy and colored glass or paint absorb part of the light and reduce the lighting effect desired and are unsatisfactory.

(2) By tipping the reflector forward enough to bring the upper edge of beam below the average eye level (*42 inches is the usual legal limit.) The distance to which the road will be lighted is very much shortened.

(3) **By diffusing the light by means of ground glass, office partition glass or specially designed "diffusing" lens,** having its surface covered by a large number of small lens or pyramids. With diffusing lenses there is a tendency to glare if the candle power of lamp is sufficient to light the road, as the light is thrown in all directions.

(4) **By using "deflecting lenses which bend or deflect that part of beam which leaves the headlamp at a rising angle** and direct this part of the beam back to the road level. Devices of this kind have the advantage of being able to limit the glare without cutting down the distance to which the light will be thrown on the road.

Some of the deflecting lenses which are constructed so as to affect all of the light leaving the headlamp, make it hit the road nearer to the car than it would with clear glass, and are not desirable.

Fig. 65.

Fig. 66.

Fig. 65 is an example of a diffusing type lens. Both sides of glass are covered with small lenses. Adjust for a straight beam for best results.

Fig. 66 is a deflecting type lens. The horizontal prisms throw light on center of road and cylinders on inside, spread toward side of road. Hood at top intended to cut off any stray rays of light which might leave the headlamps at a rising angle. Adjust for a straight beam.

Fig. 73.

Fig. 73 is a deflecting type lens explained on page 435. Adjustment is for a spreading beam.

*The most common "glare height" regulation in regard to headlamps is that at a point 75 feet or more ahead of the car, the concentrated beam from the headlamp shall not rise more than 42 inches above the road level, when the car is standing on a level. In the latest headlamp regulations, the height has been raised to 60 inches from the road surface, and the intensity of the light is limited to a maximum of 800 candle power above this point.

Rear and speedometer bulb are 2 c. p. and usually connected in series, in which case the voltage would be 3-4 volts, .84 amp. each on **6-8 volt circuit**, or 6-8 volts each of 3 c. p. .42 amp. or **12-16 volt circuit. Dome, Side, Tonneau**-5 or 6 c. p.

Mazda B, 6 to 8 volt, made in 2, 5, 17, 24 c. p.
Mazda C, 6 to 8 volt, made in 20, 32 c. p.
Mazda B, 12 to 16 volt, made in 3, 6 16 c. p.
Mazda C, 12 to 16 volt, made in 30 c. p.
Mazda B for Ford, 9 volt, are made 21 c. p.
Mazda C for Ford, 9 volt, are made 27 c. p.

Two lamps are used in "series," with double contact base only, for the Ford.

G-6, G-8, G-12, G-16½: G, designates that bulb is round or globular. 6, 8, 12 or 16½ means that many eighths of an inch. As 16½ eighths of an inch, equals 2$\frac{1}{16}$ inches di. of bulb. S, single contact; D, double contact base.

Proper voltage and base of lamps for Ford "Special" lighting systems: Genemotor, 12-16 v. D. C. base; Gray-Davis, 6-8 v. S. C.; Kemco, 6-8 v. Westinghouse, 12-16 v. S. C. (D. C. and S. C. means double and single contact base.)

CHART NO. 197—Lamp Bulbs; Voltage and Candle Power Used on 1918 Cars and Standard Sizes of Bulbs for 1919. See also pages 543 to 546.

An ideal light: (1) Sufficient light to illuminate road a distance ahead so that driver would have ample time to stop before reaching an object and penetrative powers in dust and fog. (2) Very bright light at edge of road and close to car so road could be clearly seen and followed in spite of glare from an approaching car. (3) Full width of road from fence to fence lighted for at least 200 feet ahead of car.

Fig. 72.

One make of lens designed to meet these conditions is shown in fig. 73, page 433. Note the prisms in lower half of lens concentrate the distance light as shown in A, fig. 72. The diagonal prisms in the upper half of lens bend the light. which would otherwise cause glare, to light the sides of the road from fence to fence (BB, fig. 72), and give the bright light on edge of road as shown at CC.

Adjustment and Focus For Different Lenses.

When a "diffusing" type of lens is used it makes no difference whether you have a crossed beam, spreading beam or straight beam, except that where a straight beam is used there will be less diffusion, and consequently a stronger light ahead of the car.

When a "deflecting" type of lens is used it is absolutely necessary to know whether it is intended for use with a spreading, crossed or straight beam before the focus can be made to insure satisfactory results, therefore manufacturer's instructions should be followed carefully.

If that part of the deflecting lens which is designed to bend the "glare rays" down towards the road is located in the **upper half** of the lens, a "spreading beam" must be used. If located on the **lower half**, a "crossed beam" must be used.

If the device is made of prisms having a uniform angle on both upper and lower halves of the device, a "straight beam" must be used.

Checking Lamp Adjustment.

To find out whether the lamp is set for a "spread" or "crossed beam" pass a screen such as a piece of board or paper, down in front of the headlamp. If the shadow caused by the screen moves up as the screen moves down, the filament of the lamp is in front of the focal point (fig. 10) and you have a "crossed beam." If the shadow moves down with the screen, the lamp is set for a "spreading beam."

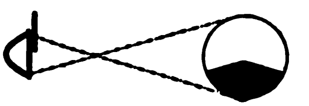

Fig. 10.

Another method to test if light is a crossed beam or spreading beam; let the light from the headlight shine on a wall or screen 10 or 15 feet ahead of the lamp. Then move the lamp bulb back in the reflector.

If the spot on the wall grows **larger** as the lamp bulb is moved toward the back of the reflector, the lamp is adjusted for a **spreading beam** and the filament is **back** of the focal point.

If the spot on the wall grows **smaller** as the lamp is moved back towards the reflecter, the adjustment is for a **crossed beam**, and the filament is **ahead** of the focal point.

If the filament is moved from as far back in the reflector as it will go, to a point as far ahead as it will go, you will find that the spot of light will first grow smaller and then grow larger, as the filament passes the focal point. The point where the spot is smallest is the point where the filament is practically at the focal point X, and the adjustment is for a **straight beam.**

These tests are of course, made with plain lens.

Focusing Headlamps with Plain Lens.

One plan would be to take car out on a level road at night and set the headlamps so that both of them point straight down the road. Then adjust or focus the position of the lamp in the reflector until the light covers a width of about 25 feet on the road at a point 150 feet ahead of the car. The headlamps should be tipped forward slightly, so as to bring the brightest part of the light on the road at a point about 150 feet ahead of the car.

If it is necessary to make the adjustment on the headlamps during the daytime in a garage, or some place of that kind, set the car so that the light will shine squarely on a wall or screen 20 feet ahead of the car, fig. 18. Adjust or focus each headlamp separately until the spot thrown by cach lamp on the wall is about 8 feet in diameter.

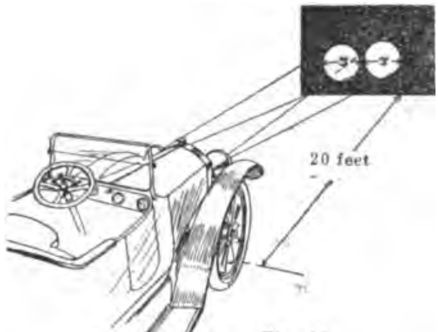

Fig. 18.

With both lamps throwing light on the wall, adjust the headlamps themselves so that the distance between the centers of the two spots on the wall will be the same as the distance between the centers of the headlamps. Tip the headlamps forward so that the centers of the two spots on the wall will be about 4 inches lower than the centers of the openings in the headlamps. This will bring the upper edge of the beam as low as practical without too much loss of distance.

Note. The above adjustment should only be used with plain glass in the headlamps, or with diffusing lenses, and may not be correct where deflecting lenses are to be used.

To Clean Reflector and Lens.

Do not forget that dust or dirt on the reflector or on the glass lens may cut down the light on the road by more than half.

To clean reflector, use a very soft, clean cloth without using pressure and in a circular motion. Never rub a reflector with a cloth or chamois skin which is covered with dust or grit. It will scratch the reflector and ruin it for service.

If a reflector becomes tarnished or scratched, take it to a silver plater and have it buffed. It cannot be properly polished in any other way.

To Clean the Glass Lens.

Absorbent cotton, dipped in alcohol and lightly rubbed in a circular motion over the surface will be found efficient.

Assisted by Mr. Frederick H. Ford. **Address of Lens manufacturers:** The Roadlighter Lens, fig. 72 and 73, are manufactrued by C. A. Shaler Co., Waupun, Wiscn.; The Warner Lens Co., 914 Mich. Ave., Chicago; Macbeth. by Macbeth-Evans Glass Co., Pittsburg; Legalite, by The Legalite Corpn., Boston, Mass.; Sun Ray, by Prismolite Co., Columbus, Ohio; Conaphore, by Edw. A. Cassidy Co., Madison Ave. and 40th St., New York. Woodworth Mfg. Corp'n, Niagara Falls, N. Y. (Clear Light Lens).

Gas Lighting.

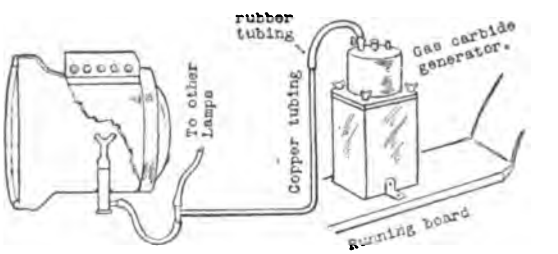

Fig. 1—Showing how small 1/8 inch copper tubing and rubber tubing connects from generator to lamps. Note the **rubber tubing** connected from the copper tubing to the lamp drops in a curve. This will place the rubber tubing at the lowest point. Gas condenses and turns to water and the water clogs the pipes and gas tips. If this rubber tubing is disconnected occasionally the condensed water will drain out.

It is always necessary that the line or leads from the gas generator to the lamps be on as much of an incline as possible. In fact, a draincock could be placed at the lowest point to advantage. The pipes to each lamp should be independent if possible.

Fig. 11—Explanation of the drip type of carbide generator: The tank (E) being filled with water at (D) the water saturates the cotton wick (H) in the tube (J) and the valve (F) being turned ON it drops into the screen tube (L) passing out of the holes at the bottom, coming in contact with the carbide, forms gas which passes out at top of generator through pipe (G). The unused carbide held in the cage is separated by the screen in the bottom and the dust or used carbide falls to the bottom (T) perfectly dry. Consequently the charge is always fresh while it lasts and ready to light or extinguish, and cleaning simply means emptying the dry dust at the bottom and refilling the cage with carbide and the tank with water. To shut off the light turn the valve (F) off. (F) being a two-way valve on the side (not lettered) the gas then contained in the generator passes out of the two-way valve into the air thus insuring perfect safety.

Fig. 11 — The solar drip type gas generator. The used up carbide shakes through the perforations into the base (T) of the generator. The water tank forms the top part of the generator.

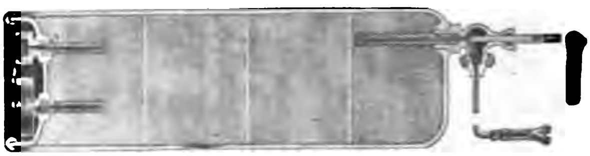

Fig. 14.—Sectional view of the gas tank.

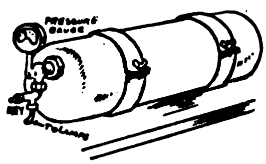

Figs. 14 and 14A. The pressure gas storage tank usually placed on the running board of car. See text for explanation of construction and use.

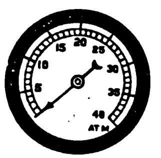

Fig. 16 — Gauge reading in atmospheres.*

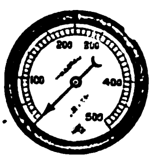

Fig. 17 — Gauge reading in pounds.

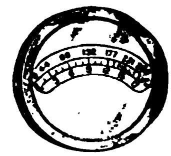

Fig. 18—Combination gauge reading in pounds and atmosphere.

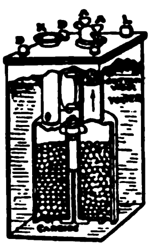

Fig. 13—Simple form of diving bell generator for acetylene gas; called the automatic type.

When the supply to lamps is shut off the pressure of gas in the inner chamber drives the water up from the calcium carbide.

Fig. 13—The automatic type of gas generator.

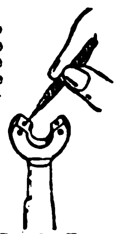

Fig. 2—How to Clean a Gas Tip.

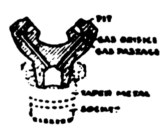

Fig. 3—Interior of a Gas Tip or Acetylene Burner.

Tips are generally made of lava. Two small holes are in each end, only one of these being discernable to the eye. The hole, however, which becomes clogged is the small hole inside the large one.

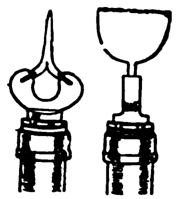

Fig. 4—Showing End and Side View of the Flame When Burner is in Good Order.

Lighting the gas by an electric spark: This system consists of a special valve and switch placed on the dash-board (D) a high tension coil (O), and a special gas lighting attachment shown at the left in cut.

The connections are as follows: The gas tank is piped to the valve and connected to a union under it. After gas passes through valve it is then carried to the lamps. Wire runs from switch to coil and from there through primary winding to battery. Through battery to ground.

An attachment (B1) is placed on each gas tip to be lighted. When lever is pressed down this opens the gas and also makes a temporary electric contact and spark jumps across points S, and lights the gas. An ignition battery or dry cells will do this work.

See also page 726 for another principle.

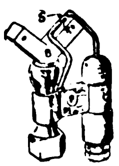

Fig. 20.

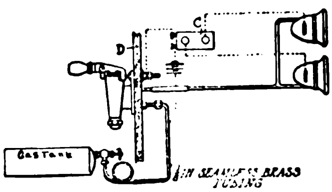

CHART NO. 198—Gas Lighting; Independent Gas Generator and the Gas Tank.

*An atmosphere equals 14.7 lbs. at sea level.

Charts 199 and 200 omitted (error in numbering).

Opening Electric Headlamps.

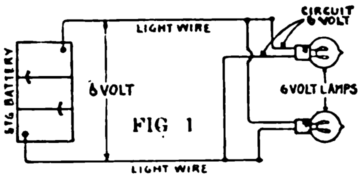
The "door" to the headlamp may be fastened on in one of several ways. There may be a hinge at the top and a screw clamp at the bottom or the hinge may be at one side and the clamp at the other. If no hinge shows, and the "door" overlaps the shell of the headlamp, the "door" can probably be removed by **pressing it in, and at the same time turning it to the left.**

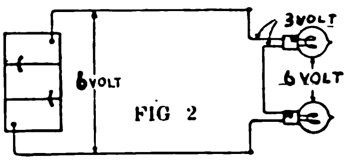
In some headlamps, the glass is held in place by a retaining spring, which slips in between the headlamp shell and the glass.

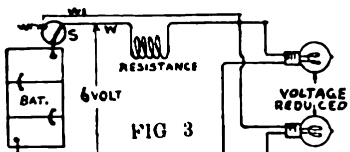
In other headlamps, the rim which holds the glass is held up against the shell by a band which fits over shoulders on both rim and shell, and is drawn up by a screw at the bottom of the headlamp.

Dimming The Headlight Lamps.

These methods of dimming the lights were formerly used when car was standing. Most cars are now equipped with small lamps in upper part of headlamp, which are only 5 c. p., therefore the methods described are now seldom used.







There are two general principles for dimming lights; by "resistance" (which causes loss of current) cut into the circuit (fig. 3), and by throwing lights in "series" connections (fig. 2).

Fig. 1, we will assume all light circuits are 6 volts in the three illustrations. In fig. 1, the two lights are connected in parallel—the terminals of each light connect with the six volt circuit.

Fig. 2; To dim by a "series" connection—the switch and wiring is arranged so that the parallel connections as in fig. 1, are cut out, and lights are connected so that current from the two light wires must flow through both lamps—"serially" or generally termed, connected in "series." If each lamp is 6 volts and there is only a 6 volt supply—then each lamp will get but 3 volts or half its voltage; hence will burn half as bright.

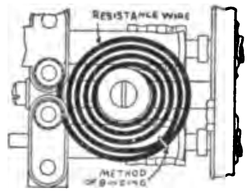


Fig. 4.

Fig. 4. Method of increasing brilliancy of lamps, when a "resistance" type of dimmer is used.

Note, part of the resistance wire is short circuited by binding as shown.

When German silver wire or some other form of resistance is used for dimming lights the principle is to cut this resistance into the line as shown in (fig. 3). The lights will then be dimmed according to the amount or length of wire placed into the circuit.

A switch (S) can be arranged so that by placing point of switch blade on WI, fig. 3, the resistance is cut out. When connected with wire W—it is cut in.

To vary the intensity of the headlights when dimmer is in circuit (Delco system, page 391), is merely a matter of shortening the path of the flow of current (the dimmer "resistance" wire) —which can be done by tieing one coil together, which will make considerable difference, fig. 4.

To do this; it is necessary to remove the switch. Remove the four bolts passing through housing at back of switch. The housing will then come apart. Remove No. 1 wire which connects with generator, before dismantling switch. Otherwise a short circuit will result.

A "Spot" Light.

Is a type of lamp, which can be placed on the wind-shield, and turned in any direction by hand. It is also well adapted for army use.

Where a great deal of night driving is done or a cross-country trip made, a spot light is of great convenience. It is fastened close to the driver's hand and can be directed at any spot desired.

Adjustment is for a "straight-beam" with filament exactly at focus point, see fig. 22, page 438.

Spot lights are prohibited in some states, and in others the law requires that the light be thrown on the ground, not more than 60, 75 or 100 feet ahead of car and must not be directed in the faces of persons approaching.

Elecric bulb is usually nitrogen type 20. or 32 c. p.

*Gas Lighting—see page 436.

There are two types of gas or carbide generators in use: the drip type and the automatic type.

In the "drip" principle of generation, the water is **usually arranged to drip directly** on the carbide, and the amount of gas formed is regulated by a tap which allows more or less water to come in contact with carbide. (Fig. 11.)

A modification of this system, allows the water to drip down a perforated metal tube, surrounded with carbide, and thus the water gradually soaks through the carbide.

All generators are now made specially with a view to ease of detachment, refilling or charging, and cleaning; this latter is specially important, as any neglect to clean out the lime residue from the container immediately after a period of use renders cleaning a matter of considerable difficulty.

Another important detail in working a generator is always to obtain the best quality of carbide, keep it in a thoroughly dry place, and tightly sealed up to prevent deterioration.

Fig. 13. The automatic type of generator; in some respects, is simpler and gives a better regulation of the gas, but it does not seem to be always reliable.

In brief, the working is as follows: The carbide is contained in a bell or chamber, with perforated sides and bottom, to admit water freely. This bell has a suitable outlet for the gas.

It is supported inside an outer vessel or tank, to hold the water. Immediately the water comes in contact with the carbide gas is generated and, if the supply tap is open this gas will pass on to the lamps. Should the tap be closed, the pressure exerted by the gas then acts inside the bell, and drives the water away from the carbide.

Should the generation of gas still continue for some time, it will force its way through the water and escape into the atmosphere, through a small vent hole, so that no dangerous pressure can develop within the generator.

It will be seen that an automatic regulation of the gas is thereby obtained, because immediately more is being generated than can be used; the water is driven away from the carbide, but as soon as there is a demand for more gas the pressure inside the bell falls and water re-enters.

The gas outlet pipe and cotton wool or horsehair filter, whence the gas reaches the top or, to which the tubes are connected to the lamps is shown at (AA).

*Gas lighting is now seldom used, but is explained for the benefit of the reader

A gas bag is provided on the gas outlet pipe inside the generator to steady the pressure.

The carbide container lifts right out of the tank by unscrewing the nuts (D D).

The tank is filled up from the aperture (K) in the plug of which is a small vent acting as a safety valve. In this, as in other forms, the gas can be turned on and off any number of times till the carbide is all used up.

***Gas Burners;—Also called Gas Tips.**

The gas burner is made up in various styles, and consumes from .25 to 1.5 cubic feet of gas per hour. By referring to figs. 3 and 4, chart 198, the reader will observe the construction.

If acetylone gas was used with an ordinary jet, it would have a yellow tint, but the oxygen drawn into the tip through the large hole raises the temperature of the flame to a point where a white blaze is obtained, therefore it is necessary that the smaller hole in the burner be kept clean.

If the flame is yellow and dim the above is probably the cause, or the pipe line needs blowing out, or the generator needs cleaning.

If the independent generator is used, it is important that all parts be perfectly clean and fresh carbide added daily, using quantity required.

Lighting the Gas.

The usual method for lighting the gas is to turn on the gas at the generator or tank and light the gas at the burners with a match.

The modern method is to turn on and light the gas from the seat. This is accomplished by a valve and electric spark. (see fig. 20, page 436.)

Non-Freezing Solution for Gas Generators.

Use plain alcohol in the proportion here given. Alcohol is a fuel, but not explosive. It will, therefore, probably give a slightly stronger gas than water, and for this reason less will be required. Do not use glycerine, as this is an explosive.

Percentage of alcohol to water: At 18 degrees, 10 per cent; at 5 degrees, 20 per cent; at —2 degrees, 25 per cent; at —9 degrees, 30 per cent; at —15 degrees, 35 per cent; at —24 degrees, 40 per cent.**

Carbide—Used in the Generators.

The chemical formula for Acetylene is C H (i. e., a compound of carbon and hydrogen). It has a characteristic pungent odor—which at once gives evidence of any leakage—and is a poison if inhaled in any quantity.

Approximately one pound of good quality calcium carbide, will generate six cubic feet of acetylene gas. It can readily be liquified or compressed but in this state it is highly explosive, and its use finds no favor in this country. What is known as dissolved acetylene however, is safe.

The gas in a moist or impure state attacks copper or brass, forming acetylene of copper, which is exceeding explosive, so much so that it will go off by slight friction or a blow. This accounts for the small explosions that are sometimes experienced when cleaning a generator.

†The Pressure Gas Storage Tank.

This tank is charged at the factory. When the tank is exhausted it is taken to the local agent and exchanged for a fully charged tank.

The gas used in the tank is acetylene gas, made from carbide—the same kind of gas used in a generator. Figs. 14 and 14A, chart 198, illustrate the Prestolite gas tank. The amount of gas in the tank is indicated by the pressure gauge. In this way the motorist can tell the quantity of gas in the tank. A key opens the valve which allows only a low pressure of gas to feed the lamps.

The piping of the gas from the gas tank to the lamps is just the same as used with an independent generator.

The Prestolite gas tank is made in three styles: Style E which weighs 23 lbs.; style B, 30 lbs., and style A, 50 lbs.

The pressure inside the tank (E) is based on a pressure of 15 atmospheres or about 50 cubic feet of gas which will supply gas for 2, ½-foot burners for 50 hours.

The tank should be placed on the car so that it can be easily removed. The running board is a convenient place. Always place tank top side up.

Prestolite Gas Tank Pointers.

Prestolite gauges, how to read them; several styles of gauges are used, some register in atmospheres, some in pounds and some in both, (see figs. 16, 17, 18, chart 198). If you wish to determine the number of pounds of pressure in your tank, reading from a gauge showing only atmospheric pressure, multiply the number of atmospheres shown, by 14.7 which is the number of pounds to which one atmosphere is equal. The result will give you the number of pounds of pressure in your tank. All atmosphere gauges are marked "ATM."

Prestolite tanks are charged to a pressure of 225 pounds (equal to approximately fifteen atmospheres) at 65 degrees Fahrenheit. If the temperature of a tank be increased 10 to 20 degrees F. the pressure will be raised 25 to 50 pounds. If the temperature be lowered, the pressure will be reduced in about the same ratio. This accounts for the rapid fall in the gauge pressure when a tank is taken from a warm garage into the cold air of the street. Change in temperature does not affect either the quantity or the quality of the gas. Consequently when the outside temperature is 65 degrees F. a properly filled Prestolite tank will show a pressure of about 15 ATM (atmospheres) when using the atmospheric type of gauge, and 225 pounds when using the gauge reading in pounds, while the gauge showing both pounds and atmospheres will indicate a pressure of 221 pounds, or 15 ATM, with corresponding variations according to the outside settled temperature, despite the fact that the first two mentioned gauges show a capacity of 40 ATM and 500 pounds, respectively.

Where to look for leaks: Note: rub soap-suds along the pipe lines and over all joints and connections. Do not use a match, any sooner than you would use one to hunt for a gas leak in your cellar.

(1) Union where attached to tank; (2) rubber hose connecting union with brass piping of car; (3) joints where rubber hose connects with union and with piping of car; (4) joints, T's or crosses where piping branches; (5) where rubber hose connects piping with lamps; (6) part of lamp to which burners are attached; (7) any point on piping where there is a liability of chafing.

Sizes and capacities of Prestolite tanks: "A"—22 inches long, 7¼ inches in diameter; contains 70 cubic feet of gas.

Using two ½-ft. burners, 70 hours lighting
Using two ⅝-ft. burners, 56 hours lighting
Using two ¾-ft. burners, 46 hours lighting

"B"—20 inches long, 6 inches in diameter; contains 40 cubic feet of gas.

Using two ½-ft. burners, 40 hours lighting
Using two ⅝-ft. burners, 32 hours lighting
Using two ¾-ft. burners, 26 hours lighting

"E"—16 inches long, 6 inches in diameter; contains 30 cubic feet of gas.

Using two ¼-ft. burners, 60 hours lighting
Using two ½-ft. burners, 30 hours lighting

Oil Lighting.

Inasmuch as electricity for lighting is now the adopted standard and is almost universally used, it is hardly worth while to deal with the kerosene oil lamp. The oil lamp when used in place of electric lights, is generally placed tail or rear lamp, to illuminate the license number and as required by law for protection of the fire department.

The brilliancy of oil lights can be improved by using a hard wick and placing cotton in the bowl of lamp. Then use gasoline or half gasoline and light cylinder oil instead of kerosene.

*Gas burners are also called gas tips—the average gas tips consume one-half foot of gas per hour. Gas tips are made in standard sizes as follows: ¼ foot, ½ foot, ¾ foot and 1 foot.

*The dash in front of the figures are "minus" signs or below zero. †See page 718 for further fetails of a gas tank

This page is provided for reference, in case reader is not familiar with words or terms used.

Acid. As used in this book refers to sulphuric acid (H_2SO_4) the active component of the electrolyte.

Active material. The active portion of the battery plates; peroxide of lead on the positives and spongy metallic lead on the negatives.

Alternating current. Electric current which does not flow in one direction only (like direct current), but rapidly reverses its direction or "alternates" in polarity so that it will not charge a battery.

Ampere. The unit of measurement of the rate of flow of electric current.

Ampere hour. The unit of measurement of the quantity of electric current. Thus, 2 amperes flowing for ½ hour, equals 1 ampere hour.

Arc burning. Making a joint by means of electric current which melts together the metal of the parts to be joined.

Battery. Any number of complete cells assembled in one case.

Battery terminals. Devices attached to the positive post of one end cell and the negative of the other, by means of which the battery is connected to the car circuit.

Buckling. Warping or bending of the battery plates.

Burning strip. A convenient form of lead in strips, for filling up the joint in making burned connections.

Case. The containing box, which holds the battery cells.

Cell. The battery unit, consisting of an element complete with electrolyte in its jar with cover.

Cell connector. The metal link which connects the positive post of one cell to the negative post of the adjoining cell.

Charge. Passing direct current through a battery, in the direction opposite to that of discharge, in order to put back the energy used on discharge.

Charge rate. The proper rate of current to use in charging a battery from an outside source. It is expressed in amperes and varies for different sized cells.

Corrosion. The attack of metal parts by acid from the electrolyte; it is the result of lack of cleanliness.

Cover. The rubber cover which closes each individual cell; it is flanged for sealing compound, to insure an effective seal.

Discharge. The flow of electric current from a battery through a circuit. The opposite of "charge."

Electrolyte. The fluid in a battery cell, consisting of specially pure sulphuric acid, diluted with pure water.

Element. One positive group, and one negative group with separators, assembled together.

Filling plug. The plug which fits in and closes the orifice of the filling tube, in the cell cover.

Flooding. Overflowing through the filling tube. With the "Exide" automatic filling tube, this can usually occur only, when a battery is charged with the filling plug out.

Freshening charge. A charge given to a battery which has been standing idle, to insure that it is in a fully charged condition.

Gassing. The bubbling of the electrolyte caused by the rising of gas set free toward the end of charge.

Generator system. An equipment including a generator, for automatically recharging the battery; in contradistinction to a straight storage system where the battery has to be removed to be recharged.

Gravity. A contraction of the term "specific gravity," which means the density, compared to water as a standard.

Grid. The metal framework of a plate, supporting the active material, and provided with a lug for conducting the current and for attachment to the strap.

Group. A set of plates, either positive or negative, joined to a strap. Groups do not include separators.

Hold-down clips. Brackets, for the attachment of bolts, for holding the battery securely in position on the car.

Hydrogen flame. A very hot and clean flame of hydrogen gas and compressed air, used for making burned connections.

Hydrogen generator. An apparatus for generating hydrogen gas for lead burning.

Hydrometer. An instrument, for finding the specific gravity of the electrolyte.

Hydrometer syringe. A glass barrel enclosing a hydrometer and provided with a rubber bulb, for drawing up electrolyte.

Jar. The hard rubber container, holding the element and electrolyte.

Lead burning. Making a joint, by melting together the metal of the parts to be joined.

Lug. The extension from the top frame of each plate connecting the plate to the strap.

Maximum gravity. The highest specific gravity which the electrolyte will reach by continued charging; indicating that no acid remains in the plates.

Oil of vitriol. Commercial name for concentrated sulphuric acid (1.835 specific gravity). This is never used in a battery and would quickly ruin it.

Plates. Metallic grids, supporting active material. They are alternately positive (brown) and negative (gray).

Polarity. Electrical condition. The positive terminal of a cell or battery, or the positive wire of a circuit, is said to have positive polarity; the negative; negative polarity.

Post. The portion of the strap extending through the cell cover, by means of which connection is made to the adjoining cell, or to the car circuit.

Rectifier. Apparatus for converting alternating current into direct current.

Resistance. Material (usually lamps or wire) of low conductivity, inserted in a circuit to retard the flow of current. By varying the resistance, the amount of current can be regulated.

Rubber sheets. Thin, perforated hard rubber sheets, used in combination with the wood separators in some types of batteries. They are placed between the grooved side of the wood separators, and the positive plate.

Sealing compound. The acid proof compound, used to seal the cover to the jar.

Sealing nut. The notched round nut, which screws on the post and clamps the cell cover.

Sediment. Active material which gradually falls from the plates, and accumulates in the space below the plates, provided for that purpose.

Separators. Sheets of grooved wood, specially treated, inserted between the positive and negative plates to keep them out of contact

Short circuit. A metallic connection between the positive and negative plates within a cell. The plates may be in actual contact or material may lodge and bridge across. If the separators are in good condition, a short circuit is unlikely to occur.

Spacers. Wood strips, used in some types to separate the cells in the case, and divided to provide a space for the tie bolts.

Specific gravity. The density of the electrolyte compared to water as a standard. (see page 585 for sp. gr. of water). Often abbreviated as "gravity" or "sp. gr." or "S. G."

Starvation. The result of giving insufficient charge, in relation to the amount of discharge, resulting in poor service and injury to battery.

Strap. The leaden casting to which the plates of a group are joined.

Sulphated. The condition of plates having an abnormal amount of lead sulphate, caused by "starvation" or by allowing battery to remain discharged.

Tie bolts. Bolts which, in some types, extend through the battery case between the cells, and clamp the jars in position.

Top nut. The hexagon nut which, in batteries with bolted connections, screws on the post, and holds the connectors and sealing nut in place.

*See page 458 for Storage Battery Trouble and page 577 Digest of Troubles.

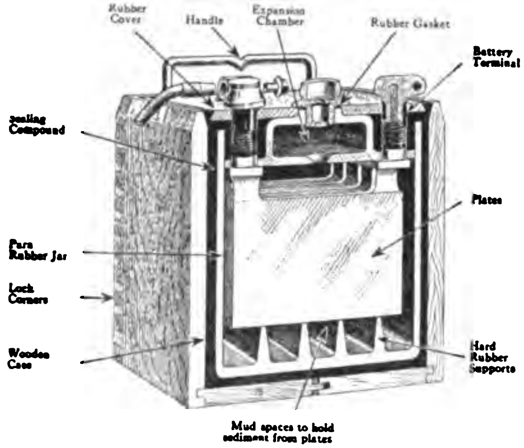

Fig. 1.—Sectional view showing location of the parts of a starting and lighting storage battery.

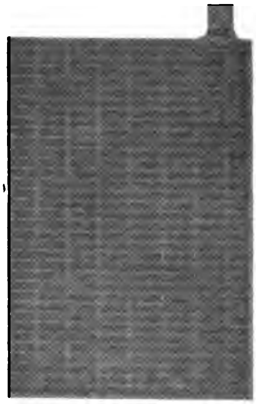

Fig. 2.—Positive plate. Faure pasted type. The color of the positive plate is dark chocolate color.

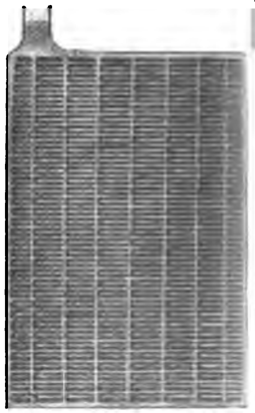

Fig. 3.—Negative plate. Faure pasted type. The color of the negative plate is gray. Note the plate is "gridded" so it will retain the paste.

The construction of a storage battery is explained in the text following. In this chart the parts of a storage battery are illustrated, also the two types of plates, the pasted plate, called Faure type, fig. 2, and the Plante type, fig. 4. The Faure type is the plate generally used.

There are more negative plates than positive plates, for instance, one type of a starting and lighting battery would have to each cell, 15 plates; 7 positive and 8 negative. The size of the plates determine the amperage output of battery.

***The voltage of a storage battery is determined by the number of cells, each cell gives, on open circuit—from 2.1 to 2.2 volts when charged, no matter how many plates or the size of the plates. If there are 3 cells to a battery, then the voltage would be 6.6 volts.**

On a discharge—a charged battery will give 2 volts per cell.

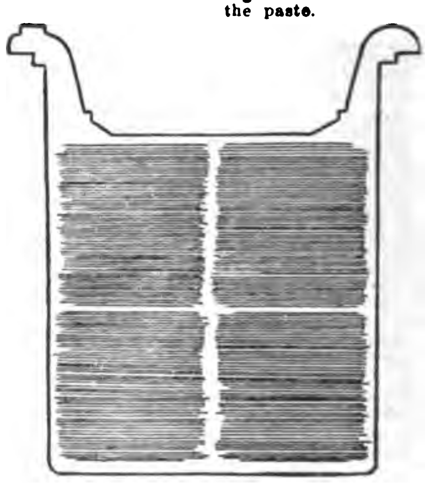

Fig. 4.—The Plante type of plate: this plate differs from the Faure or grid type as shown in figs. 2 and 3. On the Faure the lead plates are cast with grids or openings to take the paste. The Plante plate is more finely subdivided and has a spongy appearance (seldom used), see page 445.

Fig. 5. Storage battery designed for lighting and ignition. Amperage discharge seldom over 20 amperes. Therefore connectors are light. This battery is usually charged from an outside source and capacity is from 80 to 160 ampere-hours.

Fig. 5A. Storage battery designed for lighting, ignition and starting motor. Usually 90 to 120 ampere-hour capacity, as generator operated from engine charges battery. The connectors must be much heavier however, as the discharge when operating starting motor sometimes runs as high as 450 amperes; a tremendous overload.

Fig. 5A. Storage battery designed for starting motor, lighting and ignition.

CHART 201—The Storage Battery. Plates; Faure and Plante types.

Charts 199 and 200 omitted by error. *See also, page 443. Witherbee battery manufactured by Witherbee Storage Battery Co., 643 W. 43rd Street, New York.

INSTRUCTION No. 32.

THE STORAGE BATTERY: General Description, Size Battery to Use. Construction and Action. Electrolyte. Testing Battery. Hydrometer and its Use. When a Battery Needs Charging. Testing with a Voltmeter. Care of a Battery. Specific Gravity. Freezing Temperatures. Baume Scale.

General Description.

Storage batteries are described as being devices for storing electrical energy, which may be used for various purposes. They do not store the current however, but generate electricity chemically as will be explained further on.

Storage batteries are also called "accumulators." They are also called "secondary" batteries.

The storage battery is used on automobiles for starting, ignition, lighting, operating the electric horn and various other purposes. The storage battery is used for starting the gasoline engine, by supplying current to an electric motor which revolves the crank shaft of engine. It is also used to operate an electric motor, which, in turn, propels an electric vehicle.

The storage battery used on electric vehicles consists of about 42 cells. The voltage of each cell is two volts, therefore 42 cells would give 84 volts pressure. The subject of electric vehicles is treated separately.

Ignition battery: The ignition storage battery is smaller than the lighting battery. The plates of the lighting battery are heavier and there are more of them. The average amperage of an ignition battery is 60 ampere hours and voltage is usually six.

Lighting and Ignition battery: The amperage is from 80 to 160 ampere-hour capacity, and voltage is usually six volts; some times 12, 16, 18 or 24. See page 440.

There are usually three cells to the ignition and lighting battery, each cell giving two volts. These cells are placed in battery boxes, fig. 29, chart 203.

Starting batteries are similar in every respect to a lighting battery, except that the terminals are much larger in order to carry the extra heavy flow of current, as will be explained further on and page 440.

The starting batteries are furnished for 6, 12, 16, 18 and 24 volt systems, although the tendency at present favors the 6 and 12 volt size on the majority of cars.

Meaning of Amperes and Volts.

The meaning of amperes and volts is explained on page 207. The standard measure of the energy put into a battery is in terms of ampere-hours.

The capacity of a battery is measured in ampere hours. The volume of current flow is measured in amperes. A current of one ampere, flowing for one hour, is the unit by which capacity is measured, and is called ampere-hour.

Ampere is the unit of quantity, like a "gallon" of water. **Volt** is the unit of pressure, like "pounds." (See pages 207 and 208.

The ampere-hours obtainable from a battery depends upon the amount of current consumed by the ignition, starting or lighting system and the capacity or quantity of electricity the battery is made to deliver. Lowering the consumption and increasing the capacity of the battery, increases the ampere-hour capacity. The capacity of a battery is independent of its electrical pressure. Thus, a flow of 10 amperes, maintained for 8 hours, amounts to 80 ampere-hours.

***The ampere-hour capacity of a battery as stated, is dependent upon the rate of discharge.** The lower the rate, the greater will be the capacity. The same battery that has a capacity of 100 ampere-hours, at the 10 ampere discharge rate per hour, will have a capacity in excess of 100 ampere-hours if discharged at a lower rate, say of 5 amperes per hour.

An example: A certain battery will develop the following ampere-hour capacities at the indicated rates:

50.4 ampere hours at 3 ampere discharge rate for 16.8 hours.

42.5 ampere hours at 5 ampere discharge rate for 8.5 hours.

36. ampere hours at 7½ ampere discharge rate for 4.8 hours.

30. ampere hours at 10 ampere discharge rate for 3.0 hours.

Notice—See Instruction 29, page 423, for Removal of Battery when used with a generator on a car.

*See pages 327 and 427.

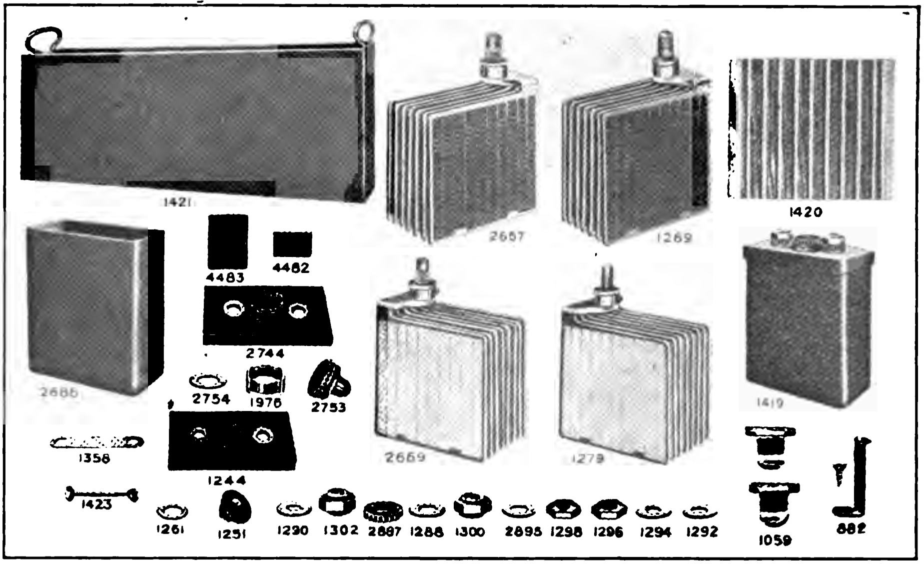

Fig. 1.—This illustration is used, to show the parts of a modern starting and lighting battery. It is the type 3-x-155-2 "Exide" make.

The Buick models: B-24, B-25, B-37, B-54 and B-55 cars use the above type and make.

Names of Parts.

1421—Wooden box in which cells are placed.
2657—Positive plate group (1 group per cell).
1269—Positive plate group (1 group per cell).
1420—Wood separator. Placed between + and — plates.
2686—Jar or cell casing. In which plates are placed.
4483—Large wood spacer. Placed between cells and case.
4482—Small wood spacer. Placed between cells.
2744—Jar cover. Same as 1244, only larger size.
2754—Filling plug gasket. Used to prevent leakage.
1976—Barrel for jar cover.
2753—Filling plug. Through which electrolyte is put in.
1358—Inter-cell connector. Joins + of one cell to — of another.
1244—Jar cover. Removed only to take out plates.
2669—Negative plate group (1 group per cell).
1279—Negative plate group (1 group per cell).
1419—Complete cell. Three used in 6 volt battery.
1423—Through bolt. Used to clamp cells in case.
1261—Filling plug gasket. Used to prevent leakage.
1251—Filling plug. Remove to put in electrolyte.
1290—Alloy washer. For negative terminals.
1302—Negative terminal nut. To fasten (—) lead wires.
2887—Alloy sealing nut. Put over terminals to prevent leakage.
1288—Alloy washer for positive terminals.
1300—Positive terminal nut. To fasten (+) lead wires.
2895—Gasket for terminals. One used under each sealing nut.
1298—Sealing nut for negative terminals.
1296—Sealing nut for positive terminals.
1294—Gasket for negative terminals.
1292—Gasket for positive terminals.
1059—Hold down clip. Used to hold case securely.
882—Hold down clip, same as above.

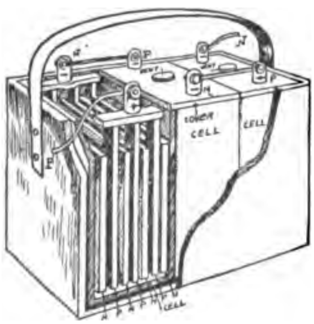

Fig. 20.

An element consists of a complete set of plates (2657 and 2669) burned together on strap, and wood and rubber separators; for a single cell. Positive plates (2657), are brown; negative plates (2669) are gray in color. There are 7 positive plates, which fit between the 8 negative plates, as shown in fig. 1 above.

Both the positive and negative plates are attached to what is termed the "positive or negative strap." In this particular battery; as an example; there are 7 positive and 8 negative plates. Notice how the plates are interposed, or alternately placed, in fig. 20.

If the battery is a large one and the discharge is heavy, such as for a starting motor, then these straps, connectors, lugs and terminals, must be very **large or heavy**, in order to carry the quantity of current necessary to do the work without heating.

There may be 13 or 15 plates to a lighting battery; 6 positive and 7 negative, or 7 positive and 8 negative—in fact this varies with different manufacturers.

Fig. 20.—An exaggerated drawing showing three hard rubber cells with three positive and four negative plates in each cell. The elements are placed in a hard rubber jar and are called "cells." The cells are then placed in a wooden box, the terminals properly connected, and it is then termed a "battery."

Note, all the positive plates are placed at one end and all of the negative plates are placed at the other end. The insulators, or separators, are placed between a negative plate and a positive plate.

The plates are immersed in a solution of sulphuric acid mixed with water, called **electrolyte. Each** cell delivers but two volts pressure, no matter how large or how small it may be. The quantity or amperage discharge, however, is governed by the size and number of plates.

When the lead lugs (N and P) are attached to the lead bar connecting the plate, they are burnt on; or melted together by an electric weld.

CHART NO. 202—Assembly of a Modern Storage Battery.

***Storage battery voltage:** A three-cell battery gives six volts, no matter what the size of the cell may be. The length of time it will maintain a certain current output, depends on the capacity, or electrical size of a battery; an ordinary jump spark coil requires about one ampere per hour, therefore a 60-ampere hour battery would operate for approximately 60 hours, as the discharge rate would be very low.

If we were to charge such a cell we would find that, regardless of the number of plates, the cell would exert on discharge an average pressure of 2 volts—that is; unless the imposed load in amperes was too heavy for the size of cell. At the beginning of discharge the pressure would be a little above 2 volts, and with the progress of discharge would gradually fall off to a little below 2 volts. So would the pressure of compressed air in a tank die down if you were to draw off some of the air.

Since the nominal voltage of a storage battery is 2 volts per cell, you can readily see that to make a 6 volt battery, we connect 3 cells "in series." And to make a 12 volt battery, we connect 6 cells "in series," which means that we join the positive post strap of one cell to the negative post strap of the next cell by means of a "link." This leaves one post in each of the two end cells. To these we fasten the terminal links of the battery, one positive, the other negative, for making bolted connections with the two cables or "leads" (pronounced "leeds") through which the battery receives and delivers energy.

How to Determine the Proper Size of Battery.

The first step in determining the proper size of battery for "lighting duty," is to decide upon the voltage of the lamps. Tungsten lamps, which consume about one third the current required by carbon lamps, should invariably be used. Table in chart 205-D shows the number of hours the various batteries will burn different lamp candle-powers, continuously on one charge. These values are calculated for tungsten filament lamps and are not applicable for carbon filament lamps.

The second step is to determine the amount of current that the battery will be required to deliver. Do this by ascertaining first, the number of lamps to be used, the voltage of each, and then determine the quantity of current each will take, then add the total, which will give the total amperage required.

In some cases not all the lamps will be operated at the same time and this should be taken into consideration. Allowance should also be made for any other current consuming devices that may be used.

Knowing the amount of current that the battery will be required to deliver, you can select a battery of the proper capacity by referring to chart 205D.

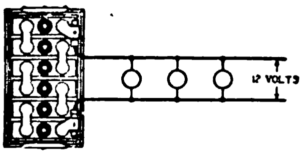
How to Determine the Number of Cells and Plates to a Cell, by the Number on Battery.

In the list of the U. S. L. battery for instance, the first letter stands for a certain general type or construction. For example in type C-607, the letter "C" indicates the use of "C" plates, "C" jars, "C" covers, etc. The last two figures, signify the number of plates per cell, and the first figure, signifies the number of cells in the battery. Thus, battery type C-607 has 6 cells of 7 plates each; type A-317 has 3 cells of 17 plates each. The suffix, or right hand letter, indicates a particular assembly or arrangement of the jars in the battery box. For example, the letter "B" in type C-607-B indicates that the 6 jars are assembled side by side in the battery box.

Exide: starting, lighting and ignition batteries: Take, for instance, the 3-XC-13-1 battery. The first number "3" signifies the battery is made up of three cells; the letters "XC" signify that the plates, separators, jars, covers, etc., which go to make up the battery, are of the type known as "XC;" the number "13" signifies that there are thirteen plates in each cell; the figure "1" signifies that the cells are assembled in the wood case side to side, this being known as No. 1 assembly. When the cells are assembled end to end the assembly is known as No. 2. The same method of designation is followed out in the LX and SX batteries, also listed in the table of "Exide" batteries.

Construction.

Cell assembly: The cells can be assembled sidewise, or endwise; as shown in chart 203.



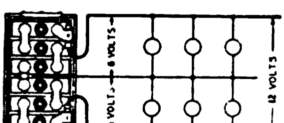


Fig. 1. A 6 cell, 12 volt battery using 12 volt lights.
Fig. 2. A 6 cell, 12 volt battery using 6 volt lights. Note the "neutral" link in the center.

Cells in case: The cells are placed in a sturdy wood case fitted with lead coated, acid-resisting handles and the whole outfit covered with acid proof paint. On all sides of each cell is a packing of sealing compound—a pitch-like substance to support the jars evenly and to exclude acid or water, which may carelessly be slopped over the battery and which would eventually ruin it.

Cell connections: All cells are connected in series, as shown in figs. 1 and 2. It is possible however, to connect the cells so that lower voltage lamps can be used on a higher voltage battery. This is explained above and in chart 205-C. It is important to note that in using a battery with a "neutral" connection the load ought to be divided equally, see chart 205-C.

*See page 440.

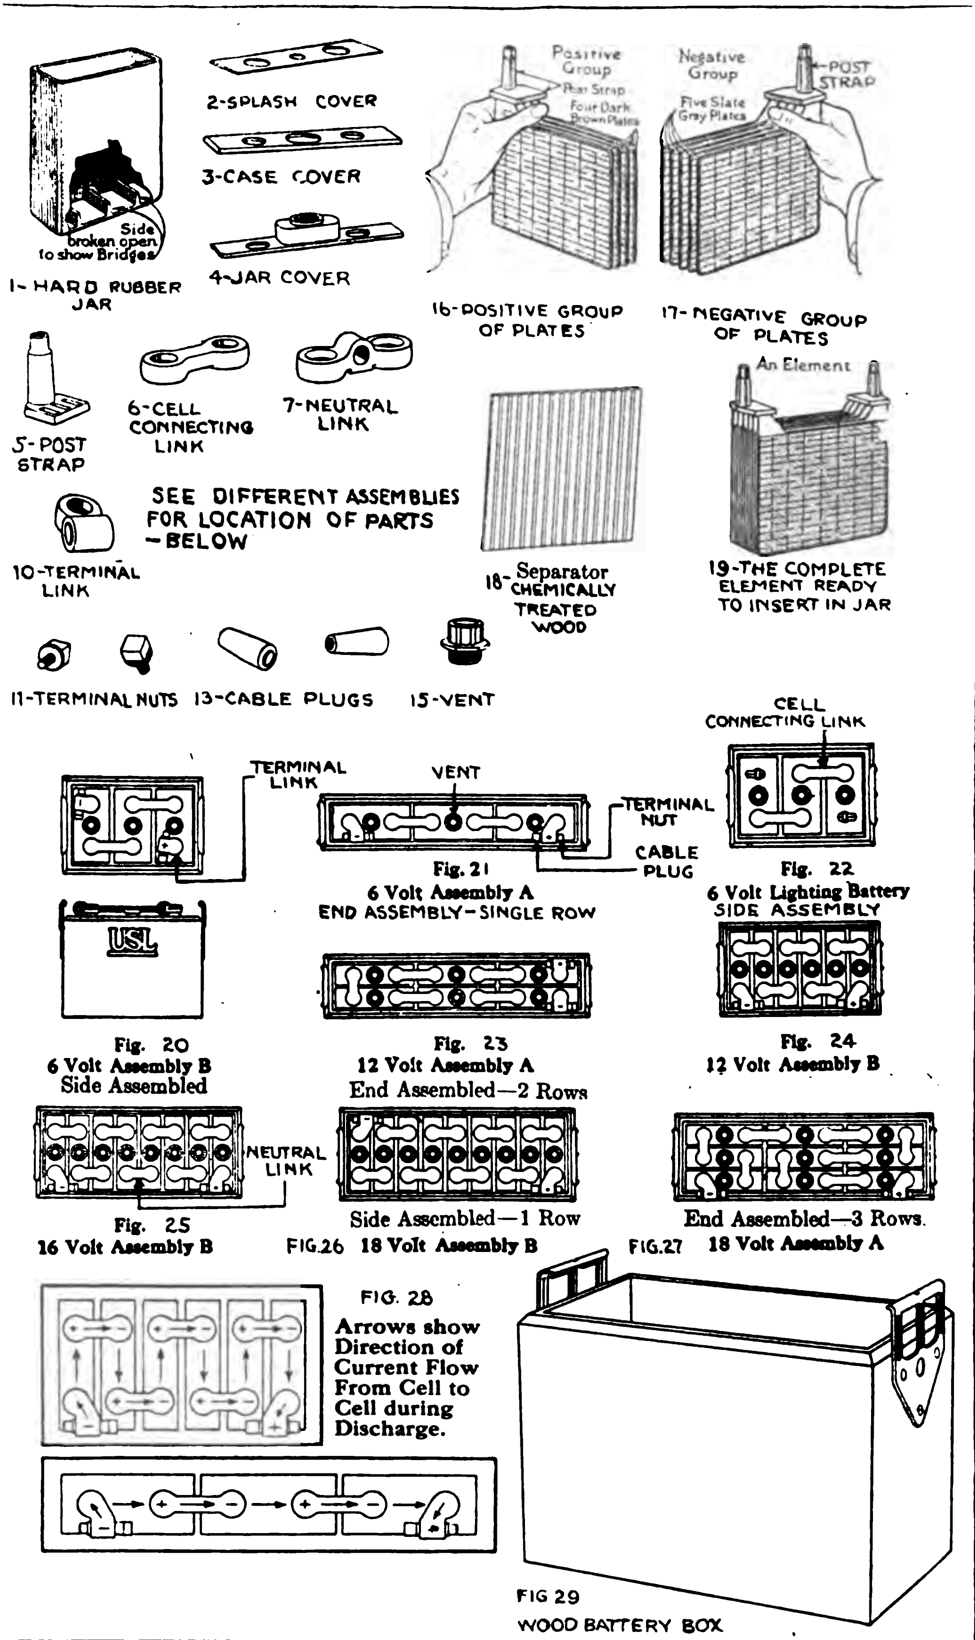

CHART NO. 203—Parts of a Storage Battery Cell. How the Cells are Assembled "Side by Side" also Endwise; in Single, Double and Three Rows. The U. S. L. as an example.

Lead burned joints. The way lead parts are fastened together, for example; where plates and links are jointed to post straps (see fig. 17 and 6, chart 203) is by "lead burning." A hydrogen gas flame is played upon each junction and fuses the parts into one solidly united piece (see also, pages 471, 726).

Cells.

A jar with parts installed, is called a cell. A 7 plate cell includes 4 negative and 3 positive plates; a 9 plate cell has 5 negatives and 4 positive and so on.

Parts of a cell: Jar itself, see fig. 1, chart 203, is made of hard rubber with bridges at the bottom. The element or plates rest on these bridges. If some of the paste falls from the plates, which is termed sediment, it will not short circuit the plates, that is, connect from one to the other, unless the sediment is allowed to accumulate to such an extent that it touches the plates.

The other parts of a cell are the plates, with wood separators, connection links, terminal link, nuts, vent caps, cover, etc.—see charts 203 and 202.

There is one group of positive plates and one group of negative plates, to each cell. The positive group is shown in fig. 16, chart 203 and the negative group, fig. 17. The two groups are interleaved with separators.

Cell Assembly.

†**Plates:** There are two kinds of plates; the Faure-type and the Plante-type. The Faure-type is the pasted type and is the plate in general use. The Plante-type, fig. 4, chart 201 is obsolete. Therefore we shall deal with the modern type only.

The plates are different in color, the positive (lead oxide) being a deep chocolate color and the negative a gray (pure lead).

The plates are pasted and formed in groups as will be explained. See figs. 5 and 6, chart 203A for a positive and a negative plate of the Exide make.

Grid: A grid made of a stiff lead alloy supports the active material pasted in between the slots in the form of a series of vertical strips, held between the grid bars and locked in place by horizontal surface ribs, staggered on the opposite sides. Fig. 3, chart 203A, shows a section through the horizontal ribs and makes clear their staggered relation.

Material: After the grids are cast they are "pasted" with oxides of lead, made into a †paste of special composition which sets in drying like cement. The plates then go through an electro-chemical process called "forming the plates," which converts the material of the positives into brown *peroxide of lead, and that of the negatives into gray, spongy lead. Fig. 5 (chart 203-A) shows the finished positive plate and fig. 6 the negative.

Lugs: Both the positive and negative plates are provided with an extension or "lug," and they are so assembled that all the positive lugs come at one side of the jar and all the negative lugs at the other, thus enabling each set to be burned together with a connecting strap giving one positive and one negative pole. The burning is done by a hydrogen flame, which melts the metal of both lugs and strap into an integral union.

Group: A set of plates burned to a strap is known as a "group" (fig. 7, chart 203A), either positive or negative. Figs. 16 and 17 chart 203, also shows a positive and a negative group. The two groups are interleaved with separators between them and the assembled group, fig. 19, is called the complete element.

Straps: The straps (fig. 7) are made of a hard lead alloy and are provided with posts to which the cell connections are made.

Separators: When the positive and negative groups are assembled together, the adjoining plates are insulated, or kept out of contact by means of wood separators ribbed side against the positive. The separators (fig. 8) are made of tough wood particularly adapted for the purpose and given a special treatment to remove harmful substances.

Element: A positive and a negative group together with the separators constitute an "element" as explained above. See fig. 19, chart 203 and fig. 9, chart 203A.

Electrolyte: The fluid, known as "electrolyte" is dilute sulphuric acid. The element is placed in the jar with the electrolyte.

Jar: The cell container is a rubber jar of special composition which will withstand the vibration of the car and any ordinary handling without breakage. The plates rest on stiff ribs or bridges in the bottom of the jar (fig. 1) allowing space for the gradual accumulation of "sediment."

Cover: The jar cover and method of sealing and venting is very important. The cover on the "Exide" battery is flanged in such a way as to give a more perfect seal to the jar than the old flat type of cover and each cell is a separate sealed unit.

Vent: From the illustration (fig. 10, chart 203A) of the vent and filling plug, it will be seen that they provide both a vented stopper (vents F, G, H) and an automatic device for the prevention of overfilling and flooding.

Case: The case in which the cells are asembled into a battery. is built of hard wood, thoroughly coated with acid proof paint, see fig. 2.

Hold-down clips: It is absolutely essential that the battery be securely held in position on the car, and for this purpose brackets which fit on the case are used. The battery is made fast to the car by means of bolts engaging the hold-down clips. (see 1059, chart 202).

Terminals: The **positive terminal** is marked (+) and can always be determined by the dark color. The **negative terminal** is a light gray color and is marked thus (—).

*Oxide of lead is 1 part oxygen and 1 part lead. Peroxide of lead is 2 parts oxygen and 1 part lead.
†See foot note pages 446, 447.

CHART NO. 203-A—Parts of a Modern Lighting and Starting Battery. (Exide as an example—(The Electric Storage Battery Co., Philadelphia, Pa.)

The reason there is an odd number of plates in a cell, is due to the fact that there is one more negative plate than positive. A negative plate is placed at each end so that there will be action on both sides of all positive plates. The positive plates are thicker and have more active material. The positive plates also have a tendency to recede from the negative and if were placed at the end, it would buckle and bend away from the negative plate—see figs. 16, 17, page 444 for arrangement of plates.

Forming the Plates.

This is a subject which concerns the manufacturer, but we will give a brief outline of how the plates are formed after assembling. Different manufacturers use different processes.

*When the elements are placed in the jar, and immersed in 1300 sp. gr. electrolyte, they are "formed" by passing an electric current (direct only) at a very low rate for a long period of time.

Another method of forming is to leave battery stand for 24 hours, then start charging at 1/18 of the capacity and charge continuously for 150 hours.

The plates go through what is called an electro chemical process that converts the paste on the positive plate into **brown peroxide of lead, and the paste on the negative plate into gray spongy lead.

Action of a Storage Battery when Charging and Discharging.

When charging a battery the electricity is not being stored, as thought by some, or as the name would imply. The action is purely chemical, and the current given off is generated by chemical action.

General: A storage battery consists of one or more cells. A cell consists essentially of positive and negative plates immersed in an electrolyte.

Simplified meaning of specific gravity: The electrolyte of the cell consists of a mixture of sulphuric acid and water. **Water is lighter than acid, therefore a hydrometer would sink deeper in water, than in acid.**

The more acid in the water, the less depth the hydrometer would sink. This depth that the hydrometer sinks, is shown on a graduated scale, and is designated "sp. gr." or simply "SG." (specific gravity).

The **voltage of one cell** about two volts. The **voltage of a battery** (with cells in "series") is the number of cells multiplied by two. (see page 440).

When a cell is being used, the current is produced by the acid in the electrolyte, **going into** and combining with **the lead** of the porous part of the plates, called the "active material." †In the positive plate, the active material is lead peroxide, and in the negative it is metallic lead in a spongy form.

Formation of lead sulphate: When the sulphuric acid in the electrolyte combines with the lead in the active material, a compound "lead sulphate," is formed.

As the discharge progresses, the electrolyte becomes weaker, due to the fact that **the acid goes into the plates,** producing the electric current and incidentally producing the compound of acid and lead, called "lead sulphate." This sulphate continues to increase in quantity and bulk, thereby filling the pores of the plates.

Drop in voltage: As the pores of the plates become thus filled with the sulphate, the **free circulation of acid into the plates is retarded;** and since the acid cannot then get into the plates fast enough to maintain the normal action, the battery becomes less active, as is indicated by the **drop in voltage** or a discharged condition.

Why a hydrometer is used to test the electrolyte or solution:—The specific gravity of water is 1000. If acid is mixed with water it will become heavier. A hydrometer would not sink as deep into the heavier solution as it would in a thinner or lighter solution.

When battery is fully charged the specific gravity would be 1285 to 1300 as the acid is out of the plates in the solution. When a battery becomes discharged the plates absorb the acid and the solution becomes thinner, therefore the hydrometer would sink as low as 1150 sp. gr., or a drop of nearly 150 points, if fully discharged.

In other words, the acid will be in the plates and the electrolyte will be reduced to almost mere water. Hence the necessity of occasionally testing with a hydrometer.

Charging Action.

To charge, direct current is passed through the cells in a direction opposite to that of discharge. This current, passing through the cells in the reverse direction, will reverse the action which took place in the cells during discharge. It will be remembered that during discharge, the **acid of the electrolyte went into and combined with the active material,** filling its pores with sulphate. and causing the electrolyte to become weaker (merely water).

Action of current: Reversing the current through this sulphate in the plates restores the active material to its original condition **and returns the acid to the electrolyte.**

Thus, during charge the electrolyte gradually becomes stronger, as the sulphate in the plates decreases, until no more sulphate remains and all the acid has been returned to the electrolyte. It will then be of the same strength as before the discharge and the same acid will be ready to be used over again during the next discharge. **Since there is no loss of acid, none should ever be added to the electrolyte.** There is, however, a loss of water from evaporation.

Object of charging: The acid absorbed by the plates during discharge is, during charge, driven from the plates by the charging current and restored to the electrolyte. This is the whole object of charging.

Gassing: When a battery is fully discharged, it can absorb current at the highest rate. As the charge progresses, the plates can no longer absorb current at the same rate and the excess current goes to

*If plate is very hard it would be necessary to charge and discharge many times.

**See foot note bottom of page 445. †See foot note page 446.

†The paste on the grids is made of red lead and weakened solution of sulphuric acid for the positive plate and litharge and weakened solution of sulphuric acid for the negative plate.

form gas. In a battery which is charged or nearly charged, the plates can absorb current without excessive gassing only at a low rate and a **high charging rate will be almost entirely used in forming gas, resulting in high temperature and wear on the plates.**

In starting and lighting systems, the aim is to provide sufficient current under average running conditions so that the battery will not be "starved," and yet the charge will be at a rate which will not cause injurious gassing.

Normal and abnormal sulphate: The sulphating which takes place during an ordinary discharge, is entirely normal. If, however, charging is insufficient, the sulphate increases and becomes hard and the plates become lighter in color, lose their porosity and are not easily charged; this is the abnormal condition usually referred to as "sulphated." This condition is usually the result of "starvation" of the battery.

High rates of discharge: A very general misapprehension has existed in the past as to the effect on a lead storage battery of discharging at very high rates. The fact that a starting battery will spin one of the big modern engines which a strong man can scarcely turn over shows what its capabilities are; and the length of time it will with proper charging and care continue to do this heavy work without giving out shows that it is not injured thereby.

Overdischarge: It is not **discharge** at any rate which injures a battery, but **overdischarge**, or, what in time amounts to the same thing, undercharge or "starvation."

"Starvation:" If a car is so run that the battery gets insufficient charge and is "starved," it cannot be expected to do its work properly.

Overcharge: Persistent overcharging not only tends to wash out the positive active material, but also acts on the positive grids, giving them a scaly appearance.

Low temperature: Temperature has quite a marked effect on a battery. Low temperature (temporarily) both lessens the ampere hour capacity which can be taken out of the battery and lowers the discharge voltage. It is as if the battery were numbed by the cold and unable to make the same effort as at normal temperature. The effect of cold is only temporary, the battery returning to its normal state upon its return to normal temperature even without charge. Starting batteries are usually designed with sufficient margin over the ordinary requirements so that they will still perform their functions under reasonably low temperature conditions. It is just as well, however, to bear in mind the effect of cold weather and to aim to keep the battery unusually well charged in winter and not expose it unnecessarily to low temperatures.

There is no danger of the electrolyte freezing in a fully charged cell; but in one which is over discharged or has had water added without subsequent charging this is liable to occur.

High temperature: High temperature is to be avoided from the standpoint of life. 110 degrees Fahrenheit is usually given as the limiting temperature, and even this would be harmful if maintained steadily.

Heating is ordinarily the result of charging at too high a current rate. If the temperature of the electrolyte in a battery is found to run excessively high, the system should be inspected; it may be out of adjustment and be charging the battery at too high a rate.

The effects of continued high temperature are to distort and buckle the plates, to char and weaken the wood separators, to soften and sometimes injuriously distort the jars and covers.

Electrolyte.

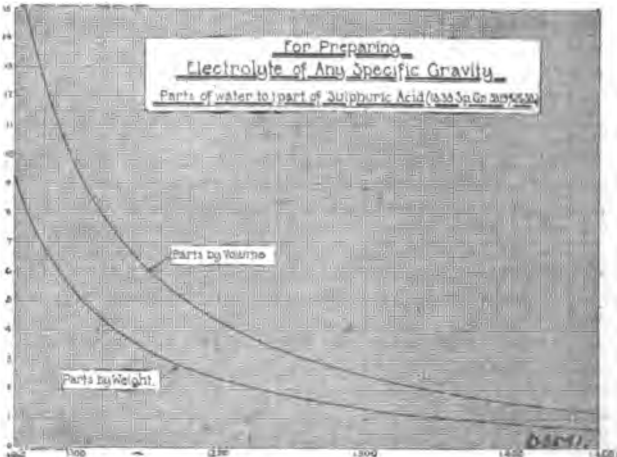

Fig. 11—How to read: If a solution of electrolyte of 1.250 sp. gr. is desired—see 1.250 at bottom—then go straight up to upper curved line (parts by volume)—then straight to the left following horizontal line—and you have 8¼ parts water to 1 part sulphuric acid.

Composition: Electrolyte as used in all types of batteries consists of a mixture of pure sulphuric acid and distilled or other pure water and is the liquid solution used in storage batteries.

Concentrated sulphuric acid is a heavy, oily liquid having a specific gravity of about 1.835. A battery will not operate if the acid is too strong and it is therefore diluted with sufficient pure water to bring it to a gravity of 1.270 to 1.300 for a fully charged battery. Stronger electrolyte than this is injurious.

To prepare electrolyte from sulphuric acid of 1.835 specific gravity, mix with water in the proportions in-

When adding new electrolyte to a repaired or cleaned battery, see page 470.

dicated in fig. 11 for the desired specific gravity, taking the following precautions:

(1) A glazed stone vessel or a lead lined tank should be used.
(2) Put the water in the vessel first.
(3) Fill the hydrometer syringe with chemically pure sulphuric acid and add it to the water by holding the nozzle under the surface. Stir the solution with a glass rod or clean piece of wood.
(4) Rinse the syringe and test the strength of the solution. If it is about 20° Baume allow it to cool, when it will be stronger.
(5) If not strong enough, add more acid.
(6) If too strong, add water.
(7) The pure acid should not be allowed to remain in the syringe.

Chemically pure electrolyte: Both the water and the sulphuric acid used in making electrolyte should be **chemically pure** to a certain standard. This is the same standard of purity as is usually sold in drug stores as "CP" (chemically pure) or by the chemical manufacturers, as "battery acid."

In this connection, the expression "chemically pure" acid is often confused with acid of "full strength." Acid may be of full strength (approximately 1.835 sp. gr.) and at the same time chemically pure. If this chemically pure acid of full strength be mixed with chemically pure water the mixture would still be chemically pure, but not of full strength. On the other hand, if a small quantity of some impurity be introduced into chemically pure acid, it would not materially reduce the strength, but would make it impure.

The usual method of determining the strengh of electrolyte is by taking its specific gravity. The method is possible on account of the fact that sulphuric acid is heavier than water. Therefore the greater the proportion of acid contained in the electrolyte, the heavier the solution, or the higher its specific gravity.

Specific Gravity.

By specific gravity is meant the relative weight of any substance compared with water as a basis. Pure water, therefore, is considered to have a specific gravity of 1, usually written 1.000 and spoken of as "ten hundred." One pound of water is approximately one pint. An equal volume of concentrated sulphuric acid (oil of vitriol) weighs 1.835 pounds. It therefore has a specific gravity of 1.835 and is spoken of as "eighteen thirty-five."

Temperature Correction.

Since electrolyte, like most substances, expands when heated, its specific gravity is affected by a change in temperature.

If electrolyte has a certain gravity at a temperature of 70 degrees Fahrenheit and it be heated, the heat will cause the electrolyte to expand, and, although the actual strength of the solution will remain the same as before heating, yet the expansion will cause it to have a lower gravity, of approximately one point (.001) for each three degrees rise in temperature.

For instance, if electrolyte has a gravity of 1.275 at 70 degrees Fahrenheit and the temperature be raised to 73 degrees Fahrenheit, this increase in temperature will cause the electrolyte to expand and the gravity to drop from 1.275 to 1.274.

On the other hand, if the temperature has been lowered from 70 degrees to 67 degrees, this would cause the gravity to rise from 1.275 to 1.276.

Since the change of temperature does not alter the actual strength of the electrolyte, changing its gravity only, the gravity reading should be corrected one point for each three degrees change in temperature.

Electrolyte becomes lighter, or of lower "gravity" as it gets warmer and vice versa, and this rise or fall of "gravity" effected by temperature change is independent of the state of charge. "Temperature corrections" are unnecessary when you compare the "gravities" of the different cells of battery at any one time, since all have about the same temperature when in health and so are affected alike. Temperature corrections are also unnecessary, when you use the hydrometer, say testing the middle cell, which we will call the "pilot cell," to secure an approximate index of the battery's condition. That is, corrections are in general unnecessary, except when there is reason for a really critical study of the battery's condition, as when you suspect things are not going well with the battery.

Note too that the actual proportion of water in the electrolyte slightly affects the "gravity" independently of the state of charge. That is the more water there is the lower the gravity. Therefore to derive the greatest benefit from your hydrometer readings try to keep the electrolyte surface between a point ¼ inch above the plates and the electrolyte level designated for your battery, either on the name plate or in the instruction pamphlet you receive with the battery. Use the glass tube lever-tester (page 455), consistently in conjunction with your hydrometer and add water promptly when it is needed.

Standard Temperature.

Standard temperature: The temperature adopted as the standard for a basis of comparison of specific gravities of electrolyte is 70° F. Thus, when we say that a specific gravity of 1.280 indicates full charge and 1.225 indicates practical discharge for **starter** purposes or 1.150 total discharge, we mean that these are the "gravities" when the electrolyte has a temperature of 70° F.

Thermometer.

Thermometer its purpose—Suppose you test the specific gravity at a time when a thermometer inserted in the electrolyte shows the latter to be **warmer** than 70° F. Note the hydrometer reading and add one point to the fourth figure for every three degrees that the thermometer shows the electrolyte to be warmer than 70° F. This corrects your reading to what it would be if the electrolyte temperature were 70° F. at that time. If the electrolyte is colder than 70° F., one point should be subtracted from the fourth figure for every three degrees that the temperature of the electrolyte is below 70° F.

Example A. Temperature of electrolyte is 100° F. Hydrometer reading is 1.275. Then 100°—70°=30° and 30÷3=10 and corrected reading is 1.275 plus .010=1.285.

Example B. Temperature of electrolyte is 40° Hydrometer reading is 1.235. Then 70°—40°=30° and 30÷3=10 and corrected reading is 1.235 minus .010=1.225

**Testing Condition of a Storage Battery with a Hydrometer Syringe.

The hydrometer syringe is the best method for testing the condition of the electrolyte. The specific gravity (abbreviated as sp. gr. meaning the density) of the solution, should be tested in each cell. This should be done regularly, and the best time is when adding water, but the reading should be taken before, rather than after adding the water.

If the electrolyte is below the top of the plates, or so low that enough cannot be drawn into the barrel to allow of a proper reading of the hydrometer, fill the cell to the proper level by adding pure water; then do not take a proper reading until the water has been thoroughly mixed with the electrolyte by the gassing at the end of a recharge.

Manipulation. The hydrometer is the glass tube with a graduated scale reading, as shown in fig. 1, (also see fig. 3, chart 204-A). The syringe is a glass tube with a rubber bulb at the top and a rubber tube for injecting into the vent opening of cell. Enough electrolyte is drawn into the glass tube to float the hydrometer. Fig. 15 illustrates three positions the hydrometer will assume when floating in the electrolyte.

In using the hydrometer, certain points should be kept in mind. In the first place, the liquid taken up by the hydrometer from one cell, should never be put into another cell, as this will be likely to cause some trouble, due to "high acid" in one cell, or due to weakened electrolyte in another. Also care should be taken when using the hydrometer, not to have any air bubbles form in the cell, as it is very difficult to get these out, and as a result, the extra electrolyte is spilled. When heated up, the bubbles disappear and the level of the electrolyte sometimes falls below the tops of the plates.

When all cells are in good order, the gravity will test about the same (within 25 points) in each cell. (Note; gravity readings are sometimes expressed in "points," thus the difference between 1.275 and 1.300 is 25 points).

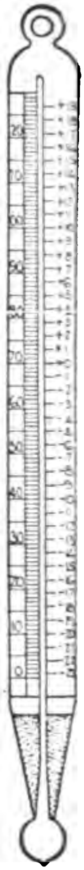

Fig. 12
Thermometer

*Hydrometer Readings.

A fully charged battery will be indicated by the hydrometer reading sinking to a level in the electrolyte anywhere between 1.280 and 1.300.

A half charged battery, the gravity will be 1.225.

A discharged battery, the gravity will be 1.150.

The storage battery will rarely crank an engine if its specific gravity falls below 1.200, although the lights will be nearly as bright as with a fully charged battery. When fully charged, its specific gravity should be between 1.280 and 1.300. As a rule, when fully charged, the specific gravity will be nearer 1.280 than 1.300, especially when the battery has been in use for some time.

One manufacturer states that when the battery is used for **starting service** the battery is practically **exhausted** or incapable of starting with as low as 1.225 gravity test. But for lighting and ignition where the amperage rate of discharge is very low, the reading could be 1.150 when exhausted. See foot note page 451.

A run down battery should be given a full charge at once.

A voltmeter can also be used to test the cells while on a charge, per page 453, or on discharge as explained on pages 416 and 410.

The "Cadmium Test" is used to test which set of plates are defective, when the battery will not hold its charge—see index.

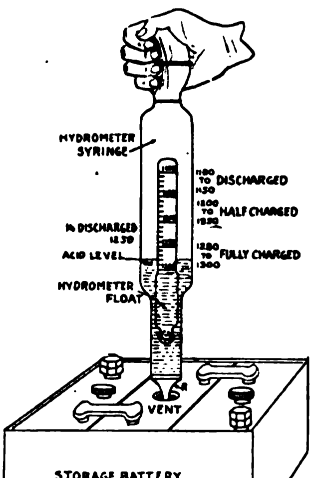

Fig. 15.—An exaggerated illustration showing how the pressing of the rubber bulb draws electrolyte from the cell, and how the hydrometer floats in the glass barrel. The level of the electrolyte when registering even with the figures indicates the specific gravity. If the electrolyte is heavy with acid the hydrometer will not sink as deep as when the acid is in the plates. See pages 447, 449 and 451 for use of the hydrometer.

Thermometer.

Fig. 12—A special thermometer for readings, as per text, pages 449-453.

On opposite side of the mercury column and parallel to the temperature scale; that is, opposite to the temperature 70 degrees is figure 0, showing that nuo correction of gravity readings is made at that temperature.

Three degrees below 70 degrees is shown minus 1, indicating that the gravity should be corrected at that temperature by deducting one point.

Three degrees above 70 degrees is shown plus 1, which indicates that the gravity at that temperature should be corrected by adding one point to the reading, as shown by the hydrometer.

The temperature of electrolyte is a very important consideration, when using a hydrometer for testing the gravity—hence the use of the above thermometer and explaination on pages 449-453.

*For a comparison of the Baume and specific gravity scale, see fig. 4, chart 204-A.

**See page 447; "Why a Hydrometer is Used For Testing" and 449; "Thermometer, Its Purpose."

HART NO. 204—The Hydrometer for Testing the (sp. gr.) Specific Gravity of Electrolyte. How to Test. The Hydrometer Syringe. The Thermometer.

†For cadmium tests, see page 864D, see also pages 416 and 410.

A Special Thermometer.

With a special scale on which the amount of correction is figured out is shown in fig. 12, chart 204. (Manufactured by the Electric Storage Battery Co., Philadelphia.)

†Freezing of Electrolyte.

The freezing point of electrolyte depends upon its specific gravity. There is little danger of freezing except with a discharged battery.

Water will freeze at 32° Fahrenheit. Hence, if the battery were to be discharged by some means to the point of where the electrolyte is near the gravity of water, the electrolyte would of course freeze near this point.

In order to avoid freezing of the electrolyte, it should always be kept in a fully charged condition. A fully charged battery will not freeze in temperatures ordinarily met. **Electrolyte will freeze as follows:**

Sp. gr. 1.150, battery discharged, 13 degrees above zero.

Sp. gr. 1.160, battery ¾ discharged; zero.

Sp. gr. 1.225, battery ½ discharged; 38 degrees below zero.

Sp. gr. 1.260, battery ¼ discharged; 60 degrees below zero.

Sp. gr. 1.280 to 1.300, battery fully charged; 100 degrees below zero.

When a battery is stored away for the winter, care should, therefore, be taken that the battery is kept in a fully charged condition.

If the electrolyte becomes frozen, the expansion will sometimes break the jar, if not, simply place it in a warm place and it will come back to its normal charge. It is best, however, to recharge it first and then pour out the old electrolyte and put in new electrolyte of specific gravity of 1.300.

The Hydrometer.

The specific gravity or density of the electrolyte is measured by an instrument called the "hydrometer"—see pages 447, 449.

This consists of a closed glass tube in the form of a short barrel with a longer stem of small diameter. Inside of the stem is a graduated scale and at the lower end a few small shot are placed—see page 450.

The hydrometer floats upright in the liquid and the point on the scale at the surface of the liquid shows the specific gravity, usually called "gravity."

Method of use: For greater convenience, the hydrometer is usually placed inside of a larger glass barrel provided with a rubber bulb on top and a suitable nozzle on the lower end. This combination is known as the "hydrometer syringe" (fig. 15, chart 204).

By squeezing the bulb, inserting the nozzle into the electrolyte and releasing the bulb, electrolyte is drawn up into the glass barrel. Sufficient should be drawn up to float the hydrometer clear of the rubber plug in the bottom.

To prevent the hydrometer from sticking to the side of the barrel, it is necessary that the syringe be held in a vertical position. The reading is taken at the surface of the electrolyte and when there is no compression on the bulb.

In recording the gravity of the different cells, it is customary to begin with the cell at the positive end.

When the readings have been taken, be careful to put the electrolyte back into the same cell from which it was taken. Failure to do this often leads to trouble; that is, electrolyte is often taken out of one cell, the gravity noted and the electrolyte put back into another cell. The result is that the amount of electrolyte taken out of the first cell is eventually replaced with water, leaving the electrolyte weaker; whereas the electrolyte which was taken out and put into another cell would make the electrolyte of that cell stronger, resulting in irregularity in the different cells.

When to take a hydrometer reading: Take a hydrometer reading of each cell with the hydrometer syringe at least once a week and **just before adding water.**

If hydrometer readings are taken after adding water and before the car is run, they are of no value, as only water or very weak electrolyte will be drawn into the syringe. This is due to the water being lighter than the electrolyte, and therefore remaining on the surface until thoroughly mixed by running the car.

Take hydrometer readings at any time that any part of the **electric system does not work properly,** as they may indicate the trouble. See also, page 864D.

*Hydrometer Readings.

This information is given in chart 204 and as follows:

Specific gravity—1.280	fully charged
Specific gravity—1.260	three-quarters
Specific gravity—1.225	one-half
Specific gravity—1.160	one-quarter
Specific gravity—1.150	discharged

An exhausted battery should be removed from the car and given a full charge.

When the gravity will not rise above 1.225 or 1.250 from generator charge on car—this may be due to excessive use of lights, together with slow running of the car, which cuts down the charging current from the generator, or it may be due to trouble in the system—see pages 422, 457.

The remedy is to use lights sparingly, until the gravity rises above 1.250. If gravity will not rise above 1.250 within a reasonable time, look for trouble in the system.

*Where battery is used for starting motors 1.275 to 1.300 sp. gr. at 70° F.—is the "full charge," or top mark for battery specific gravity. A battery with gravity below 1.225 can hardly inject the requisite energy into the starter to spin the engine, so that 1.225 is the practical low mark.

Then 1.280 minus 1.225 = .055, termed 55 points, covering the range between full charge and complete discharge.

Of course, a battery with gravity below 1.225 can operate the lights at a lower gravity. Suppose you try a hydrometer diagnosis and find the reading to be 1.255. Then 1.280 minus 1.255 equals 22½ out of the 55 points of full range, from which you know that your battery is half charged or half discharged. 1.260 indicates three quarters charged or one quarter discharged.

†A battery's capacity is considerably less during zero weather than summer heat—see page 422.

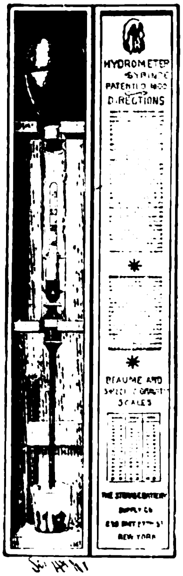

*Fig. 1—Hydrometer syringe outfit for shop use.

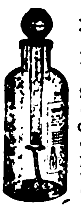

Fig. 9. The "Workrite" hydrometer outfit sells for $1.50 including hydrometer. Hydrometer is placed in bottle with distilled water.

Types of Hydrometers.

Two types of hydrometers are shown in fig. 1 and fig. 2. Fig. 1 is a large size garage outfit, whereas No. 2 is a smaller outfit.

Fig. 3, shows a Baume scale on the left and a specific gravity scale on the right. The comparison is shown in fig. 4.

"The "electrolyte" tester. Fig. 3 gives an arbitrary reading without showing the exact scale of the liquid in degrees, thus likened to the floating or sinking of an egg in brine to determine its strength, and is recommended for small batteries where it is not essential to get the exact specific gravity.

The glass balls in the instrument are hollow, and are accurately calibrated to float or sink in a certain strength of acid, and as mentioned in the description, they show by floating or sinking the condition of the acid near enough for all practical purposes and have the further advantage of requiring the least amount of acid to make the test.

It requires only a tablespoonful of acid, and the acid is returned to the cell without removing the instrument from it.

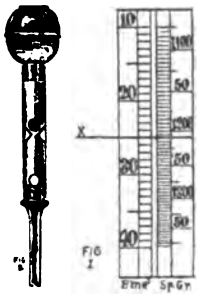

Fig. 3.—Electrolyte tester. Fig. 1 shows a Baume scale on the left and a sp. gr. on the right—see table below.

Directions for testing battery with an "electrolyte tester." Compress the bulb and insert the nozzle through the cover of the battery and allow the acid to fill the tube.

If the acid is at its proper strength 30 to 32 degrees Baume or 1.260 to 1.280 specific gravity, both balls will remain in the center of the tube when the battery is fully charged.

If both balls float, the acid is too strong and it should be reduced by adding water.

If both balls sink when the battery is discharged, the battery should be fully charged, and then if the white ball does not float, stronger acid should be added.

Finding Polarity.

It is necessary to know the positive (+) and the negative (—) pole of a battery when charging.

To find polarity, or which is negative (—) and positive pole (+) of electric wires or battery terminals several methods can be used. Best plan is fig. 5. Others are shown in A, which is a special paper which shows a color for negative and different color for positive; B, the potato if skin is off will show green for positive; C, D and E show other methods.

The storage battery polarity can be told by color of terminals. Positive (+) is a dark color and negative (—) light color.

FIG. 4 COMPARISON OF THE BAUME AND SPECIFIC GRAVITY SCALES AT 60° FAHRENHEIT.

Degrees Baume	Specific Gravity	Degrees Baume	Specific Gravity	Degrees Baume	Specific Gravity	Degrees Baume	Specific Gravity
0	1.000	17	1.133	34	1.306	51	1.542
1	1.007	18	1.142	35	1.318	52	1.559
2	1.014	19	1.151	36	1.330	53	1.576
3	1.021	20	1.160	37	1.342	54	1.593
4	1.028	21	1.169	38	1.355	55	1.611
5	1.036	22	1.179	39	1.368	56	1.629
6	1.043	23	1.188	40	1.381	57	1.648
7	1.051	24	1.198	41	1.394	58	1.666
8	1.058	25	1.208	42	1.408	59	1.686
9	1.066	26	1.218	43	1.421	60	1.707
10	1.074	27	1.229	44	1.436	61	1.726
11	1.082	28	1.239	45	1.450	62	1.747
12	1.090	29	1.250	46	1.465	63	1.768
13	1.098	30	1.261	47	1.479	64	1.790
14	1.107	31	1.272	48	1.495	65	1.812
15	1.115	32	1.283	49	1.510	66	1.835
16	1.124	33	1.295	50	1.526		

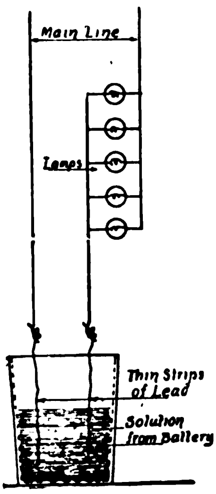

Fig. 5.—To determine the polarity of the charging circuit, if a suitable voltmeter is not at hand, dip the ends of the two wires into a glass of water in which a teaspoonful of salt has been dissolved, care being taken to keep the wires at least an inch apart. When current is on, fine gas bubbles will be given off from the negative wire.

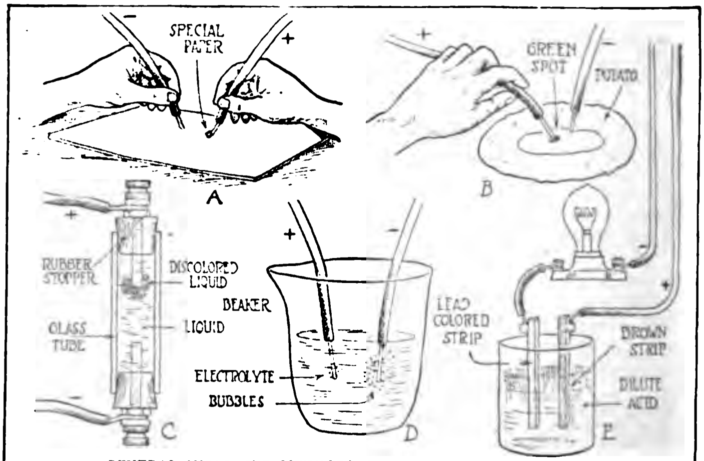

SEVERAL INDICATED METHODS OF DETERMINING POLARITY

A shows the use of pole-finding paper, which denotes polarity by color; B illustrates the use of a potato to determine polarity; C is a glass tube filled with liquid, which is discolored by the action of the current; D is a beaker filled with acidified water, the negative pole having the most bubbles around it; E is a miniature storage battery, one of the plates of which becomes discolored when in contact with positive pole

CHART NO. 204-A—Electrolyte Tester. A Scale Reading in Baume and Specific Gravity. Polarity Testing: Finding the Positive and Negative Terminal of Electric Wires for Charging.

If after the battery has been fully charged, the gravity again falls to 1.250 or less, it indicates there is trouble somewhere in the system which must be located and corrected, and battery should be charged from an outside source. (see also, page 864D for "cadmium tests.")
